Chapter 19

Renal and extrarenal regulation of body fluid composition

David L. Goldstein

Department of Biological Sciences, Wright State University, Dayton, OH, United States

19.1 Introduction

Avian osmoregulation comprises a set of physiological controls that function to protect the amount and concentration of water and solutes in the intracellular and extracellular fluids (ECFs) (Table 19.1). Achieving that regulation requires balancing the input and output of water and electrolytes and involves the interacting contributions of the kidneys, intestinal tract, salt glands (when present), skin, and respiratory tracts (as routes of evaporative water loss). The integration of these organs is unique in birds among the vertebrates. Birds lack a urinary bladder, and avian urine enters the lower intestine, where it may be significantly modified in the coprodeum, colon, and ceca. Under some circumstances, in some species, the salt glands are critical for osmoregulatory balance, and the majority of total water loss may be evaporative, not excretory, with the relative roles of skin and respiration varying among species and conditions. The present chapter will focus most heavily on anatomical and functional organization of the kidneys and lower intestine, but will also examine aspects of those other organs of osmoregulation.

19.2 Intake of water and solutes

19.2.1 Drinking

Total water fluxes in free-living birds scale allometrically with an exponent of about 0.65 (Tieleman and Williams, 2000; Song and Beissinger, 2019; see Table 19.2). Some birds, especially carnivores and frugivores, acquire all needed water through their food, and a few species, particularly small, xerophilic birds, can survive on the metabolic water produced from a dry diet even in the absence of drinking water (Bartholomew, 1972). For most birds, though, drinking is an important avenue of water intake.

The rate of drinking by birds in the laboratory follows a regular relation with body mass: birds weighing 100 g or more drink approximately 5% of body mass per day, but at progressively smaller body masses drinking rates rise, to about 50% per day for birds 10−20 g (Bartholomew and Cade, 1963; Skadhauge, 1981, Cpt. 2). Birds with salt glands, drinking saline water, may drink substantially more than those without salt glands, using some of the water to excrete the ingested salt via the salt glands and thereby retaining a volume of salt-free water (Hughes et al., 1989). In nectar feeding birds, including specialists like honeyeaters, hummingbirds, and sunbirds, caloric intake comes mostly from their liquid diet. If nectars are dilute, then intake adequate to meet calorie balance may entail drinking three to five times body mass per day, similar to water influxes of aquatic amphibia (Collins, 1981; McWhorter and Martínez del Rio, 1999; Nicolson and Fleming, 2003; Nicolson and Fleming, 2014). Indeed, water fluxes in free-living nectarivores are higher than for birds generally (Song and Beissinger, 2019). The strategy for handling those high rates of fluid ingestion includes primarily modulation of intestinal water uptake in sunbirds and honeyeaters, and primarily modulation of renal water reabsorption in hummingbirds (Nicolson and Fleming, 2014).

Except for those species able to survive without any drinking water (see Krag and Skadhauge, 1972; Skadhauge and Bradshaw, 1974), minimum water requirements are typically one-third to one-half of the ad libitum drinking rate (Skadhauge, 1981).

The physiological stimuli that initiate drinking are threefold: cellular dehydration, extracellular dehydration, and angiotensin II. The osmoreceptor cells that respond to cellular dehydration (i.e., to an osmotic loss of cellular water induced by a rise in ECF osmolality) are localized in periventricular regions of the hypothalamus (Thornton, 1986a; Kanosue et al., 1990). Their response may be specific to the

TABLE 19.1 Typical normal values of some regulated osmoregulatory variables in birds.[a]

Total body water	60–70 mL/100 g body mass
Extracellular fluid volume	20–25 mL/100 g body mass
Plasma volume	3.5–6.5 mL/100 g body mass
Plasma osmolality	320–370 mosmol/kg water
Plasma Na^+	150–170 meq/L
Plasma K^+	2–5 meq/L
Plasma uric acid	0.1–1 mmol/L

[a]*Values are typical for adult birds.*
Data are taken primarily from Skadhauge (1981), which should be consulted for references to original literature. The ranges presented encompass most of the variability among data compiled in that review.

TABLE 19.2 Allometric relations in avian osmoregulation, expressed in the form $Y = aM^b$, where M is mass in g.

Variable Y	Units	A	b	Reference
Field water flux	mL/d	1.41	0.66	Tieleman and Williams (2000)
Kidney volume	mm^3	8.0	1.15	Casotti et al. (1998)
Number of glomeruli	Number	3090	0.77	Yokota et al. (1985)
Glomerular filtration rate	mL/min	0.013	0.76	Bennett and Hughes (2003)
Effective renal plasma flow	mL/min	0.1	0.71	Bennett and Hughes (2003)
Salt gland dry mass, marine species	Mg	0.37	0.877	Gutiérrez et al. (2012)
Evaporative water loss, passerines at 25°C	mL/d	0.21	0.81	Gavrilov and Gavrilov (2019)
Evaporative water loss, nonpasserines at 25°C	mL/d	0.16	0.79	Gavrilov and Gavrilov (2019)

Na^+ concentration in the cerebrospinal fluid, rather than to the total osmolality (Thornton, 1986b; Kanosue et al., 1990).

Stimulation of drinking by extracellular dehydration can be demonstrated through the effects of hemorrhage or injection into various fluid compartments of a nonabsorbed, osmotically active compound such as polyethylene glycol. Both of these manipulations elicit responses consistent with the interpretation that the receptors (presumably mechanoreceptors sensitive to stretch or tension) are in the interstitial, rather than the vascular, compartment of the ECF (Kaufman and Peters, 1980; Takei et al., 1989). The dipsogenic effects of extracellular volume depletion may be mediated by angiotensin II (Takei et al., 1989).

Angiotensin II, administered either centrally (into the cerebrospinal fluid) or peripherally, elicits drinking in a wide variety of birds (Takei et al., 1989). The primary sites of action of this hormone appear to be the preoptic area and subfornical organ (Takei, 1977; Gerstberger et al., 1987; Simon et al., 1992), where TRPV1-type vanilloid receptors may contribute to osmosensing (Aman et al., 2016). In these circumventricular regions, the mRNA for AT1R-type angiotensin II receptors is upregulated in response to osmotic stress (Aman et al., 2016).

In addition to angiotensin II, other compounds within the brain may be involved in eliciting drinking. At least some pathways between dipsogenic centers in the brain (e.g., connecting preoptic area and subfornical organ) appear to use adrenergic nerve fibers (Takei et al., 1989; Denbow and Sheppard, 1993). A variety of peptides can either stimulate or inhibit drinking in birds (Takei et al., 1989), though the physiological significance of these compounds has not been defined.

When birds are dehydrated, all of the stimuli for drinking (intracellular and extracellular dehydration and angiotensin II) are elicited simultaneously. When dehydrated birds regain access to water, they may drink substantially more water than required to restore their cellular and extracellular water deficits (Takei et al., 1988; Goldstein, 1995). However, much of this water is excreted in a dilute urine or is absorbed slowly from the intestinal tract, and so aspects of fluid balance may remain in deficit despite the copious intake. In these circumstances, restoration of cellular fluid balance (osmolality) and distension of the intestinal tract with water appear to terminate drinking, even while blood volume remains depressed and angiotensin II levels remain elevated (Takei et al., 1988). With drinking as with release of antidiuretic hormone (see below), the osmolality of the ECF is a more potent stimulus (is more closely regulated) than its volume.

19.2.2 Solute intake

At least one bird, the pigeon (*Columba livia*), expresses a salt appetite in response to sodium depletion (Epstein and Massi, 1987). This response appears to depend on a synergistic action of angiotensin II and aldosterone (Massi and Epstein, 1990). In a variety of other birds, drinking rates may increase with increasing salinity of the drinking water,

with maximal drinking rates typically at 0.15−0.3 M NaCl (see review in Skadhauge, 1981, Cpt. 2). The maximum saline concentration that is drunk voluntarily is likely set by the bird's ability to extract free water, which results from the balance between renal concentrating ability and other routes of water gain and loss.

19.3 The kidneys

19.3.1 Anatomy

19.3.1.1 Gross anatomy

The avian urinary organs consist of a pair of kidneys and the ureters, which transport urine to the urodeum of the cloaca. There is no urinary bladder, though the cloaca may serve as its functional equivalent in some species and circumstances (see below).

The avian kidney lies within a cavity formed by the ventral surface of the synsacrum. The mass of the two kidneys is proportional to (body mass)$^{0.9}$, and represents approximately 0.8% of body mass in birds without salt glands, 1.4% in birds with salt glands (Hughes, 1970a; Franz et al., 2009).

The external appearance of the avian kidney is elongate and trilobed, with anterior, middle, and posterior divisions (Johnson, 1968; Michałek et al., 2016). Within each division, the kidney is divided into numerous subunits. In the cortex, nephrons are arranged around branches of the efferent venous system (central veins). These cortical units (cortical lobules) contribute nephron elements (collecting ducts and loops of Henle) to several medullary subunits; conversely, each medullary subunit receives nephron elements from several cortical units (Johnson et al., 1972). The medullary elements are wrapped in a sheath of connective tissue to form medullary cones. A kidney lobule (Figure 19.1) is defined as a medullary cone and the region of cortex that it drains. The numbers of kidney lobules, and the number per gram of kidney, vary substantially among species (Johnson and Mugaas, 1970; Goldstein and Braun, 1989, Barceló et al., 2012).

19.3.1.2 Nephron types and numbers

The structure of avian nephrons is highly heterogeneous. The smallest nephrons are located most superficially (Figure 19.1) and have simple glomeruli (Figure 19.2A). Because they resemble nephrons of reptilian kidneys, particularly in that they lack loops of Henle, these nephrons have been termed reptilian-type (RT) nephrons (Huber, 1917). Nephron size increases progressively with depth from the kidney surface. Those located most deeply have larger, more complex glomeruli (Figure 19.2B) and do possess a loop of Henle, leading to the name mammalian-type (MT) nephron. Between definitive RT and MT

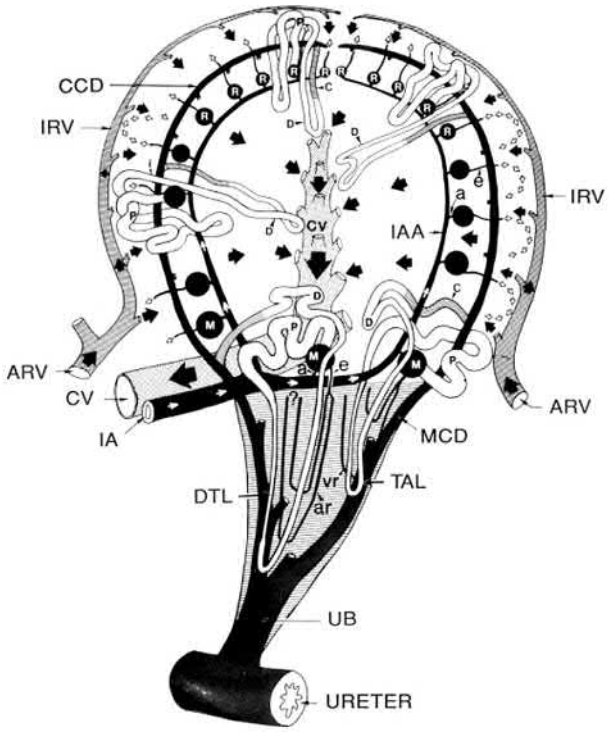

FIGURE 19.1 A typical kidney lobule from the domestic fowl. The lobule consists of a medullary cone and all cortical tissue that feeds into it. Abbreviations (in alphabetical order) are: *a*, afferent arteriole; *ar*, arteriole rectae (descending vasa recta); *ARV*, afferent renal (portal) vein; *C*, connecting tubule; *CCD*, cortical collecting duct; *CV*, central (intralobular renal) vein; *D*, distal tubule; *DTL*, descending thin limb of Henle's loop; *e*, efferent arteriole; *i*, intermediate segment; *IA*, intralobar artery; *IAA*, intralobular artery; *IRV*, interlobular renal vein; *M*, mammalian-type (MT) glomerulus; *MCD*, medullary collecting duct; *P*, proximal tubule; *R*, reptilian-type (RT) glomerulus; *TAL*, thick ascending limb of Henle's loop; *UB*, ureteral branch; *vr*, venule rectae (ascending vasa recta). *Figure is from Wideman (1988). Reprinted by permission of CRC Press, Boca Raton, Florida.*

nephrons is a continuous gradation of nephrons (Goldstein and Braun, 1989; Roush and Spotts, 1988; Mobini and Abdollahi, 2016), including those with elongated, looping intermediate segments that are not bound into the medullary cones (Boykin and Braun, 1993). The RT/MT terminology has largely been replaced with the terms loopless (LLN), transitional (TN), and looped (LN) nephrons (Braun, 1993; Boykin and Braun, 1993). Avian glomeruli may have filtration barriers that are less restrictive than those of mammalian kidneys, potentially permitting larger and more highly charged molecules to enter the urine (Casotti and Braun, 1996).

Both nephrons with and those without loops of Henle empty in a highly regular pattern into common collecting ducts (Boykin and Braun, 1993). Collecting ducts conjoin as they descend through the medullary cone, and the terminus of the medullary cone is a single large collecting duct that empties directly into the ureter. The avian kidney has no renal pelvis.

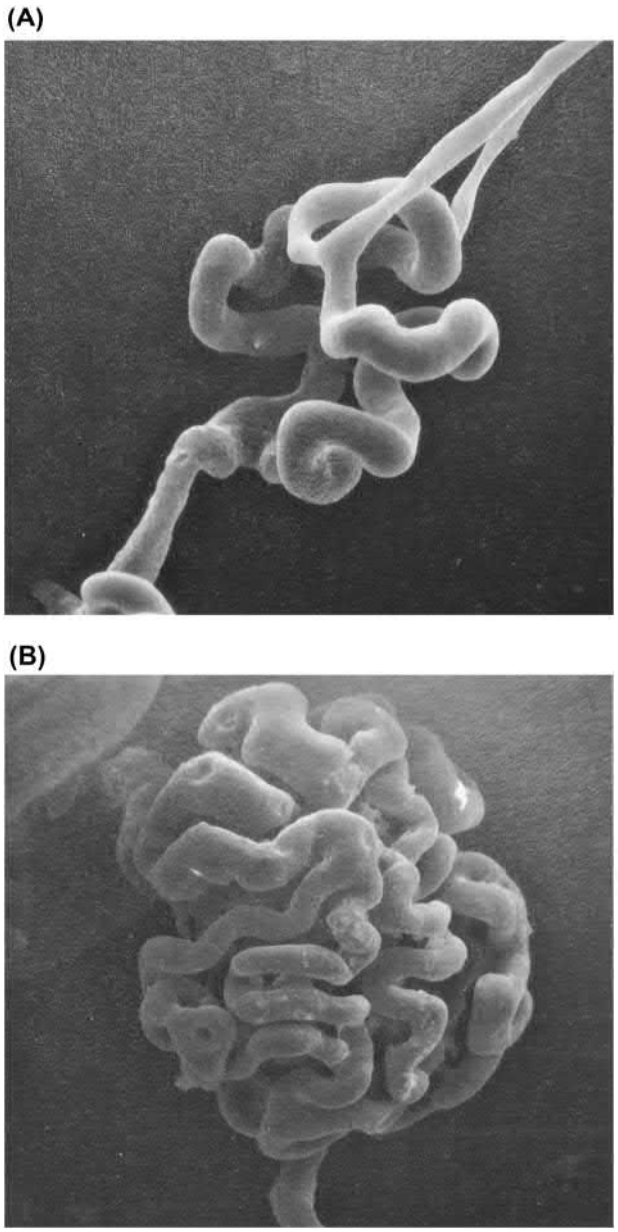

FIGURE 19.2 (A) Glomerulus from a reptilian-type nephron. Note the simple looping pattern and lack of cross-branching in these capillaries. (B) Glomerulus from a mammalian-type nephron, with a longer, more complex capillary network. *Photographs courtesy of G. Cassotti and E. J. Braun.*

Of the total nephron population, between 10 and 30% possess loops of Henle in most species examined (Goldstein and Braun, 1989). An exception is found in Anna's hummingbird, *Calypte anna*, whose kidneys, with more than 99% loopless nephrons, are capable of producing copious dilute urine in response to dilute nectar diets (Casotti et al., 1998). Several studies suggest habitat-related patterns in kidney structure, such as smaller kidneys, larger volume of medulla, or smaller volume of cortex in desert species (Thomas and Robin, 1977; Warui, 1989; Casotti and Richardson, 1992). Likewise, birds with greater osmoregulatory challenge (granivorous birds eating dry diets; passerines encountering high salt intake) may have greater percentages of medullary mass (Goldstein et al., 1990; Barceló et al., 2012; Peña-Villalobos et al., 2013). It is not yet clear how these variations relate to the different proportions of looped, transitional, and loopless nephrons.

19.3.1.3 Blood flow

The avian kidney receives both arterial and afferent venous (portal) blood supplies and is drained by efferent venous flow (Figure 19.3). The overall pattern of flow is complex; see Wideman (1988) for a detailed review.

19.3.1.3.1 Arterial supply

Each division of the kidney is supplied by a separate artery (Figure 19.3). The arteries branch upon entering the kidney

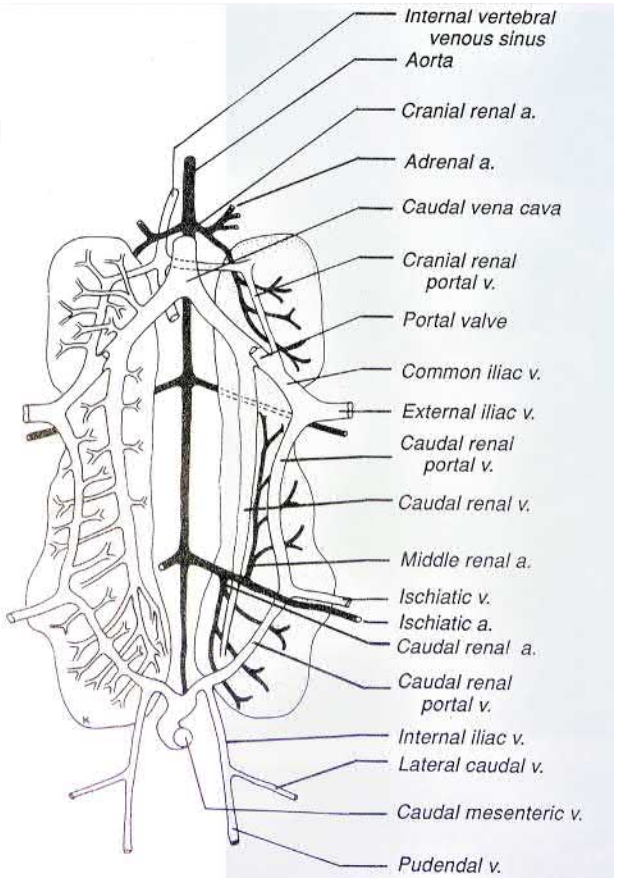

FIGURE 19.3 Major blood vessels in the avian kidney. The kidneys are drawn as though transparent, and in the left kidney only the major venous trunks are shown to permit an indication of finer levels of vessel branching. The internal vertebral venous sinus has been displaced to one side so that it can be seen. *Reproduced from King (1975) with permission.*

to form intralobar and then numerous intralobular arteries, from which arise the short afferent arterioles supplying the glomeruli.

Efferent arterioles from glomeruli of loopless nephrons empty into sinuses surrounding the cortical tubular elements, thereby forming the peritubular blood supply. In contrast, the efferent arterioles leaving glomeruli of looped (MT) nephrons enter the medullary cones to form a mesh-like network of vessels, the vasa recta (Figure 19.4). Whether the outflow from the vasa recta enters peritubular sinuses surrounding cortical components of the MT nephrons, or instead whether it enters directly into the intralobular veins, is as yet unclear (Figure 19.5).

19.3.1.3.2 Renal portal system

The second afferent blood supply to the kidney, the renal portal supply, receives blood flow from both the ischiadic and the external iliac veins. A valve, the renal portal valve, is located between the renal portal vein and the common iliac vein (Figure 19.3). This smooth muscle sphincter receives both adrenergic (stimulatory, causing valve closure) and cholinergic (inhibitory, allowing valve opening) innervation (Burrows et al., 1983). Blood from the external iliac vein may flow directly into the vena cava when the renal portal valve is open or, instead, be forced into the renal portal vein when the valve is closed.

FIGURE 19.4 The vasa recta of Gambel's quail, revealing the mesh-like, rather than simple ascending and descending, appearance of the vessel network. *Photograph courtesy of E. J. Braun.*

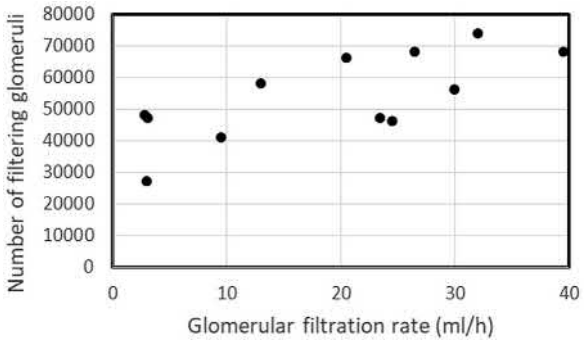

FIGURE 19.5 The number of filtering glomeruli (evaluated by infusion of the stain Alcian blue, which binds to the negatively charged filtration barrier as it is filtered) in Leach's storm petrels (*Oceanodroma leucorhoa*) whose GFR varies over a wide range in response to intravenous infusion of NaCl. *Experimental conditions are described in Goldstein (1993).*

Once in the renal portal vein, blood may enter the low-pressure peritubular sinuses formed from the efferent arterioles; the mixed portal and postglomerular blood then flows out of the kidney through efferent veins. Alternatively, blood may flow out of the kidney into vertebral sinuses or, via the caudal mesenteric vein, to the liver. The pattern of flow through these various pathways may be highly variable both among animals and within an individual animal over time (Akester, 1967; Odlind, 1978; Oelofsen, 1973; Wideman, 1988), presumably because of varying states of regulation of vascular resistances and of valve status. The functional significance of the portal system and its valve may relate in part to regulating systemic hemodynamics, particularly during times of leg muscle activity (see Wideman, 1988), and in part to regulating renal hemodynamics, particularly when arterial blood pressure or flow is reduced (Wideman, 1991; see below).

Since Sperber's (1948) convincing demonstration of portal circulation to the renal cortex, many investigators have used the so-called "Sperber technique" in studies of avian kidney function. In this approach, a compound is infused into one leg vein (and hence into the renal portal circulation), and function of the ipsilateral kidney is compared with that of the contralateral kidney that does not receive the portal infusate. Portal blood does not perfuse the glomeruli or the renal medulla, and so the Sperber technique has enabled evaluation of mechanisms and regulation of transport of organic and inorganic compounds by cortical tubular elements.

19.3.1.3.3 Venous drainage

Blood from the peritubular sinuses drains into central (intralobular) veins, which coalesce into interlobar veins. These join to form the efferent renal vein, which empties into the posterior vena cava.

19.3.2 Physiology

19.3.2.1 Overview

The primary function of the kidneys is eliminative—that is, to facilitate excretion of wastes, toxins, and excess water and solutes. To accomplish this, the kidneys receive a large fraction of the cardiac output, and from this, the entire body fluid volume is filtered through the glomeruli several times each day. Most of this volume and its solutes are then reabsorbed by the renal tubules from the urine back to the blood. Some substances, though, may additionally be secreted by the tubules into the urine. The end product of filtration, reabsorption, and secretion enters the ureters as urine.

19.3.2.2 Renal blood flow

For any substance, renal clearance is defined as the volume of blood from which that substance is removed (cleared) by the kidneys per unit time. Hence, if a substance is completely removed from the plasma (by filtration and secretion) during a single pass through the renal vasculature, renal clearance and renal plasma flow (RPF) are the same (and renal blood flow can be calculated by accounting for hematocrit). The clearance (C, mL/min) of any substance, X, is calculated from the formula: $C = U_X V/P_X$, where U_X and P_X are the urine and plasma concentrations of the substance and V is the urine flow rate (mL/min). In mammals, RPF has typically been measured as the clearance of para-amino hippuric acid (PAH), which is cleared with an efficiency of approximately 90%. This substance has been used in several studies of birds as well. However, the complexity and inaccessibility of the avian renal vasculature has made it difficult to determine the extent to which PAH is actually removed from the blood in the kidneys. Measurements in a reduced avian kidney model (with a single arterial supply and accessible renal vein) indicated PAH extraction efficiency between 50 and 75% (Wideman and Gregg, 1988), suggesting that PAH clearance is likely to underestimate RPF. Nevertheless, the values of RPF measured by Wideman (and corrected for PAH extraction) are on the lower end of values measured in other studies, which average approximately 40 mL/kg body mass min (e.g., Nechay and Nechay, 1959; Sperber, 1960; Holmes et al., 1968; Wideman, 1988; Roberts, 1992).

Measurement of RPF as C_{PAH} includes both arterial and portal contributions to RPF. Alternatively, RPF has been measured from the distribution of radioactive microspheres infused into the heart, thereby providing a measure of renal arterial blood flow, without the portal contribution. Results from these studies suggest that avian kidneys receive 10−15% of cardiac output. Along with mathematical models of avian renal blood flow (Shideman et al., 1981), these studies collectively suggest that under baseline conditions approximately 50% of avian renal blood flow might derive from the renal portal system, the remainder from arterial flow.

In the domestic fowl, renal blood flow can be autoregulated over a range of arterial pressures from about 100 to below 40 mm Hg (Wideman and Gregg, 1988). An important contributor to this autoregulation is the renal portal flow; as arterial pressure falls to the lower end of the autoregulatory range, arterial flow diminishes, but portal flow increases complementarily (Wideman, 1991). The mechanism for this coordination is unknown, but it presumably functions to maintain perfusion of the cortical tubule elements during times of reduced glomerular (and postglomerular) blood flow (see below).

Despite the ability to autoregulate, avian renal blood flow varies substantially in some circumstances. For example, in feral chickens, salt loading increased renal blood flow by more than 100% (Roberts, 1992).

19.3.2.3 Glomerular filtration

Filtration of plasma through the glomerular capillaries is the primary step in formation of avian urine. Whole kidney glomerular filtration rate (GFR) is the sum of the single nephron glomerular filtration rates (SNGFRs). SNGFR is determined by the difference between net hydrostatic pressure favoring filtration and oncotic pressure opposing it, by the hydraulic conductivity (permeability to water) of the glomerular filtration barrier, and by the surface area for filtration. Primarily because of the simplicity of avian (as compared with mammalian) glomeruli, and hence their small surface area, SNGFR in birds is low. However, because birds have more glomeruli per kidney, whole kidney GFRs are similar in birds and mammals (Yokota et al., 1985).

GFR (whole kidney or single nephron) is measured as a special case of clearance. If a substance is freely filtered and is neither secreted nor reabsorbed by the renal tubules, then the amounts filtered from the plasma and excreted in the urine are the same. The clearance of such a substance provides a measure of the GFR. Avian GFR has been measured as the clearance of inulin, polyethylene glycol, sodium ferrocyanide, iothalamate, iohexol, and others (Scope et al., 2013; Gasthuys et al., 2019).

SNGFR during mannitol diuresis has been measured in the kidneys of two species, Gambel's quail (*Callipepla gambelii*) and the European starling (*Sturnus vulgaris*), using the ferrocyanide precipitation technique (Braun and Dantzler, 1972; Braun, 1978), which permits simultaneous evaluation of filtration rates in both superficial and deep nephrons. SNGFR on average was 6−7 nL/min in loopless nephrons of both species, about 11 nL/min in "short-looped" (transitional) nephrons of the quail, and about 15 nL/min in "long-looped" nephrons. SNGFR also has

been measured in the most superficial, and hence smallest, loopless nephrons by micropuncture (Laverty and Dantzler, 1982; Roberts and Dantzler, 1990). Those values of SNGFR were much lower, from 0.25 to 0.5 nL/min. It is likely that nephrons exist with a continuum of filtration rates within that broad measured range.

Whole kidney GFR (mL/h) in normally hydrated birds varies with body mass (M, in grams) as $GFR = 1.24 \times M^{0.69}$ (Yokota et al., 1985). This equation predicts a GFR of 6 mL/h for a 10 g bird, 30 mL/h for a 100 g bird, and 145 mL/h for a 1000 g bird. Within this general relationship exists substantial variability both among and within species. For example, the GFRs of Gambel's quail and coturnix quail (*Coturnix coturnix*), both approximately 150 g, are about 15 and 36 mL/h, respectively (Braun and Dantzler, 1972; Clark and Sasayama, 1981); female Pekin ducks (*Anas platyrhynchos*) have higher GFR than males (Hughes et al., 1989), perhaps associated with different kidney sizes (Hughes et al., 1992). One might speculate that the low GFR of Gambel's quail is adaptive and provides a lesser urine flow in this desert bird. However, existing data do not support robust generalizations about habitat- or diet-related variation in GFR.

Like RPF, GFR of birds is autoregulated over a broad range of blood pressures, from 110 down to 60 mm Hg in the domestic fowl (Wideman and Gregg, 1988). This autoregulation was not affected by dietary sodium intake, as might be expected if tubuloglomerular feedback (changing renal vascular constriction in response to varying NaCl delivery to the distal tubule) were the responsible mechanism (Vena et al., 1990); these authors therefore implicated a myogenic mechanism of autoregulation, in which renal arteriolar smooth muscle responds to stretch (pressure). Despite the potential for autoregulation, GFR in birds is variable and changes in GFR contribute to regulation of urinary excretion, as discussed below.

19.3.2.4 Regulation of water excretion

The avian kidney filters a large volume of fluid, approximately 11 times the entire body water each day for a 100 g bird, and then reclaims most filtered water by tubular reabsorption. In normally hydrated birds, the percent of filtered water that is reabsorbed is typically greater than 95%. Variation from this "normal" situation can be achieved through regulation of either the rate of filtration or the rate of reabsorption, both of which may be influenced by the avian antidiuretic hormone arginine vasotocin (AVT).

19.3.2.4.1 Arginine vasotocin

AVT is a small peptide hormone released from the neurohypophysis. Circulating concentrations of AVT average about 10 pg/mL in normally hydrated birds (e.g., Möhring et al., 1980; Rice et al., 1985; Stallone and Braun, 1985; Gray and Erasmus, 1988; Gray et al., 1988; Gray et al., 2004; Aman et al., 2016). The primary stimulus for additional AVT release is a rise in ECF osmolality. In several species, the circulating concentration of AVT increases by 0.25−2 pg/mL for each mmol/kg rise in plasma osmolality (Möhring et al. et al., 1980; Arad et al., 1986; Stallone and Braun, 1986; Gray et al., 1988). A decrease in ECF volume (experimental hemorrhage) also may stimulate AVT release, but with less sensitivity than the response to osmolality (Simon-Oppermann et al., 1984; Stallone and Braun, 1986). Concentrations of AVT in dehydrated birds are typically 30−60 pg/mL (e.g., Stallone and Braun, 1986; Gray et al., 1988; Gray and Erasmus, 1988), though some higher values have been reported (Goldstein and Braun, 1988; Hughes et al., 1993). AVT receptors, possibly of the AVPR1A subtype (Wu et al., 2019), likely exist in both the vasculature and the tubules of the avian kidney (Goldstein, 2006).

19.3.2.4.2 Regulation of glomerular filtration rate

Reduction in GFR is a consistent component of the avian response to dehydration (Table 19.3) and to infusion of AVT (e.g., Ames et al., 1971; Gerstberger et al., 1985, Figure 19.6). This could reduce urine flow both directly (by a reduced throughput of water) and indirectly (by allowing enhanced tubular reabsorption and urine concentration). The diminished GFR may be brought about by an AVT-induced constriction of afferent arterioles (Braun and Dantzler, 1974), leading to a reduction or complete cessation (intermittency) of filtration in some or all nephrons (Figure 19.5). Superficial (loopless) nephrons appear most sensitive to AVT, and AVT therefore reduces the contribution of those nephrons, which lack loops of Henle and the ability to produce a concentrated urine, to urine production.

During flight, when birds risk dehydration from enhanced evaporative water loss, urine flow does diminish, but reduction of GFR appears to contribute just modestly to that antidiuresis (Giladi et al., 1997; Gerson and Guglielmo, 2013).

Birds also are able to increase GFR in response to ECF expansion induced by oral or intravenous water loading (Korr, 1939; Krag and Skadhauge, 1972; Roberts, 1992). Nevertheless, in three lineages of avian nectarivores, diuresis induced by consuming dilute liquid diets occurs by changes in tubular reabsorption, without change in GFR, despite changes in circulating AVT concentrations (Goldstein and Bradshaw, 1998; Gray et al., 2004; Hartman Bakken and Sabat, 2006; Purchase et al., 2013). Yet, GFR does vary through the day in all three nectarivore lineages, with progressive diurnal increase as dietary water is consumed and apparent nearly complete cessation at night (Hartman Bakken et al., 2004; Nicolson and Fleming,

TABLE 19.3 Representative responses of avian glomerular filtration rate to osmoregulatory challenge.

Species	Condition	Glomerular filtration rate (% of control)	Reference
House sparrow (*Passer domesticus*)	30 h dehydration	46	1
Starling (*Sturnus vulgaris*)	One d dehydration	42	2

2014). That nighttime reduction in GFR is seen in other small birds as well (Goldstein and Rothschild, 1993).

19.3.2.4.3 Tubular water reabsorption and the urinary concentrating mechanism

Tubular reabsorption of water in birds can range from more than 99% of the filtered volume to as low as 60% in some nectar feeders (Hartman Bakken and Sabat, 2006). As a result, the final concentration of avian urine can vary from dilute (approximately 40 mmol/kg) to hyperosmotic (2–3 times the plasma osmolality).

Both micropuncture studies of superficial proximal tubules (Laverty and Dantzler, 1982) and studies of isolated, perfused proximal tubules from deeper (transitional) nephrons (Brokl et al., 1994) suggest that, as in mammals, the avian proximal tubule reabsorbs about 70% of the filtered volume of water. That reabsorption depends on active sodium transport but not on the presence or reabsorption of bicarbonate (Brokl et al., 1994). Water reabsorption may be facilitated by the water channel protein aquaporin 1 expressed in the brush border membrane (Nishimura and Yang, 2013).

Fine tuning of water reabsorption occurs not in the proximal tubule but in more distal nephron segments. Like in mammals, birds' ability to produce a urine more concentrated than the plasma derives from the actions of a countercurrent multiplier system producing a gradient of osmolality along the depth of the renal medulla.

Earlier studies of the avian renal medulla revealed a number of the basic features associated with a countercurrent multiplier mechanism of urine concentration. Loops of Henle, providing counter-directional flow, extend into the renal medulla in parallel with collecting ducts. ^{22}Na autoradiography suggested active Na^+ reabsorption within the medullary cone (Emery et al., 1972), and this

was consistent with an osmotic gradient composed primarily of NaCl along the length of the medulla (Skadhauge and Schmidt Nielsen, 1967b; Emery et al., 1972). However, for the avian descending and ascending limbs of Henle to act as single-effect countercurrent multipliers (i.e., countercurrent multipliers whose energy source is a single active transport process, as proposed for the mammalian kidney (see, e.g., Jamison and Kriz, 1982)), they must possess two additional characteristics: (1) the ability to generate energy sufficient to develop a transverse difference in osmotic pressure and (2) differences in permeabilities. Several studies have sought to assess those characteristics.

19.3.2.4.3.1 Descending thin limb The transition from pars recta (straight descending limb of the proximal tubule) to descending thin limb (DTL) occurs with an abrupt transition in cell morphology near the base of the medullary cone (Braun and Reimer, 1988). The physiological properties of avian DTL have been studied for just the upper segment of a single species (*Coturnix coturnix*; Nishimura et al., 1989). Coturnix DTL segments fail to generate an electrical potential both when bathed in isosmotic media and when exposed to a transepithelial ion gradient; these properties derive from an absence of electrogenic ion transport, combined with high but nearly equal permeabilities to Na^+ and Cl^- (Nishimura et al., 1989). Coturnix DTL has a low permeability to water (Nishimura et al., 1989).

19.3.2.4.3.2 Thick ascending limb The avian loop of Henle makes the transition from DTL to thick ascending limb (TAL) before the hairpin turn (Figure 19.7). In cellular morphology, the avian TAL resembles other vertebrate diluting segments (Nishimura, 1993; Braun and Reimer, 1988). Functional properties include a lumen-positive voltage that requires Na^+ and Cl^- and is inhibited by the loop diuretics bumetanide and furosemide, the ability to transport NaCl against transepithelial electrochemical gradients, and low permeability to water and net water transport (Miwa and Nishimura, 1986; Nishimura et al., 1986). Ion reabsorption by the TAL is sensitive to solute delivery (enhanced either by increased flow or concentration; Osono and Nishimura, 1994), but is not affected by AVT (Miwa and Nishimura, 1986), forskolin, or isoproterenol (Osono and Nishimura, 1994). The combination of active salt reabsorption and low-water permeability implies that tubular fluid is diluted as it passes through the TAL.

19.3.2.4.3.3 Collecting duct The avian collecting duct receives dilute urine from both the TAL and from loopless nephrons, and so water reabsorption into the hyperosmotic interstitium to concentrate the urine requires that this nephron segment is, or can become, permeable to water. Indeed, infusion of AVT into the systemic circulation, at least at low doses, increases urine osmolality and reduces urine flow with little or no change in GFR (Ames et al., 1971; Stallone and Braun, 1985, Figure 19.6), suggesting enhanced permeability of the distal nephron.

Despite these findings in whole-animal studies, direct assessment of AVT's actions on isolated, perfused avian collecting ducts has failed to reveal a significant effect of the hormone (Nishimura, 1993). mRNA for AQP2, the primary ADH-responsive aquaporin (water channel

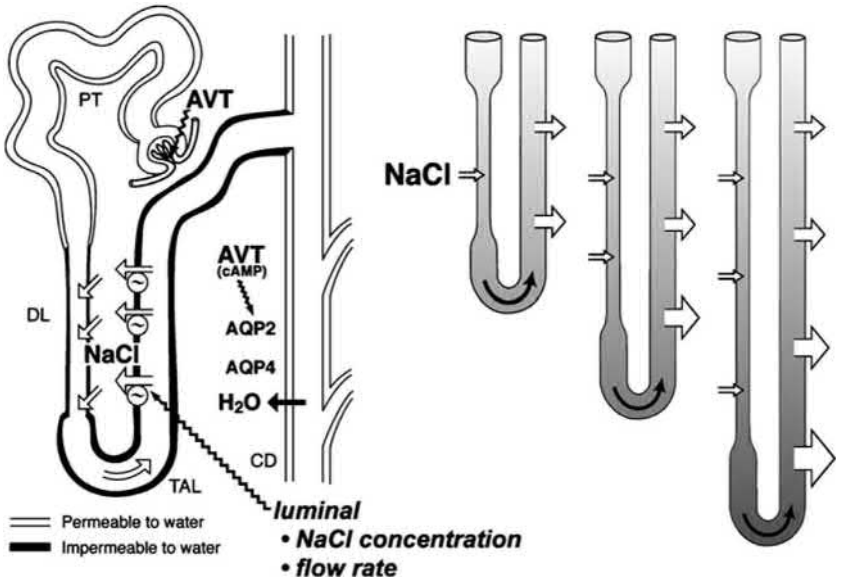

FIGURE 19.7 A proposed model for the avian urine concentrating mechanism. Tubule segments illustrated with heavy lines have low permeability to water. Possible sites of regulation include arginine vasotocin–induced reduction of the filtered load (shown), flow-sensitivity of the thick ascending limb, and cyclic adenosine monophosphate–mediated changes in water permeability of the collecting duct. To the right is pictured the hypothetical cascade effect of the concentrating mechanism that results from the presence of loops of Henle of varying length. *Figure from Nishimura (1993).* © *Cambridge University Press 1993; reprinted with the permission of Cambridge University Press.*

protein) in mammalian collecting ducts, was expressed in both medullary and superficial portions of the quail kidney, and in both regions the expression was somewhat increased by water deprivation (Nishimura and Yang, 2013). However, the coturnix quail collecting duct had a moderate baseline permeability to water even in the absence of AVT, and although forskolin (10^{-4} M), which activates cyclic adenosine monophosphate production, induced a substantial increase in permeability, AVT did so only slightly. Thus, the role of AVT-induced aquaporin expression in avian antidiuresis remains equivocal.

19.3.2.4.3.4 Urinary concentrating mechanism Nishimura (Nishimura, 1993; Osono and Nishimura, 1994) has proposed a general model of the avian urinary concentrating mechanism that incorporates the evidence described above (Figure 19.7). The single effect that drives urine concentration is active ion reabsorption by the TAL. These reabsorbed ions enter the DTL by passive diffusion without accompanying water flux. The low-water permeability of the DTL maintains volume flow through the loop, which should favor ion reabsorption by the flow-sensitive TAL. The result is that urine is concentrated as it descends through the DTL, then diluted as it ascends the TAL. The segment of thick descending limb that occurs prior to the tip of the loop should contribute to the concentrating effect (Marcano et al., 2006). Simultaneously, the interstitium surrounding the loop accumulates ions and becomes concentrated. The sensitivity of the TAL to solute delivery means that the tip of the loop (at the start of the TAL epithelium) should be the site of greatest ion reabsorption, and this should contribute to generating a concentration gradient in the medulla. These effects are amplified by the countercurrent flow, and may be further enhanced by interaction among loops of Henle which turn at different depths in the medullary cone (Layton, 1986). As the urine subsequently descends through the collecting duct, it may equilibrate osmotically with the interstitium via the baseline permeability to water of this nephron segment. Mathematical modeling of the avian kidney suggests that the effectiveness and efficiency of urine concentration can be adjusted by varying the flow and transport parameters among a population of nephrons (Marcano et al., 2006).

The exact role of AVT in this mechanism remains to be clarified. However, even if AVT acts primarily by reducing filtration rates of RT nephrons, not by an effect on tubular water permeability, then the decreased flow through the collecting ducts would permit greater equilibration of water between tubule and interstitial fluid. Other aspects of anatomical organization of the avian kidney, such as the separation of descending and ascending limbs of Henle by a ring of collecting ducts (Cassoti and Richardson, 1993), also may have (undescribed) impact on the concentrating mechanism. Lastly, it is notable that NaCl may account for just a small proportion of total osmolality (Skadhauge, 1977; Hughes et al., 1992; Goldstein, 1993b); the roles of ions other than NaCl in urine concentration deserve examination.

19.3.2.4.3.5 Net effect: avian urinary concentrating ability The net effect of the medullary concentrating mechanism is that birds typically are able to concentrate urine to an osmolality 2−3 times that of plasma. [An exception to this is a report that salt-marsh savannah sparrows, *Passerculus sandwichensis beldingi*, when drinking seawater, excreted cloacal fluid with an osmolality 4.5 times that of plasma (Poulson and Bartholomew, 1962).] The urinary concentrating ability generally varies inversely with body mass, so that small birds (10−25 g) concentrate to about 1000 mmol/kg, larger birds (>500−1000 g) mostly to about 600−700 mmol/kg (Goldstein and Braun, 1989). This pattern may result from the dependence of urine concentration on metabolically active processes (active ion reabsorption) that act at lower rates with increasing body mass (Greenwald, 1989). It remains unclear the extent to which other features of kidney anatomy, such as the proportions and number of looped and unlooped nephrons, the lengths of medullary cones, or the proportions of kidney mass composed of medullary tissue, relate to urinary concentrating ability independent of the effect of body mass (Johnson, 1974; Goldstein and Braun, 1989; Warui, 1989). At least within closely related species, urine concentration does seem to be related to the proportion of medullary tissue in the kidneys (Skadhauge, 1981).

19.3.2.5 Regulation of sodium excretion

19.3.2.5.1 Patterns of response

One of the important functions of the avian kidney is to regulate sodium excretion; sodium is the primary extracellular cation, and its content in the ECF largely determines the ECF volume and hence contributes to blood pressure regulation. Regulation of sodium excretion by the avian kidney has been examined under two general circumstances. In the first, dietary sodium intake is varied; typically these animals are able to regulate plasma sodium concentration within the normal range. In the second, birds are infused with saline, typically at a high concentration that challenges homeostasis and ultimately leads to a rise in plasma sodium concentration and osmolality.

Acclimation to increasing salt intake results, as expected, in enhanced renal salt excretion. This may involve an increase (Hughes, 1980), decrease (Hughes et al., 1989; Dawson et al., 1991), or no change (Holmes et al., 1968; Hughes, 1980; Goldstein, 1990) in GFR (Table 19.3). The renal response depends at least in part on the level of NaCl intake. For example, chukars (*Alectoris chukar*) responded to an increase from 0.25 to 2 meq Na^+/d primarily by reducing intestinal sodium absorption, with little renal

response, whereas a further increase to 10 meq/d induced a reduction in tubular sodium reabsorption (Goldstein, 1990). NaCl drinking solutions at concentrations beyond the kidneys' regulatory ability may induce dehydration and an accompanying reduction in GFR (Roberts and Hughes, 1983).

Infusion of hyperosmotic salt loads induces different responses in different species (Table 19.3). Some birds respond with large increases in GFR and reduced fractional Na^+ reabsorption (Laverty and Wideman, 1989; Roberts, 1992). In others, GFR doesn't change (Skadhauge and Schmidt-Nielsen, 1967a; Gerstberger et al., 1985; Hughes et al., 1993) or diminishes (Braun and Dantzler, 1972; Dantzler, 1966; Goldstein, 1993b). In birds with salt glands, the unchanging GFR in response to saline drinking or infusion may reflect the ability of the salt glands to excrete NaCl and thereby preserve body water. Among other species, the different responses may relate to different strategies of osmoregulation—whether to preserve extracellular volume at the expense of a rising osmolality (i.e., to retain the infused sodium, but thereby retain water), or to preserve osmolality at the expense of reduced volume (i.e., to excrete the solute load, but lose water along with it).

19.3.2.5.2 Mechanisms of regulation

A number of hormones may be involved in producing the varied patterns of sodium excretion.

19.3.2.5.2.1 Arginine vasotocin A rising extracellular osmolality would be expected to stimulate release of AVT and, indeed, saline infusion can result in elevated AVT concentrations (Koike et al., 1979; Arad et al., 1986). However, saline infusion may expand the ECF, and the consequent decrease in circulating AVT levels may allow GFR to rise. Yet other studies have measured stable or substantially increased GFR even while AVT was increased (Roberts, 1992; Hughes et al., 1993). This may reflect a countervailing effect of atrial natriuretic peptide (ANP) (see below) released in response to extracellular volume expansion.

19.3.2.5.2.2 Renin/angiotensin Birds possess a complete renin/angiotensin system: avian nephrons have a juxtaglomerular apparatus (Morild et al., 1985), and their plasma contains renin activity, angiotensin I, and angiotensin II (reviewed by Wilson, 1989). In ducks (*Anas platyrhynchos*), circulating levels of angiotensin are elevated during ECF volume contraction (Gray and Simon, 1985), as may occur when drinking high-saline concentrations (Zenteno-Savin, 1991). Seemingly in contrast with this, infusion of angiotensin II (ANGII) into ducks (Gray et al., 1986) or into the renal portal vein of chickens (Langford and Fallis, 1966; Stallone and Nishimura, 1985) stimulates natriuresis and diuresis without any change in GFR, suggesting that ANGII inhibits sodium reabsorption through a direct tubular action. Thus, the physiological effects of angiotensin vary with the osmoregulatory status of the animal. With salt and volume depletion, angiotensin stimulates reduction in GFR, urine flow, and sodium excretion (Gray and Erasmus, 1989); salt and volume loading, on the other hand, change the response so that angiotensin becomes natriuretic and diuretic. The mediator of this change has not been determined, though Gray and Erasmus (1989) suggest that prostaglandins are likely candidates.

19.3.2.5.2.3 Aldosterone Circulating concentrations of aldosterone may or may not be elevated by a diet low in NaCl or during dehydration (Skadhauge et al., 1983; Klingbeil, 1985; Árnason et al., 1986; Goldstein, 1993a). The hormone is presumed to have an action on the avian kidney similar to that seen in mammals—that is, promoting sodium conservation.

19.3.2.5.2.4 Atrial natriuretic peptide Birds, like other vertebrates, secrete a peptide hormone (29 amino acids in the chicken) from the heart atria (Toshimori et al., 1990). Infusion of chicken ANP increases renal sodium and water excretion both in the domestic duck (Gray et al., 1991; Schütz et al., 1992) and chicken (Gray, 1993), and, conversely, attenuating ANP concentrations during conditions of volume loading attenuates renal excretion (Gray et al., 1997). Although receptors for ANP have been localized on both the glomeruli and the renal tubules (Schütz et al., 1992), the mechanism of action of the hormone, including the relative contributions of glomerular versus tubular effects, remains unresolved.

19.3.2.6 Regulation of calcium and phosphate excretion

19.3.2.6.1 Calcium

Normally the avian kidney reabsorbs more than 98% of filtered calcium (Wideman, 1987) by a pathway that is apparently saturable and normally operates near its maximum capacity. Procedures that increase the filtered load of calcium, such as intravenous infusion of calcium or injection of exogenous parathyroid hormone (PTH, which increases GFR and plasma calcium levels), result in enhanced renal calcium excretion (Clark et al., 1976). On the other hand, in most birds (but not all; Clark and Mok, 1986), the normal pattern of reabsorption depends of PTH; calcium excretion is markedly increased by parathyroidectomy and is restored to control levels by PTH administration (Clark and Wideman, 1977; Clark and Sasayama, 1981). The single clearance study of the effects

of calcitonin failed to demonstrate any significant effect on renal calcium excretion (Clark and Wideman, 1980).

A cellular mechanism of calcium reabsorption and stimulation by PTH, which may occur in the TAL (Braun and Dantzler, 1987), has been proposed by Clark and Wideman (1989). Calcium likely moves across the apical cell membrane down an electrochemical gradient. Reabsorption across the basolateral membrane would then be accomplished by active transport, perhaps involving a calcium ATPase. PTH, which is known to activate cellular cyclic AMP production (e.g., Dousa, 1974; Pines et al., 1983), could promote this reabsorption via actions either on the apical permeability or the basolateral mechanism of reabsorption.

19.3.2.6.2 Phosphate

In chickens, approximately 60% of the filtered load of phosphate is excreted in the urine, a result of the simultaneous operation of a reabsorptive pathway, which reclaims about half of the filtered phosphate, and a low level of secretion (Wideman, 1987). PTH both inhibits phosphate reabsorption (Cole, 1985, in Clark and Wideman, 1989) and stimulates its secretion (Wideman and Braun, 1981). As a consequence, in the absence of PTH (i.e., following parathyroidectomy), urinary phosphate excretion falls to near zero (Clark and Wideman, 1977). In contrast, administration of PTH to intact birds can result in renal excretion of more than twice the filtered load of phosphate (Wideman and Braun, 1981). No effect of calcitonin on renal phosphate excretion has been demonstrated (Clark and Wideman, 1980).

In starlings, individual proximal tubules of superficial RT nephrons may exhibit either net secretion or net reabsorption of phosphate (Laverty and Dantzler, 1982), and this may be the site of regulation of phosphate transport. The cellular mechanism of phosphate reabsorption involves a saturable, sodium-dependent transporter located in the apical membrane (Grahn and Butterworth, 1982; Renfro and Clark, 1984). Inhibition of this transport is mediated by cyclic AMP (Cole, 1985) acting via protein kinase C and protein kinase A (Dudas et al., 2002). The mechanism of activation of phosphate secretion remains unknown. Phosphate infused only into blood supplying the renal tubules (via the renal portal vasculature) accounted for only a small fraction of net phosphate transport into the tubule lumen during times of net secretion (Wideman and Braun, 1981). The secreted phosphate may derive primarily from a pool that is sequestered within the tubule cell (Wideman, 1984).

In addition to its effects on calcium and phosphate transport, PTH may have other actions on the kidney, including most consistently increases in GFR, sodium excretion, and urine flow (Clark and Wideman, 1989).

19.3.2.7 Nitrogen excretion

The end products of nitrogen metabolism excreted by the kidneys in avian urine include urates, ammonia, urea, creatinine, amino acids, and others (Table 19.4). Urates are the predominant compounds under all circumstances, though ammonia may account for as much as 25% of total urinary nitrogen. The proportions of different nitrogenous wastes may vary with feeding cycle and age (Lyons and Goldstein, 2002). After entering the lower intestine from the ureters, modification of the urine by bacterial metabolism and intestinal transport can diminish urates in the final excreted fluid (Crouch at al., 2020) and can even

TABLE 19.4 Patterns of nitrogen excretion in avian urine.[a]

Species	Condition	Total N (g/L)	Urate (% of total)	NH_4 (% of total)	Urea (% of total)
Domestic fowl (*Gallus domesticus*)	Fed	4.4	84.1	6.8	5.2
	Fasted	2.4	57.8	23.0	2.9
	Low protein	11	54.7	17.3	7.7
	High protein	13	72.1	10.8	9.7
Turkey vulture (*Cathartes aura*)	Fed	61	87	9	4
	Fasted	13	76	17	7
American kestrel (*Falco sparverius*)	Wild nestlings, age three weeks	54.6	80.4	6.4	7.3
	Captive adult fed chicks	46.7	81.4	5.6	4.9

[a]*Data extracted from summary table in Skadhauge (1981) for fowl and turkey vulture, and from Lyons and Goldstein (2002) for kestrel. Other nitrogenous components of the urine, including creatinine, amino acids, and purines always accounted for <10% of total nitrogen.*

produce "apparent ammonotely" (Tsahar et al., 2005). The present discussion will focus on the excretion of urates by the kidneys; urinary ammonia will be discussed in the following section, as it relates to acid/base regulation.

Urate in avian plasma is thought to be all or mostly unbound to proteins and hence filterable through the glomeruli (see discussion in Dantzler, 1978). Nevertheless, with a plasma urate concentration of 0.1−0.7 mM, glomerular filtration can only account for 10−20% of the total urate excreted by the kidneys. Shannon (1938) was the first to demonstrate conclusively that the clearance of urate exceeds that of inulin, and >90% of urate in avian urine derives from tubular secretion. The source of the secreted urates is primarily the liver, though renal synthesis may account for 3−20% of the total (Martindale, 1976; Chin and Quebbemann, 1978).

Slices from avian renal cortex (Platts and Mudge, 1961; Dantzler, 1969), but not of medullary cones (Dantzler, 1969), accumulate urate in vitro, suggesting that urate secretion occurs in cortical nephron elements. Micropuncture studies of superficial proximal tubules of RT nephrons, as well as studies of urate transport by isolated proximal tubules from deeper (transitional) nephrons, have confirmed that these nephron segments secrete urate (Laverty and Dantzler, 1983; Brokl et al., 1994). Studies of isolated proximal tubules in vitro (Brokl et al., 1994) indicate that urate secretion involves transport across the basolateral membrane against an electrochemical gradient, apparently via organic anion transporters OAT and OAT3 (Dudas et al., 2005). The flux from cell to tubule lumen is down an electrochemical gradient and involves the multidrug resistance protein MRP4 (Bataille et al., 2008, Ding et al., 2009). Net urate transport in proximal tubules is always secretory, but perfused tubules show a substantial simultaneous reabsorptive flux that apparently occurs through a paracellular route. In vivo, though, there is no evidence for such a reabsorptive pathway (Nechay and Nechay, 1959).

Once secreted, the chemistry of urates in urinary solutions is complex. The acid form of urate (uric acid) has a low aqueous solubility (0.38 mmol/L), but with a pK of 5.6 and a typical urinary pH of 6 to 7, most molecules will exist as monobasic urate. Urate could form salts with a variety of cations in the urine, but sodium and potassium urate are most likely because of the abundance of these ions. The solubilities of sodium and potassium urate (6.8 and 12.1 mmol/L, respectively) substantially exceed those of uric acid; nevertheless, the high concentrations of urates in the liquid fraction of the urine exceed values accounted for by these solubilities (McNabb et al., 1973; McNabb, 1974).

Urates apparently are able to exist in solution at supersaturated concentrations because they form stable colloidal suspensions. The stability of these colloids is increased through their interaction with mucoid materials in urine (Porter, 1963). These mucopolysaccharides and glycoproteins are most abundant in distal nephron segments where the urine concentration is likely to be highest (McNabb et al., 1973; Nicholson, 1982). The concentrated aqueous colloids probably minimize formation of urate crystals and thereby facilitate passage of urates through the nephron.

Nevertheless, urates do exist in precipitated form in avian urine. This is not in the form of crystalline masses, but rather as spheres a few microns in diameter (Figure 19.8; Folk, 1969; Lonsdale and Sutor, 1971) that form as alternating layers of urate and mucoid materials with associated water (Minnich, 1976).

Anywhere from <5% to >75% of urinary Na^+ and K^+ are associated with the precipitated urate fraction of urine rather than existing in free solution (Hughes, 1972; McNabb et al., 1973; Braun, 1978; Long and Skadhauge, 1980, 1983b; Laverty and Wideman, 1989; Dawson et al., 1991). In part, the charge configuration of the water and mucopolysaccharide layers of the urate spheres may sequester cations (McNabb and McNabb, 1975). Elemental analysis of urate spheres from several avian species indicated that Na^+ and K^+ were usually the most abundant cations, with K^+ usually the more abundant ion (Casotti and Braun, 2004). The trapped ions would not contribute to urinary osmolality and may present a means of enhancing ion excretion beyond the limited concentrating ability of the avian kidney.

19.3.2.8 Renal contribution to acid/base regulation

Birds maintain an alkaline arterial pH of approximately 7.5, despite a constant metabolic production of acid. Most of this acid, resulting from hydration of CO_2, is excreted as respiratory CO_2. However, nonvolatile acids, e.g., H_2SO_4

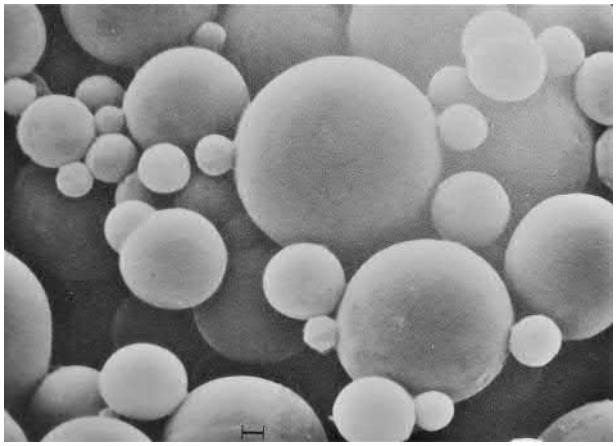

FIGURE 19.8 Scanning electron micrograph of urate spheres from the urine of Gambel's quail (*Callipepla gambelii*). The scale bar represent 1 μm. *Photograph courtesy of Giovanni Casotti and Eldon J. Braun.*

and H_3PO_4, are also a threat to acid/base homeostasis, and the kidneys must excrete the protons equivalent to these metabolic end products. Thus, while avian urine pH may range under experimental conditions from less than five to about eight (Sykes, 1971; Long and Skadhauge, 1983a), avian urine is typically acidic, with a pH in the range of 5.5−7.5. The renal defense of arterial alkaline pH is thus presumed to consist of two components, conservation of base (bicarbonate) and excretion of acid (H^+, largely buffered).

Avian renal conservation of bicarbonate is thought to be accomplished by mechanisms similar to those existing in the mammalian kidney. That is, secreted H^+ combines in the tubule lumen with filtered HCO_3^- to form CO_2 that diffuses back into the tubule cells. There, catalyzed by carbonic anhydrase, it rehydrates and dissociates into H^+ and HCO_3^-. The HCO_3^- is then reabsorbed into the blood across the basolateral membrane. Overall, birds, like mammals, can accomplish virtual complete reabsorption of filtered bicarbonate during periods of acidosis (Anderson, 1967). It is likely that bicarbonate reabsorption in the avian kidney occurs in the distal nephron, where carbonic anhydrase activity is most prominent (see Laverty, 1989; Gabrielli et al., 1998). Consistent with this, micropuncture studies of starling proximal tubules found no evidence for preferential reabsorption of bicarbonate in this nephron segment (Laverty and Alberici, 1987).

The lack of acidification of proximal tubule fluid, even in acidotic birds, suggests that H^+ secretion, too, may take place in distal nephron segments (Laverty and Alberici, 1987). The mechanism of avian renal H^+ secretion is likely to be accomplished at least in part by Na^+/H^+ exchange (Laverty, 1989). The minimum urinary pH achievable by the avian nephron is 4.5−5, and so adequate acid excretion requires that most urinary hydrogen ions be excreted in buffered form. Three compounds—ammonia, phosphate, and urate—serve as the primary urinary buffers in birds.

As noted above, ammonia may constitute up to one quarter of the total nitrogen excreted in avian urine. The urinary excretion of ammonia is inversely related to the pH of the urine (Wolbach, 1955; Long and Skadhauge, 1983a). This ammonia is presumed to derive from cellular metabolism (deamination reactions) and secretion in the distal nephron. The production of ammonia can be enhanced by infusion of the amino acids D,L-alanine, L-leucine, and glycine (Wolbach, 1955), and chronic metabolic acidosis in the chicken leads to increased activity of glutaminase in the kidney (Craan et al., 1982). Ammonia secretion is presumed to occur by nonionic diffusion. Uncharged NH_3 diffuses from the tubule cells into in the various surrounding fluid compartments. In the acidic urine of the tubule lumen, NH_3 is protonated to ammonium, NH_4^+, which permeates cell membranes more slowly than NH_3 and so is effectively trapped there for excretion.

The phosphate buffer system (HPO_4/H_2PO_4), with a pK of 6.8, also plays an important role in urinary buffering. H_2PO_4 may account for approximately 20−30% of total acid excretion at typical urinary pH, but may increase substantially when phosphate is infused during times of production of acidic urine (Wolbach, 1955; Sykes, 1971). The contribution of phosphate to acid excretion declines as urinary pH rises, perhaps because of a preferential reabsorption of the basic form of the buffer (HPO_4), which would be more abundant at the higher pH (Long and Skadhauge, 1983a).

The final major contributor to buffering of avian urine is urate/uric acid (pK 5.8). The contribution of this system to acid excretion is undoubtedly substantial (Wolbach, 1955) but is difficult to quantify accurately because of uncertainty about the chemical form of the colloidal precipitate. Calculations based on the assumptions either that all precipitated U/UA exists as UA (Lonsdale and Sutor, 1971) or that the precipitated U/UA is in equilibrium with the supernatant, suggest that U/UA constitutes 25−50% of net acid excretion (Long and Skadhauge, 1980, 1983a).

19.3.2.9 Molecular regulation: the next frontier

In recent years, understanding of normal and pathological physiology of the mammalian kidney has been advanced substantially by investigation of underlying molecular mechanisms. In particular, transcriptomic sequencing (RNA seq) has elucidated patterns of gene expression, and its responses to physiological challenge and disease, at the level of the individual renal tubule (Lee et al., 2015) and cell type (Chen et al., 2017). In birds, genome sequences now are available for diverse species (Zhang et al., 2014), and RNAseq has been applied to a number of questions related to avian physiology, development, and pathology (Jax et al., 2018). However, those approaches have been applied to avian kidneys in just a small number of studies (e.g., Hao et al., 2019; Park et al., 2017; Zeferino et al., 2017), with RNA extracted from whole kidneys or kidney regions (e.g., renal cortex). Because patterns of gene expression, and the consequent cellular mechanisms, are specific to tubule segments and cell types within the kidney (see references above), studies of whole-kidney transcriptomics in birds to date can provide just a preliminary view of physiological mechanisms.

One insight that has emerged from these molecular investigations in mammals is that, in addition to protein-based regulation, function of the kidneys is significantly influenced by expression of noncoding RNAs. That includes both short noncoding RNAs like microRNA (see Sun and Lerman, 2019; Ramanathan and Padmanabhan, 2020) and long noncoding RNAs (Ignarski et al., 2019). Such mechanisms remain unexplored in avian kidneys.

19.3.2.10 The final urine—composition and flow

One might expect that any analysis of kidney function would begin with examination of urine flow and composition. However, collection of urine from conscious birds is difficult. Urine flows from the ureters into the coprodeum, colon, and ceca, where it may be modified. A variety of approaches have been used to circumvent these difficulties. In some studies, the possibility of urine flow into the hindgut is removed, either by colostomy (in which the lower intestine is exteriorized and the ureters empty into a blind cloacal pouch; Hart and Essex, 1942; Holmes et al., 1982; Karasawa and Maeda, 1992; Belay et al., 1993) or by exteriorizing the ureters (Hart and Essex, 1942; Dicker and Haslam, 1972). Besides the potential for consequences from surgery, these techniques suffer from the possibility that urine flow is influenced by the very fact that the urine can no longer interact as normal with the lower intestine. Alternatively, urine can be collected directly from the cloaca. This may be done over an extended time via collecting devices sewn over the ureteral openings (Anderson and Braun, 1985), though again potentially disrupting normal osmotic regulation. Alternatively, a filtration marker can be infused at a constant rate, such as by an implanted micropump; urine flow rate then can be calculated based on urine collected via brief insertion of a cannula over the ureteral openings (Goldstein and Braun, 1988; Goldstein and Rothschild, 1993). This approach imposes the least interruption of normal function but provides just an "instantaneous" urine flow rate.

In unanesthetized birds with free access to water, urine flow rate is in the range of 0.5–3 mL/kg$^{.7}$h (Goldstein, 1990, using the same body mass scaling factor, kg$^{0.7}$, as pertains to GFR), and urine osmolality is typically close to isosmotic with plasma. During dehydration, urine flow diminishes and osmotic concentration increases to two to three times that of plasma. The composition of this urine has been analyzed in detail in only a small number of studies. In chickens eating grain (30 meq Na^+/kg), Na^+ and Cl^- together accounted for just over 10% of the total osmolality of 582 mM/kg (Skadhauge, 1977). The most abundant solutes were NH_4^+, phosphate, and K^+ (Table 19.5), and just 41% of the osmotic space could not be accounted for by measured solutes. In chickens eating a diet with three times the sodium content of the grain, Na^+ and Cl^- in the urine rose about threefold, NH_4^+ was substantially diminished, and other measured solutes changed by just small amounts (Table 19.4; Skadhauge, 1977). These findings—relatively high concentrations of NH_4^+, phosphate, and K^+, with Na^+ and Cl^- together accounting for less than 50% of the osmotic space—are representative of other studies as well. However, with salt loading, Na^+ concentrations can rise to as much as 30–50% of the total osmotic space in some species both with and without salt glands (Goldstein, 1990, 1993b; Bennett and Hughes, 2003).

19.3.2.11 Function of the ureters

The ureters of birds are surrounded by smooth muscle which normally possesses tone and is capable of peristalsis (Gibbs, 1929). The ureters act to "milk" the urine from the kidneys, but they also offer significant resistance to the flow of urine. Because the ureters are direct extensions of the collecting ducts, ureteral resistance may influence flow rates through the nephrons. Consistent with this, Hughes (1987) found that severing the ureter just caudal to the kidney increased urine flow and reduced urine osmolality, suggesting that a more rapid transit through the nephron impaired ion and/or water reabsorption. The state of ureteral tone and extent of peristalsis may be under the influence of the sympathetic nervous system (Gibbs, 1929).

19.4 Extrarenal organs of osmoregulation: introduction

Despite their limited urine concentrating ability, birds are as effective as mammals at water conservation. In both groups, small, desert-dwelling species are able to survive on seed diets without drinking water (Krag and Skadhauge, 1972; Skadhauge and Bradshaw, 1974); however, the

mechanisms responsible for those capabilities differ in the two vertebrate classes. Water conservation in birds does result at least in part from renal mechanisms, including the ability to reduce GFR and to increase tubular reabsorption of water, but desert birds lack the notable urine concentrating abilities of their mammalian counterparts. Uricotelism, too, may facilitate water conservation, as it provides a means of excreting nitrogenous waste with a minimum of water loss (because of the insolubility of the urates and hence their lack of contribution to the urinary osmotic concentration) (Smith, 1953). Beyond this, avian osmoregulation depends additionally on several other organs that regulate salt and water losses.

19.5 The lower intestine

19.5.1 Introduction

Urine leaving the avian ureters enters the urodeum of the of the lower intestine and, in most birds, flows in an orad direction, via retrograde peristalsis, from the urodeum into both coprodeum and colon (rectum) (Figure 19.9). This retrograde flow brings the urine into contact with the chyme coming from the ileum (the urine may form a coating around a central core of feces) and exposes the urine to the absorbing columnar epithelia of the coprodeum and colon (the stratified squamous epithelia of the urodeum and proctodeum are nontransporting). Retrograde flow may extend all the way to the ileo-colonic junction, and urine may enter the paired caeca in species possessing those organs. Ions, water, and organic products of bacterial fermentation [short-chain fatty acids (SCFAs)] may be absorbed in the ceca. Urinary refluxing may serve a variety of functions, including reclamation of water, electrolytes, nitrogen, or energy that would otherwise be lost.

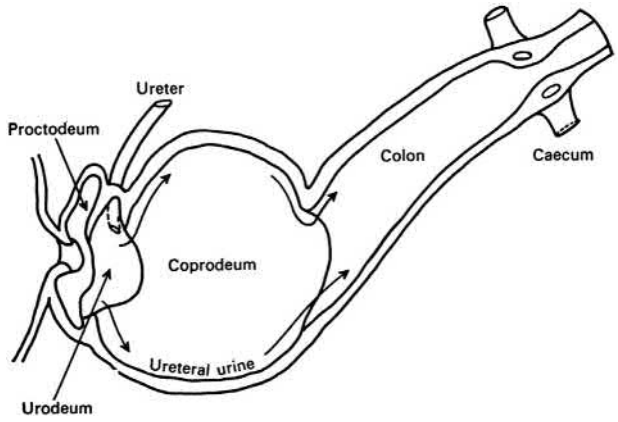

FIGURE 19.9 Lower intestine of the domestic fowl. Arrows indicate the retrograde flow of urine from urodeum to coprodeum, colon, and ceca, as well as possible directions for net fluxes of water and NaCl in coprodeum and colon. *Modified from Choshniak et al. (1977); reproduced with permission.*

19.5.2 Transport properties of coprodeum, colon, and cecum

19.5.2.1 Basic transport mechanisms in coprodeum and colon

Although coprodeum and colon, in most birds, form a common storage chamber for ureteral urine and chyme, their transport properties differ markedly.

This section is largely based on studies on the domestic fowl, as surveyed by Skadhauge (1973, 1981, 1993), Goldstein (1989), and Elbrønd et al. (1993), but the mechanisms observed in the fowl are generally observed in other avian species as different as the galah (*Cacatua roseicapilla*) and the emu (*Dromaius novaehollandiae*).

19.5.2.1.1 Transport of NaCl and water

Both coprodeum and colon have electrolyte transport properties that are regulated by, and change markedly in response to, humoral factors induced by changes in NaCl intake (Figure 19.10). Broadly speaking, the rate of Na^+ absorption is activated by NaCl depletion and suppressed by NaCl loading. The transport patterns must therefore be described and characterized in relation to the NaCl content of the diet.

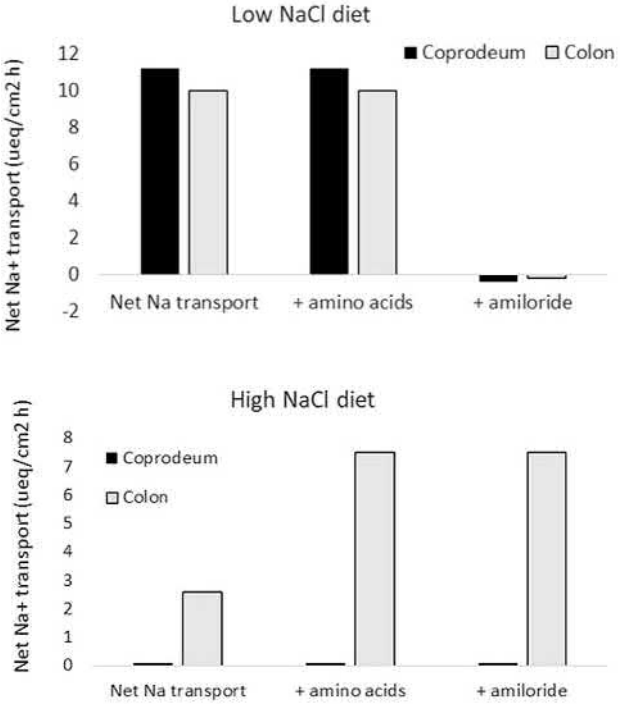

FIGURE 19.10 Effect of dietary NaCl on transport properties of coprodeum and colon in domestic fowl. Illustrated are Na^+ transport rates in the absence of luminal organic substrates (open bars), in the presence of luminal leucine and lysine (*light stippling*), and in the presence of the sodium channel blocker amiloride (*dark stippling*).

The coprodeum can be characterized as a "medium-tight" epithelium (3−500 Ω × cm^2). On a low-NaCl diet, coprodeum absorbs Na^+ at a high rate, 10−20 μeq/cm^2 hour in vitro under short-circuit conditions (Figure 19.10), and about 100 μeq/kg bodyweight × hr in vivo. Under open-circuit conditions, a transepithelial lumen-negative electrical potential difference (PD) of 40−60 mV develops in vitro, and similar differences from lumen to plasma can be measured in vivo. The PD drives passive Cl^- transport in vivo, resulting in absorption of near-neutral NaCl, whereas there is no net Cl^- transport under short-circuit conditions in vitro. Na^+ transport is completely suppressed by NaCl loading; the PD may be reversed due to a small, persisting K^+ and H^+ secretion. The cellular mechanism behind the huge change in sodium absorption is a large increase in the Na^+ permeability of the apical membrane of the enterocytes (Bindslev, 1979; Clauss et al., 1987). The Na^+ permeability is characterized by a single channel conductance of four pico-Siemens (Christensen and Bindslev, 1982). The Na^+ transport occurs through a uniform layer of cells with near-identical transport pattern (Holtug et al., 1991). There seems to be little adaptation of the Na-pump located at the basolateral membrane, as the concentration of ouabain-inhibitable Na/K-stimulated ATPase did not increase after NaCl depletion, nor did the activity or histochemical location of the K-paranitrophenylphosphatase (Mayhew et al., 1992). In coprodeum, no transport of nutrients (glucose/amino acids) is measurable, nor can solute-linked water flow be detected in vivo (Rice and Skadhauge, 1982a) or in vitro (Bindslev, 1981).

Colon from birds (domestic fowl and galah) on a low-NaCl diet has a Na-absorbing capacity and other transport characteristics similar to coprodeum, including absence of stimulation of Na^+ transport by hexoses or amino acids. The colonic epithelium is more "leaky" (80−100 Ω × cm^2) than coprodeum and consequently has a lower transmural PD, 15−20 mV in vitro and in vivo. Concomitant with this, solute-linked water absorption can be measured in colon, 16 μL/cm^2 hr in vitro (Bindslev, 1981) and 150 μL H_2O/kg bodyweight × hr in vivo (Rice and Skadhauge, 1982a).

For birds on high-NaCl intake, colonic transport parameters are markedly different from those of coprodeum (Figure 19.9). Rather than being suppressed, Na^+ absorption continues at 5−10 μeq/cm^2 hr, but only when glucose and amino acids are present on the luminal side (Lind et al., 1980a; Clauss et al., 1991; Rice and Skadhauge, 1982b). These nonelectrolytes are now co-transported with Na^+ (Lind et al., 1980b), the transport of which is not inhibited by the Na^+channel blocker amiloride (which totally suppresses Na^+ absorption in both coprodeum and colon from NaCl-depleted birds). NaCl-loading thus induces in the avian colon a switch-over from a Na^+ channel to Na^+/nutrient cotransport. The latter is half-saturated by glucose and amino acid (lysine or leucine) concentrations less than 2 mM; Na^+ absorption will therefore be activated whenever there is chyme in the colon.

19.5.2.1.2 Transport of other ions

K^+ is secreted into coprodeum and colon, as observed in the domestic fowl and the emu in vivo and in the domestic fowl in vitro (see Skadhauge, 1981). Only at high-intraluminal concentrations of K^+ this ion will be absorbed. At concentrations of K^+ typically found in ureteral urine, the net secretion of K^+ from coprodeum and colon is around 10 μmol/kg body weight x hr (Skadhauge and Thomas, 1979). As measured in the Ussing chamber (see survey by Skadhauge, 1993, p.73−74), the net secretion of K^+ in coprodeum and colon is usually around 0.5 mmol/cm^2 hr, less than 5% of the concomitant Na^+ absorption.

Both ammonium and phosphate ions are absorbed from the coprodeum and colon in vivo in the domestic fowl (Skadhauge and Thomas, 1979) and in the emu (Dawson et al., 1985). In both species, higher absorption rates were observed at higher luminal concentrations. H^+ is secreted, presumably by an apical H^+/Na^+ exchanger (see Skadhauge 1993). This secretion leads to an acid microclimate on the mucosal surface (Holtug et al., 1992), though this is also influenced by products of enterocyte metabolism (Laverty et al., 1994). The acid microclimate aids in colonic absorption of SCFA's, particularly propionate (Holtug et al., 1992).

19.5.2.1.3 Quantitative role of coprodeum versus colon

When the absorptive areas and the local transport rates of the two organs are compared, the colon has in all species examined a much higher total capacity. The colon therefore functions as the "work-horse" (Thomas, 1982) for recovery of salt and water from ureteral urine and chyme, whereas coprodeum functions as a final "tuner" of total excretion.

19.5.2.2 Dietary and hormonal regulation of coprodeal and colonic transport

Both the amount of NaCl in the diet, which induces the low/high switch-over of Na-transport, and the time-sequences of that transition have been elucidated in the domestic fowl. No other dietary components have been identified that have a measurable influence on NaCl transport.

Árnason and Skadhauge (1991) provided domestic fowls with six levels of NaCl intake ranging from 0.25 to 25 mmol/kg bodyweight day and observed plasma levels of several hormones (aldosterone, corticosterone, prolactin, and AVT) and the sodium absorption and induced chloride secretion of colon and coprodeum. The low levels of NaCl intake resulted in increasing levels of plasma aldosterone,

and colon and coprodeum absorbed sodium by an amiloride-suppressible mechanism. The highest levels of NaCl intake increased the concentration of prolactin and AVT in plasma. The intake range of 3−6 mmol NaCl/kg bodyweight day presented the least osmoregulatory stress (i.e., being sensed neither as NaCl depletion nor as a NaCl load). Aldosterone was clearly the main inducer of the high rate of Na^+ transport in coprodeum.

As Na^+ intake by chickens is depleted, Na^+ transport and aldosterone levels rise to a new steady state over a week (Thomas and Skadhauge, 1982; Árnason et al., 1986). In contrast, in the opposite protocol, acute resalination (NaCl loading), plasma aldosterone is suppressed in 8 h, and net Na^+ absorption in 24 h (Skadhauge et al., 1983; Árnason et al., 1986). The implication is that absence of aldosterone induces rapid closure of functional apical Na^+ channels.

Aldosterone supplementation during resalination maintained the low-salt pattern of colonic transport (high amiloride-sensitive short-circuit current and low glucose-stimulated short circuit) and prevented expression of sodium/glucose cotransporter (SGLT)-like protein in those tissues (Laverty et al., 2001). Thus, aldosterone suppresses both activity and protein expression of hen colonic SGLT.

Studies with external aldosterone injections reveal, however, that the hormonal (and dietary) regulation of coprodeal Na^+ transport is more complicated. Supramaximal injections of aldosterone over 24 h, the time normally needed to cause a full switch-over of an epithelium to maximal Na^+ transport rate, only induced 10−30% of the net Na^+ transport induced by full adaptation to a low-NaCl diet (Clauss et al. 1984, 1987). If instead the aldosterone was injected during the first 24 h of acute resalination, the sodium absorption was maintained at the high rate characteristic of low-NaCl adapted birds. This effect declined over 3−5 days, when the 24 h aldosterone injection was postponed later and later, to the moderate level of Na^+ transport induced by aldosterone in birds on a chronic high-NaCl intake (Clauss et al., 1984). The reason for this apparent change in sensitivity to aldosterone is a structural change induced by the hormone, entailing an increased number of both enterocytes and apical microvilli on the individual cell (see next section). This enlarges the apical area by 400%. The apparent change in aldosterone sensitivity was not caused by recruitment of aldosterone receptors (Sandor et al., 1989).

The colon of the domestic fowl does not exhibit these delayed transport changes (Clauss et al. 1984, 1991), but this organ does not change apical microvilli with diet. On the other hand, the difference in histologic appearance of colon from salt-marsh versus upland savannah sparrows (Goldstein et al., 1990) is indeed similar to that of coprodeum from high-versus low-salt chickens. The differences seen in characteristics of lower intestinal tissues from hens on low- versus high-salt diets also are largely replicated in two northern species, the rock ptarmigan (*Lagopus mutus*) and the common murre (*Uria aalge*, which possesses salt glands) that naturally ingest low- and high-salt diets, respectively (Árnason et al., 2015). Interspecific variations in colonic function, such as lack of hexose-stimulated transporter activity in *U. aalge* and amino acid cotransporter activity in proximal regions of *L. mutus* colon, may reflect natural histories and diets of the species, or could represent phylogenetic variation in gut properties.

19.5.2.3 Ultrastructural adaptation and molecular induction

Continued NaCl depletion induces in white Plymouth Rock chickens a very late effect: a structural change of the individual epithelial cells (Figure 19.11) as well as of the entire organ. This was investigated by tandem measurements of coprodeal ultrastructure and sodium transport (amiloride-suppressible short-circuit current) in vivo (Mayhew et al., 1990). The high aldosterone/low NaCl diet involves modulations of the level of mRNA that codes either for the Na-channel or a post-transcriptional regulator of the channel, since the mRNA from low-NaCl but not high-NaCl diet coprodeum expresses an amiloride-suppressible Na^+ uptake after injection into *Xenopus* oocytes (Asher et al., 1992). The microvillous surface area increased in birds chronically exposed to the low-NaCl diet, from 32 to 49 μm^2/cell without changing cell size (Figure 19.11), and the total cell number per organ increased from 270 to 420 million. The total effect was a 135% rise in apical area (Elbrønd et al., 1991; Mayhew et al., 1992). Supramaximal doses of aldosterone injected over 2−6 days also induced a substantial increase of the microvillous surface area (Elbrønd et al., 1993). This enlargement of apical area occurred more rapidly than the rate of cell turnover, and hence involved remodeling of the existing cell population (Elbrønd et al., 1993). The late effect of aldosterone to increase cell number then leads to synthesis of cells with near identical sodium transport capacity, as demonstrated by uniform histochemical localization of Na/K ATPase activity (Mayhew et al., 1992), by immunochemical localization of the amiloride-sensitive Na^+ channel (Smith et al., 1993), and by measurements of the local Na^+ transport rates by the vibrating microprobe technique (Holtug et al., 1991). The basolateral membrane area did not change significantly per individual cell following chronic NaCl depletion (Mayhew et al., 1992).

19.5.2.4 Salt and water transport in the caeca

The paired caeca are of variable size; large caeca are typically associated with herbivory and granivory (McLelland, 1989). In vivo perfusion studies in the domestic fowl demonstrate substantial absorption of NaCl and

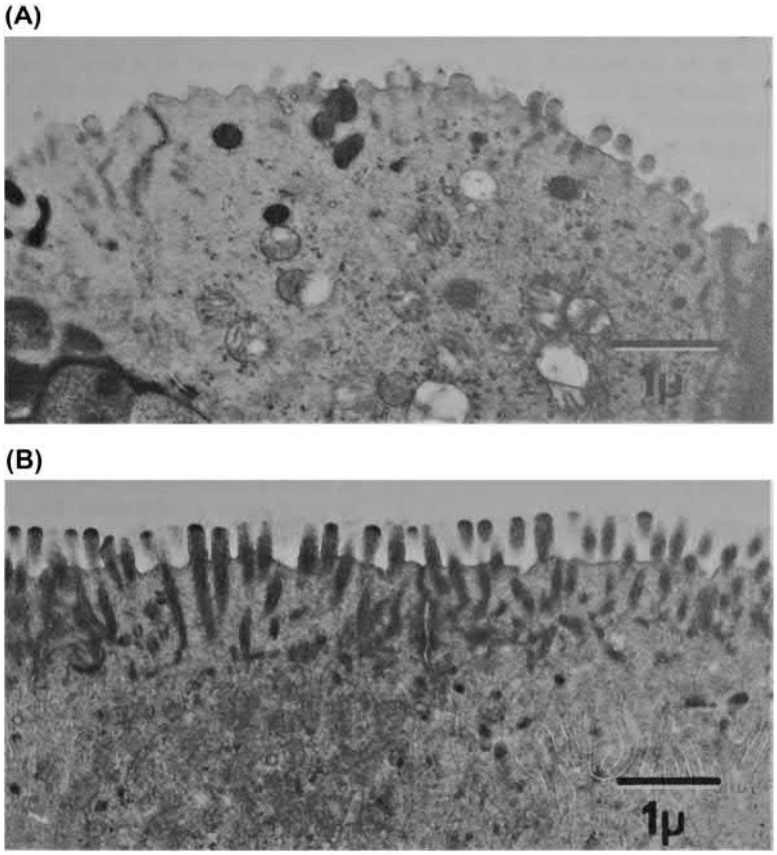

FIGURE 19.11 Transmission electron micrographs of the apical region of coprodeal epithelial cells from chickens eating either (A) a high-NaCl diet or (B) a low-NaCl diet. Note the differences in height and density of apical microvilli, providing the low-NaCl birds with a substantially enhanced absorptive surface area. *Photograph courtesy of Dr. Vibeke Elbrønd.*

water, and secretion of K^+. The Na^+ absorption is stimulated by acetate; NaCl absorption is enhanced by luminal glucose and stimulated by aldosterone (Rice and Skadhauge, 1982c; Thomas and Skadhauge, 1989a). Anatomically the caecum in the chicken has a large end (the bulbus) and a narrow neck region (see Dantzer, 1989). The bulbus had higher transport rates of both Na^+ and amino acids than the neck region (Thomas and Skadhauge, 1989b).

19.5.3 Postrenal modification of ureteral urine

19.5.3.1 Basic patterns: Hydration/NaCl loading

The interplay of kidney and cloaca depends on flow rate and ionic and osmotic concentration of ureteral urine in relation to the transport capacities of the epithelia of the lower gut. The osmotic permeability coefficient and the sodium transport rate are most important, since these parameters determine the net rates of absorption/secretion in the parts of the lower gut in which urine is stored (or flows through). One would expect the fractional effect of cloacal storage to be limited if the flow rate of ureteral urine is high. This would apply both to water reabsorption in the hydrated state and for NaCl absorption during NaCl loading. In the domestic fowl (see Skadhauge, 1973), consideration of all relevant parameters, including the resulting osmolality and Na^+ concentration of the contents of the lower gut, permits calculation that only about 2% of ureterally excreted water and NaCl will be reabsorbed in the hydrated and salt loaded state, respectively. Cloacal storage little modifies the excretory function of the kidney in these functional states. In contrast, substantial modification of urine (particularly reabsorption of NaCl) occurred in the starling even during brisk urine flow induced by mannitol diuresis (Laverty and Wideman, 1989); the transport properties of the lower intestine of this species are unstudied.

19.5.3.2 Basic patterns: Dehydration/NaCl depletion

Quantitative studies of flow rate and composition of ureteral urine of dehydrated birds, and the transport parameters of coprodeum and colon, have been carried out in three species of seed-eating land birds, the domestic fowl, the galah, and the house sparrow (*Passer domesticus*). The values obtained on the fowl and the galah have been treated by a computer simulation of the retrograde flow into the

cloaca and the integrated effect on salt and water transport (Skadhauge and Kristensen, 1972; Skadhauge, 1973). The result obtained is that 10–20% of ureterally excreted water, and 70% of Na^+, is absorbed in the cloaca of both species. This occurs in the galah despite its higher urine osmolality because of a counteracting higher rate of solute-linked water flow and lower osmotic permeability coefficient (Skadhauge, 1981). The house sparrow (Goldstein and Braun, 1988) and the budgerigar (Krag and Skadhauge, 1972) seem to have a similar interaction of cloacal recovery of NaCl and water, though in the house sparrow, the transport properties of the colon more closely parallel those of hen coprodeum (Goldstein, 1993a).

The relevance of the computer calculations has received independent support from two sources. First, slow perfusion experiments of coprodeum/colon in the domestic fowl with fluids simulating ureteral urine in the dehydrated state have demonstrated net water absorption from liquids up to 200 moM higher than plasma osmolality. Second, the computer simulation (Skadhauge, 1973) resulted in near-identical absorption rates as calculated from a detailed study with and without exteriorization of the ureters (Dicker and Haslam, 1972).

In only one study, (Skadhauge and Thomas, 1979) has the cloacal fractional absorption of K^+, NH_4^+, and PO_4 been quantitatively assessed. In the domestic fowl, it was shown that the cloaca changes the ureteral output by an additional secretion of 20% of K^+, and absorption of 8% of NH_4^+, and 2% of PO_4. Thus the cloaca seems to assist significantly in secretion of K^+, but storage in that organ has minor effect on NH_4^+ and PO_4 transport.

19.5.3.3 Special case: birds with salt glands

Schmidt-Nielsen et al. (1963) suggested that birds with salt glands might maintain high rates of intestinal salt and water reabsorption during times of substantial NaCl intake, routing the NaCl to the salt glands for excretion and thereby retrieving free water. Examinations of this problem have focused on two species, the domestic duck and the glaucous-winged gull. In both species, Na^+ uptake in the small intestine remained undiminished during saline acclimation (Hughes and Roberts, 1988). In the hindguts of the two species, the colon carries the majority of NaCl absorption and solute-linked water flow, with coprodeum being of minor size and with lower transport capacity per cm^2 serosal area. Even during salt loading, continued urine flow is necessary to maintain nitrogen excretion, and at least in ducks urine apparently continues to enter the rectum and even the ceca in saline acclimated birds (Hughes and Raveendran, 1994). Colons of both species uphold high NaCl absorption rates in the salt-loaded state (Skadhauge et al., 1984a; Goldstein et al., 1986); any NaCl that is excreted by the kidney may therefore be reabsorbed with water postrenally and finally secreted by the salt gland, thereby leaving a volume of "free water." This system operates in the duck to save approximately 0.5 mL water/kg body mass hr (Skadhauge et al., 1984a), but, because of the gull's small lower intestine and relatively low urinary NaCl concentrations, its contribution is likely minor in this species (Goldstein et al., 1986).

19.5.3.4 Special case: the ratites

In the large, flightless ratite birds, the weight of the gut and its contents is not as critical as in flying species, liberating the lower gut to take on additional functions. In the ostrich (Skadhauge et al., 1984b), the colon of the adult male is more than 10 m long and functions as a fermentation chamber, with SCFA concentrations up to 120 mmol. To a minor extent, this is paralleled by the rhea, *Rhea americana*. In both ostrich (Skadhauge et al., 1984b) and rhea (Skadhauge et al., 1993), renal concentrating ability is approximately 800 mmol/kg, but the role of the lower intestine in postrenal modification of urine appears to differ. The ostrich has a strong sphincter between coprodeum and terminal colon, and no influx of urine into colon has been observed (Skadhauge, 1983). No feces is stored in the coprodeum, which therefore functions similar to a mammalian bladder (urine storage without modification) in this species. The transport properties of the coprodeal wall have not been measured in the ostrich. The dorsal diverticulum from the proctodeum of the rhea does contain ureteral urine and is lined by a single layer of cuboidal cells with possible reabsorptive capacity (Skadhauge et al., 1993; Elbrønd et al., 2009). However, the small size of this diverticulum relegates its possible functional role to minor importance.

In contrast to these species, the emu, *Dromaius novaehollandiae*, has a conventional, small coprodeum/colon where little fermentation occurs. The dehydrated emu has a low urine-to-plasma ratio of osmolality (1.4) and a fairly high urine flow rate. To compensate, the absorption capacity of coprodeum/colon is high, resulting from extensive mucosal folding (Skadhauge et al., 1991). The cassowary (*Casuarius casuarius*) has a macroscopic anatomy of coprodeum/colon similar to that of the emu (Skadhauge et al., 1993).

19.5.3.5 Quantitative role of the caeca in osmoregulation

The main function of caeca in avian physiology is nutritional, as these organs, when present and large, take part in the digestion of fine particulate matter, food fiber, and the production of SCFA (see reviews in Braun and Duke, 1989). Furthermore, conservation of nitrogen by bacterial metabolism of uric acid of ureteral origin is possible

(Braun, 1993). Large fractions of intestinal and ureteral water and solutes move together with solids of small particle size into the caeca by peristalsis and antiperistalsis in the ileum and colon, respectively (see Skadhauge, 1981, chapter 3). Quantitative studies of caecal function (see Skadhauge, 1981), based on inflow studies of unabsorbable water markers from either ureteral urine or after oral ingestion, suggest inflow rates of about 20% from both sources. In the domestic fowl, the simple (serosal) surface area of the ceca is similar to that of coprodeum and colon, but the Na^+ and water transport rates per unit body mass are approximately threefold higher (Thomas and Skadhauge, 1989b). The transport capacity for NaCl and water reabsorption from chymus and urine is therefore large, perhaps larger than colon plus coprodeum. The quantitative rate of caecal water absorption has been estimated from 5% to 38% of body weight per day. Despite this, ligation of the ceca may have little overall effect on osmoregulation [Skadhauge, 1981 p38, and others (see Braun and Duke, 1989)], probably because of compensation by other organs (Hughes et al., 1992). The contribution of the ceca may become essential only during the combined stress of poor feeding and salt and water depletion (Thomas, 1982; Thomas and Skadhauge, 1989b).

19.5.3.6 Overall: integration of kidneys and lower intestine

The excretion of waste nitrogen as relatively nontoxic uric acid may have evolved in association with development within the closed system of the shelled egg. However, as a consequence, birds risk loss of substantial energy, protein, and nitrogen associated with urinary uric acid. Retrograde movement of urine into the lower intestine may serve a critical role in conserving those metabolites. At the same time, avian kidneys elaborate a urine that can be two or more times the concentration of the plasma, and movement of that urine into the intestinal system could undo the osmotic work of the kidneys. Nevertheless, the transport properties of the lower intestines are such that even during times of urine concentration, the gut is able to effect a net conservation of water and electrolytes. Overlain on all of these systems is the ability of birds to regulate lower intestinal motility (Brummermann and Braun, 1995) such that exposure of urine to the transporting and nontransporting regions of the lower intestine may be adjusted to meet the changing physiological demands of nutrition and osmoregulation. The mechanisms of that coupling have received just preliminary investigation (Vranish and Braun, 2011). All together, the kidneys and lower intestine constitute a system with apparent redundancies and inefficiencies but that confers homeostatic capabilities over a wide diversity of habitats and diets.

19.6 Salt glands

Although the presence of supraorbital glands in marine birds was known for many years, it was not until 1958 that their salt-secreting function was defined (Schmidt-Nielsen et al., 1958). Functional salt glands exist in approximately 10 orders of birds, including all those with marine representatives and at least two orders of terrestrial birds (several falconiformes (Cade and Greenwald, 1966) and the roadrunner [*Geococcyx californianus*, order Cuculiformes; Ohmart, 1972)]. Within related groups, glands are larger in species exposed to hypersaline food and water; thus, marine species have larger glands than coastal or terrestrial birds (Staaland, 1967; Gutiérrez et al., 2012).

19.6.1 Anatomy

The salt glands, which constitute from 0.1 to 2% of body mass, are located in depressions usually in or above the orbits (e.g., Schmidt-Nielsen, 1959; Siegel-Causey, 1990, Figure 19.12). They are distinct from lacrimal or Harderian glands. The basic structural unit of the salt gland, the lobe, consists of blind-ended secretory acini (tubules) which drain into central ducts (canals). Toward the blind end of the tubule are small, relatively undifferentiated peripheral cells, whereas most of the length of the secretory tubules is composed of principal secretory cells (Ernst and Ellis, 1969). Capillary blood flow runs counter to flow in the secretory tubules. Each gland contains numerous lobes

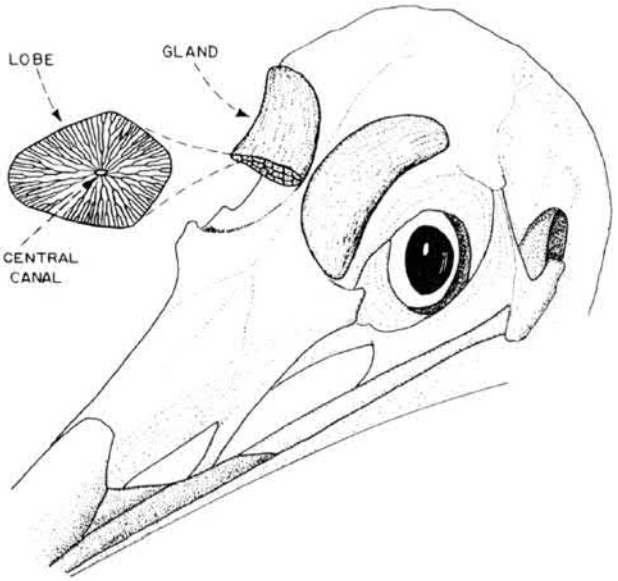

FIGURE 19.12 The supraorbital salt gland of the herring gull. Branching secretory tubules are arranged radially around the central canal. *Reproduced with permission from Schmidt-Nielsen (1960).*

whose final common ducts drain into the nasal cavity. Salt gland secretion either drips from or is shaken from the bird's beak.

Acclimation of a bird to increasing salt intake typically induces growth of the salt gland (Guttiérez et al., 2012; but see Rocha et al., 2016), accompanied by an enhanced secretory capacity. Growth of the secretory tubules includes cell hypertrophy and hyperplasia, increased membrane folding and mitochondrial density, and enhanced activity of several cellular enzymes, including Na/K ATPase, the enzyme responsible for establishing the ion gradients that drive secretion (Holmes and Phillips, 1985).

The main innervation to the salt glands is from the VIIth cranial nerve, a branch of which enters the secretory nerve ganglion near the orbit (Ash et al., 1969). Postganglionic parasympathetic fibers, which may release both acetylcholine and vasoactive intestinal peptide (VIP), then ramify through the gland, with terminals on both secretory cells and blood vessels. The blood vessels and tubules also receive adrenergic input from neurons likely running both in the walls of arteries and through the secretory nerve ganglion (Peaker and Linzell, 1975; Gerstberger, 1991).

19.6.2 Function

19.6.2.1 Stimulus for secretion

Secretion by the salt glands may be initiated by stimulation of either central or peripheral receptors. The central receptors appear to be osmoreceptors in the region of the third cerebral ventricle, with a responsiveness to the Na^+ (or other cation) concentration, not just to total osmotic concentration (Gerstberger et al., 1984).

Peripheral osmoreceptors, which are located in the vicinity of the heart and large arteries nearby, communicate with the central nervous system via the vagus nerve, the severing of which eliminates salt gland responsiveness to systemic salt loading (Hanwell et al., 1972). There are also reports of salt gland secretion during dehydration (e.g., Stewart, 1972), when ECF volume would be reduced but osmolality increased.

Numerous experiments also point to an important role for systemic volume receptors. In some species (mallard ducks, but not glaucous-winged gulls; Hughes, 1989a, b), isosmotic expansion of the ECF is sufficient to stimulate salt gland secretion. Moreover, a rise in extracellular Na^+ concentration without a rise in ECF volume may be insufficient to initiate secretion (Ruch and Hughes, 1975; Hughes, 1989b); volume and osmolality act in concert to jointly achieve a threshold for secretion (Hammel, 1989). Some evidence suggests that the ECF receptors occur not in the vasculature, but in the interstitial space (Hammel et al., 1980).

It is likely that variation in experimental results, including differing importance of volume and osmolality as stimuli for salt gland secretion, relates to variation among species. The most detailed experimental work in this field has been done using domestic ducks, descendants of wild mallards. These birds are never exposed to seawater in their natural habitat, and they are quite intolerant of saline (Schmidt-Nielsen and Kim, 1964). Studies of birds more highly adapted to saline may yield different results (Hughes, 1989b).

19.6.2.2 Secretion mechanism and fluid composition

The fluid produced by avian salt glands is typically nearly pure NaCl, with trace concentrations of K^+, HCO_3^-, Ca^{++}, and Mg^{++} (though K^+ concentrations up to 100 mM and Ca^{++} concentrations up to 50 mM may occur in some situations; Hughes, 1970b; Cade and Greenwald, 1966). The concentration of NaCl in the secretion varies among species from approximately 500 to 1000 mM (see Skadhauge, 1981, Cpt. 7), being more concentrated in species with higher salt intakes, such as those which eat marine invertebrates.

The cellular mechanism of secretion by salt gland principal cells is difficult to study in situ because of the complex anatomy of the tubules and their encasement in connective tissue. Knowledge of this process has therefore come from a variety of in vitro approaches, including studies of tissue slices, isolated dispersed cells (Shuttleworth and Thompson, 1989), and cell culture (Lowy et al., 1989). These studies collectively have suggested a model of secondary active Cl^- transport. In this model (Figure 19.13), a basolateral ouabain-sensitive Na/K ATPase establishes an inwardly directed Na^+ gradient. This gradient provides the energy for furosemide-sensitive inward transport of $Na^+/K^+/2Cl^-$, also across the basolateral membrane. Cl^- then passes down its electrochemical gradient through (putative) apical Cl^- channels into the tubule lumen. The resulting trans-tubule electrical potential (inwardly negative) provides the driving force for passive peritubular Na^+ transport. Activation of secretion also entails a brief intracellular acidification which is compensated for by a HCO_3^--dependent alkalinization as secretion is sustained (Shuttleworth and Wood, 1992). Activation of secretion can be stimulated via either of two intracellular second messenger systems, phosphatidyl inositol/Ca^+ [linked to stimulation of muscarinic acetylcholine receptors (Snider et al., 1986; Hildebrandt and Shuttleworth, 1993)] or cyclic AMP [linked to β-adrenergic stimulation or VIP (Lowy and Ernst, 1987; Lowy et al., 1987)].

These two signaling pathways apparently occur in the same cells and interact to effect appropriate responses to stimulation (Krohn and Hildebrandt, 2004).

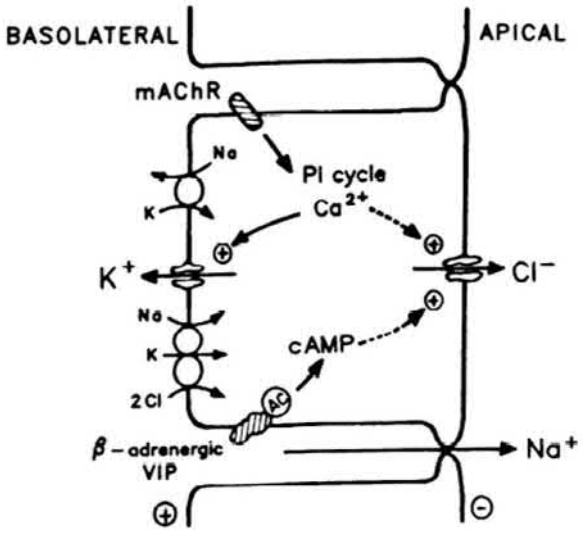

FIGURE 19.13 Proposed mechanisms of secretion by principal secretory cells in the avian salt gland. *Reproduced, with permission, from Lowy (1989).*

The concentration of the solution as elaborated by the cells lining the secretory tubules is unknown, and a variety of mechanisms have been proposed for attaining the final concentration of secreted fluid. Marshall et al. (1985) proposed that tubular cells secrete an isotonic fluid that is concentrated by the subsequent withdrawal of water along the ducts. With a final secretion rate as high as 10% of gland blood flow rate, secretion of virtually the entire plasma would be initially required. Other theories (see Holmes and Phillips, 1985; Butler et al., 1989; Gerstberger and Gray, 1993) suggest instead that the hypertonicity is generated within the tubules themselves, potentially with subsequent dilution in the ducts via osmotic water flow through aquaporins (AQP5?; Mueller et al., 2006). In various studies, the concentration of secreted fluid either increases, decreases, or does not change with the rate of secretion, and so this relationship does little to help clarify the concentrating mechanism.

Adequate secretion by the salt glands requires adequate blood flow, and this increases more than 10-fold during active secretion (Hanwell et al., 1971; Kaul et al., 1983). Over a wide range of blood flow and secretion rates, the salt glands extract a relatively constant fraction (between 15% and 20% in the Pekin duck) of the NaCl passing through the gland (Kaul et al., 1983).

19.6.2.3 Regulatory mediators

Stimulation of salt gland secretion is activated by the parasympathetic nervous system (Fänge et al., 1958) acting through muscarinic receptors for acetylcholine and independent receptors for VIP (Gerstberger, 1988). These mediators activate the principle cell secretory mechanism as well as vasodilation and enhanced blood flow (see Butler et al., 1989; Gerstberger, 1991). Secretion is inhibited by anesthesia or disturbance, at least in part via sympathetically mediated vasoconstriction.

The only hormone that directly stimulates secretion is ANP, which activates the gland via high-affinity receptors (Schütz and Gerstberger, 1990; Gerstberger, 1991). A substantial literature did suggest a role for corticosterone, but following adrenalectomy, maintenance of normal fluid balance through saline drinking water and adequate feeding restores salt gland function even in the absence of corticosterone (Butler, 1987).

Angiotensin II also may have a direct influence on salt gland secretion, though in this case inhibitory. The hormone acts by stimulating centrally mediated vasoconstriction of salt gland blood vessels (Gerstberger et al., 1984; Butler et al., 1989, 1999) and is independent of a role for catecholamines (Butler, 1999, 2007; Heinz and Gray, 2001). Peripherally produced angiotensin may be able to cross the blood brain barrier and activate these central responses.

19.6.3 Contribution of the salt glands to osmoregulation

The quantitative contribution of the salt glands relative to the kidneys has been evaluated in a few species (Skadhauge, 1981, Cpt. 7, Hughes, 2003). During conditions that stimulate the salt glands (salt loading or dehydration), typically $> 75\%$ of excreted Na^+ is lost via the salt glands. However, the division of water loss between salt glands and kidneys depends of the water load; during a copious saline load, the two organs may be equally responsible for water excretion, whereas during dehydration, the renal losses of water may be substantially reduced. The salt glands also may eliminate more than one third of excreted K^+ following a salt load, despite the relatively low concentration of K^+ in salt gland fluid. These generalizations derive from relatively few studies conducted over short experimental time spans; the relative roles of the organs under natural conditions undoubtedly reflect dietary intakes of salts and water and must vary considerably over time. For example, the spontaneous salt gland secretions of Pekin ducks varied with, and nearly matched, the NaCl concentration of their drinking water (Hughes et al., 1992).

19.7 Evaporative water loss

Evaporative losses of water from the respiratory tract and the skin constitute an important component of avian water balance. Rates of evaporation increase with body mass and with the thermoregulatory demand for evaporative heat loss (Gavrilov and Gavrilov, 2019).

Respiratory water loss is an inevitable consequence of the high rates of ventilation demanded by endothermy. It has long

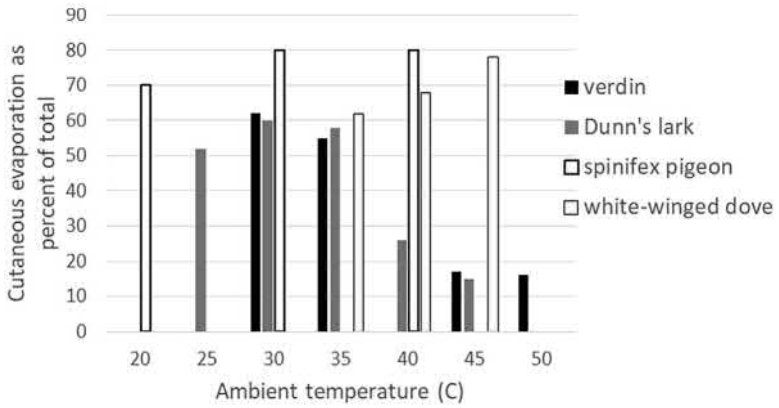

FIGURE 19.14 Relative contribution of cutaneous evaporation to total evaporative water loss in two passerine species (*darker bars*) and two columbiform species (*lighter bars*). Note that cutaneous evaporation diminishes in importance at higher temperatures in the former species but increases in the latter. *Data for verdin and spinifex pigeon from Wolf and Walsberg (1996); for Dunn's lark from Tieleman and Williams (2002); and for heat-acclimated white-winged doves from McKechnie and Wolf (2004).*

been appreciated that birds modulate respiratory evaporation, e.g., by panting or gular flutter, as a means of defending body temperature in the heat, and in many avian orders the majority of evaporative heat (and water) loss at high temperatures derives from respiratory surfaces (Dawson, 1982; Wolf and Walsberg, 1996; O'Connor et al., 2017).

In other avian groups, despite birds' lack of sweat glands, equally effective evaporative heat dissipation can be achieved across cutaneous surfaces (Wolf and Walsberg, 1996; McKechnie et al., 2016). In a number of species, the cutaneous resistance to diffusion of water vapor decreases markedly at elevated ambient temperatures, thereby enhancing evaporative heat loss (e.g., Marder and Ben-Asher, 1983; Webster and Bernstein, 1987; Withers and Williams, 1990; Wolf and Walsberg, 1996). The composition and physical state of lipids in the stratum corneum of the skin may be a major determinant of the resistance to evaporative water loss (Champagne et al., 2015) and can vary both intra- (Munoz-Garcia et al., 2008; Champagne et al., 2016) and interspecifically (Haugen et al., 2003; Ro and Williams, 2010). Thermally induced changes to those lipids might underlie increases in cutaneous evaporation. Adrenergically mediated increases to cutaneous blood flow (Marder and Raber, 1989) also may contribute to regulation of cutaneous water loss.

Evaporation typically accounts for approximately 50% of total water loss in a variety of species given unlimited water in the laboratory (summarized in Skadhauge, 1981, Chapter 4). That may rise to 80% during dehydration, when excretory water losses are minimized (Skadhauge, 1981). It does appear that the magnitude of evaporative water loss can be modulated in response to hydric conditions. For example, dehydrated birds may reduce evaporation via respiration (Crawford and Schmidt-Nielsen, 1967) or the skin (Arad et al., 1987), and budgerigars (*Melopsittacus undulatus*) can maintain constant EWL in the face of varying relative humidities (Eto et al., 2017). The mechanisms of those regulated changes are not described (Figure 19.14).

For a discussion of the role of evaporative water loss in thermoregulation, the reader should consult Chapter x (Table 19.5).

Acknowledgments

This chapter is dedicated to Erik Skadhauge, who coauthored a previous edition of this chapter and who contributed so much to the field of avian osmoregulation; to Maryanne Hughes, who took joy in unraveling the mechanisms of salt and water regulation; and to Eldon Braun, whose unending fascination with the physiology of birds has been inspiring.

Chapter 20

Respiration

Frank L. Powell

Department of Medicine Division of Pulmonary, Critical Care, Sleep Medicine, University of California, San Diego La Jolla, CA, United States

20.1 Overview

The primary function of the respiratory system is *gas exchange*—delivering oxygen from the environment to the tissues and removing carbon dioxide from the tissues. Maintaining a constant body temperature in birds and mammals requires high levels of oxygen consumption and exercise in birds—namely flapping flight—creates the highest oxygen demand of any vertebrate. The structure of the avian respiratory system is very different from the mammalian lung and some of these differences support more efficient gas exchange, while others may be alternative evolutionary solutions to common problems for all air-breathing vertebrates.

Generally, the respiratory system acts as a servant to the rest of the organism by delivering enough oxygen and removing sufficient carbon dioxide for metabolic demands. As oxygen demand increases, a variety of respiratory responses insure an adequate supply of oxygen, which involve the lungs, respiratory mechanics, the pulmonary circulation, transport of oxygen and carbon dioxide in blood, pulmonary and tissue gas exchange, and the coordination of all these mechanisms by the respiratory control system. The respiratory system has a huge surface area exposing the body to the environment that requires defense mechanisms also. Individual sections in this chapter focus on each of these physiological mechanisms. References are made to mammalian respiratory physiology, so the reader can consult the extensive literature available for more details on fundamentals concepts. In birds, the respiratory system is also critical for thermoregulation (by evaporative water loss) and nonrespiratory functions such as vocalization, but these are not covered in this chapter. Current research problems and important unanswered questions are highlighted in sections labeled *Frontiers*.

20.1.1 Oxygen cascade

Figure 20.1 shows how these physiological transport steps function in series to transport oxygen from the environment to the cells. This is often referred to as the "oxygen cascade" because oxygen level (quantified as partial pressure, or P_{O_2}) decreases at each step in the model. Breathing movements bring fresh air into the lungs, and the heart pumps oxygen-poor blood to the lungs. Oxygen diffuses from gas to blood in the lungs, and this oxygen-rich blood returns to the heart via the pulmonary circulation. Arterialized blood is pumped to the various organs and tissues of the body via the systemic circulation. Finally, oxygen diffuses out of the systemic capillaries to metabolizing tissues and ultimately to the mitochondria inside cells. Carbon dioxide moves out of the cells to the environment through these same steps in the opposite direction from oxygen. Each of these steps is covered in the sections below, with an emphasis on respiratory structure function-relationships that are unique to birds, especially in comparison with mammals. Mammals are the only other vertebrates that achieve avian levels of oxygen demand during exercise.

20.1.2 Symbols and units

Table 20.1 provides a list of abbreviations used in this chapter, which are based on a few simple conventions. Primary variables are symbolized with a capital letter, and a dot over the variable indicates the first derivative with respect to time (e.g., units for inspired ventilation, $\dot{V}_I$, are L/min). Modifiers are small capitals for the gas phase and lower-case letters for liquid or tissues. Finally, a specific gas species is indicated with a subscript. Respiratory gas volumes (e.g., ventilation) are reported for physiological

Sturkie's Avian Physiology. https://doi.org/10.1016/B978-0-12-819770-7.00033-5

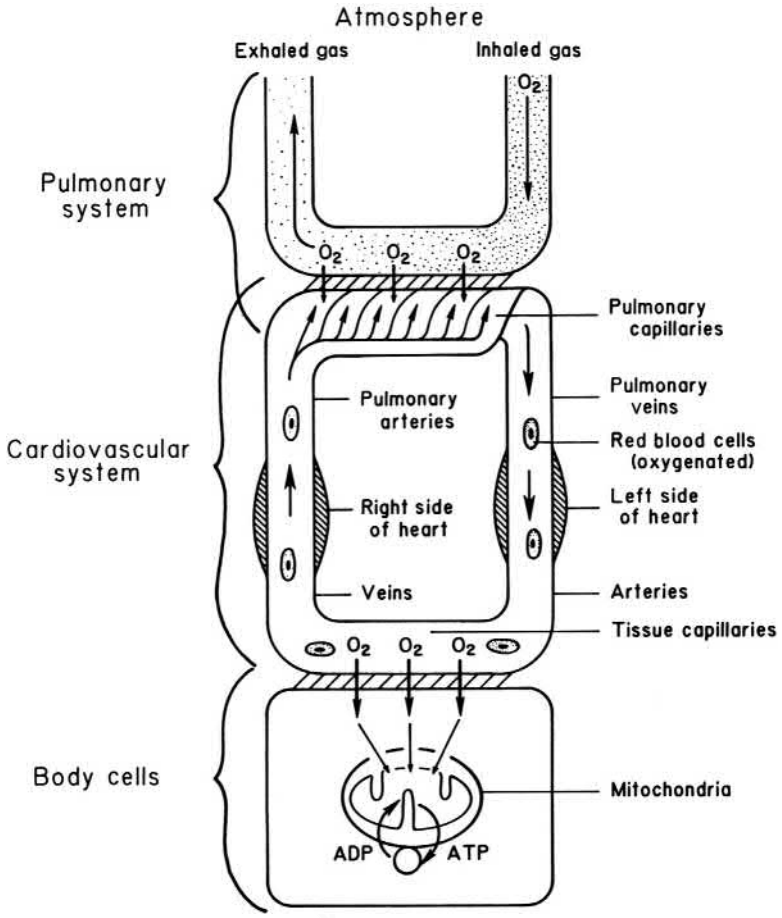

FIGURE 20.1 General model of the oxygen transport in birds. *Modified from Taylor and Weibel (1981).*

conditions (BTPS, body temperature and pressure, saturated) unless otherwise noted. Amounts of oxygen (O_2) or carbon dioxide (CO_2) are expressed in mmoles (e.g., O_2 concentration in mmol/L = mM). Pressure is expressed in Torr (7.5 Torr = 1 kPa).

20.2 Anatomy of the avian respiratory system

The structure of the avian respiratory system is unique among the vertebrates, with small lungs which do not change volume during breathing, and nine large air sacs which act as bellows to ventilate the lung but do not participate directly in gas exchange (Figure 20.2). The total volume of the respiratory system in a bird (i.e., lungs and air sacs) is larger than that in a comparably sized mammal ($\approx$15 vs. 7% of body volume), but the avian lung itself is smaller ($\approx$1%–3% of body volume). It is hypothesized that evolution of bipedal locomotion selected for a caudal expansion of the respiratory system in dinosaurs and air sacs further expanded with the evolution of flight (Farmer, 2006). Both avian and mammalian lungs evolved to support increased oxygen uptake by subdividing into smaller individual gas exchange units which increased surface area. However, the functions of ventilation and gas exchange were separated into the air sacs and parabronchial lungs in the *heterogeneous* partitioning of the avian respiratory system; in contrast, *homogenous* partitioning of the mammalian respiratory system resulted in alveolar lungs that perform both gas exchange and ventilation (Duncker, 1978) as discussed below.

Also in contrast to mammals, the avian thoracic cavity is essentially at atmospheric pressure (vs. subatmospheric), and there is no diaphragm to functionally separate it from the abdominal cavity. The parietal and visceral pleura surrounding the lungs are fused so there is no intrapleural space in birds as there is in mammals either (Maina, 2017). This section covers basic respiratory system anatomy necessary to understand respiratory function, but the reader is referred to several excellent monographs and reviews for more details (Duncker, 1971; King and Molony, 1971; Maina 2017; Mania et al., 2010; McLelland, 1989b). Terminology according to the *Nomina Anatomica Avium* is used here (King, 1979). Details of the blood-gas barrier and the anatomy of the pulmonary circulation are covered in later sections.

TABLE 20.1 Symbols in respiratory physiology.

Primary variables (and units)	
C	Concentration or content (mM = mmmol/L)
D	Diffusing capacity ($mmol_{O_2}$/(min·Torr)
P	Partial pressure or hydrostatic pressure (Torr or cm H_2O)
V	Gas volume (Liters, L, or mL)
$\dot{V}$	Ventilation (L/min)
$\dot{Q}$	Blood flow or perfusion (L/min)
$\dot{M}$	Gas flux (mmol/min)
Modifying symbols	
D	Dead space gas
E	Expired gas
$\bar{E}$	Mixed-expired gas
I	Inspired gas
T	Tidal gas
a	Arterial blood
c	Capillary blood
m	Membrane
t	Tissue
v	Venous blood
$\bar{V}$	Mixed-venous blood
Examples	
$P_{I_{O_2}}$	=Partial pressure of O_2 in inspired gas
$P_{a_{O_2}}$	Partial pressure of O_2 in arterial blood
$P_{\bar{V}_{O_2}}$	Partial pressure of O_2 in mixed-venous blood
$\dot{M}_{O_2}$	O_2 consumption per unit time
$\dot{V}_P$	Ventilation of the parabronchi per unit time

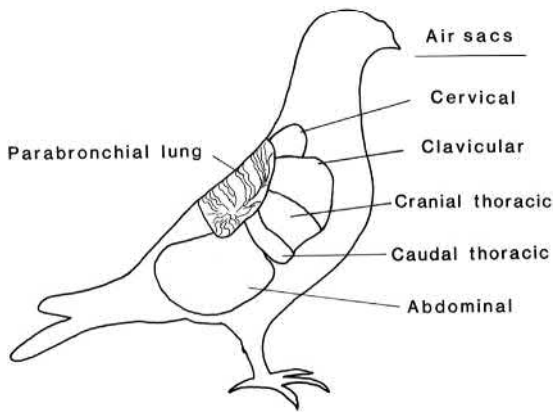

FIGURE 20.2 Respiratory system of a pigeon consisting of the parabronchial lung and air sacs.

20.2.1 Upper airways

Birds can breathe through the nares or mouth. Oronasal structures tend to heat and humidify inspired gas, and filter out large particles that could potentially damage the delicate respiratory surfaces. The oronasal cavity is separated from the trachea by the larynx, which opens into the trachea through the slit-like glottis. The laryngeal muscles contract with breathing to open the glottis during inspiration and decrease the resistance to inspiratory airflow. This rhythmic opening of the glottis is useful when attempting to intubate a bird. The trachea has complete cartilaginous rings in most avian species and plentiful smooth muscle. Interesting exceptions include the "double trachea" of penguins, with a medial septum dividing the trachea into two tubes, and the slit-like opening on the ventral surface of the trachea in emus, which is responsible for their characteristic booming call (McLelland, 1989a). The anatomy and physiology of

the larynx and trachea have been reviewed in detail (McLelland, 1989a).

Tracheal volume is an important determinant of "dead space" ventilation, and therefore gas exchange. Hinds and Calder (1971) measured tracheal volume in 27 species of birds and found in situ volume (V in ml) was related to body mass (M_B in kg) as: $V = 3.7\ M_B^{1.09}$. This equation underestimates tracheal volume in Pekin ducks (Bech et al., 1984; Hastings and Powell, 1986b) and pigeons (Powell, 1983) and overestimates the value for male chickens (Kuhlmann and Fedde, 1976), although the error is less than 25%. Tracheal volume is 4.5 times larger in birds than in comparably sized mammals (Hinds and Calder, 1971) and birds generally compensate for this increased dead space with a deep and slow breathing pattern (Bouverot, 1978). Several species of birds possess tracheal elongations, which loop inside the neck, but their function is unknown (McLelland, 1989a).

The trachea bifurcates into two primary bronchi at the syrinx, which is the vocal organ for birds (King, 1989). Like the mammalian larynx, it is a mechano-muscular valve that regulates pressure in distal airways to control airflow to the upper respiratory-vocal tract during expiration and singing. Most of the research on the syrinx has focused on vocalization and neurobiology of bird song that may have implications for the central control of breathing in birds (reviewed by Schmidt and Wild, 2014). In many species (e.g., chickens and ducks), but not all, this bifurcation occurs inside the thoracic cavity where the trachea runs through the clavicular air sac. Because of this position, the syrinx offers no protection for the lungs as the larynx does in mammals. Similar to the avian trachea, the syrinx shows considerable variation between species, and males in some species exhibit large bullae with unknown functions.

20.2.2 Lungs

The avian lung is located dorsally in the thoracoabdominal cavity of birds (Figure 20.2) and is invaginated by spinal processes anchoring the dorsal surface of the lung. Most of the volume of the lung (≈70%) is the parabronchi where gas exchange occurs (see below) and the remainder includes the pulmonary circulation and bronchi, which are illustrated in Figure 20.3 for a representative species.

20.2.2.1 Conducting airways

In most cases, the extrapulmonary primary bronchi, between the syrinx and the lungs, are relatively short. The intrapulmonary primary bronchus travels through the entire length of the lung, entering on the medioventral aspect and exiting at the caudal border of the lung into the ostium of the abdominal air sac (see below). The secondary bronchi can be considered in two functional groups based on their origin from the primary bronchus. The cranial group consists of four or five medioventral secondary bronchi, originating from the medioventral intrapulmonary primary bronchus. These cranial secondary bronchi branch further to form a fan covering the medioventral surface of the lung. The caudal group consists of 6–10 mediodorsal secondary bronchi, which also branch to form a fan over the mediodorsal surface of the lung.

A third group of secondary bronchi includes a variable number of lateroventral bronchi in most species, which also branch off caudal parts of the primary bronchus. The first or second laterobronchus forms a short connection to the posterior thoracic air sac (see below). Other lateroventral bronchi may penetrate lateroventral parts of the lung to variable degrees in different species, but they do not form a regular branching fan like the other secondary bronchi.

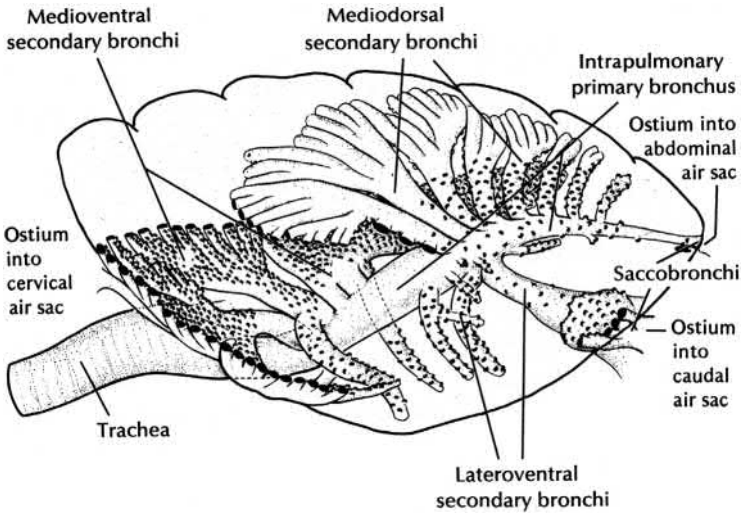

FIGURE 20.3 Bronchial arrangement in the left lung of the mute swan (*Cygnus olor*). *Modified from Duncker (1974).*

The primary and secondary bronchi are conducting airways because they do not participate in gas exchange. Cartilaginous semirings and smooth muscle support the primary bronchi, but the walls of the secondary bronchi are flaccid, and require on adhesion to the surrounding lung or pleura to remain open. The respiratory epithelium is ciliated with variable amounts of goblet cells in different species in the trachea, primary and secondary bronchi (Duncker, 1974).

20.2.2.2 Parabronchi

Parabronchi are the functional unit of gas exchange in the avian lung. They are also called "tertiary bronchi" because they can originate from the secondary bronchi, but parabronchus is the preferred terminology because they also originate from further branches of secondary bronchi (Figure 20.3). Most of the parabronchi are organized as a parallel series of several hundred tubes connecting the medioventral and mediodorsal secondary bronchi (Figure 20.3). Such parabronchi are called *paleopulmonic* parabronchi, and together with the primary and cranial and caudal groups of secondary bronchi, they comprise the simplest scheme of bronchial branching in the avian lung (Duncker, 1974).

In all birds except some penguins, there are additional parabronchi called *neopulmonic* parabronchi (Duncker, 1974). These parabronchi are not organized as regular parallel stacks of tubes but may exhibit irregular branching patterns. Neopulmonic parabronchi may connect another set of caudal laterodorsal secondary bronchi to caudal air sacs (see below) or other parabronchi. Neopulmonic parabronchi never comprise more than 25% of the parabronchi, and there are large species variations. However, it has not been possible to demonstrate any phylogenetic or evolutionary significance to neopulmonic versus paleopulmonic parabronchi, despite the implication of the terms (Maina, 1989, 2017). The functional significance of these different kinds of parabronchi is considered below.

Figure 20.4 illustrates the structure of a parabronchus and how they are organized in parallel, appearing like a honeycomb in cross-section. Gas exchange occurs in the walls of these tubes that are 0.5−2.0 mm in diameter and can be several mm long depending on the size of the bird (Duncker, 1971; Maina, 1989). The parabronchi are separated from each other along their length by a boundary of connective tissue and larger pulmonary blood vessels. The parabronchial lumen is lined by a meshwork of connective tissue and smooth muscle, which outlines the entrances to atria radiating from the parabronchial lumen. The atria lead to infundibulae and, ultimately, the air capillaries which are 2−10 μm in diameter and as long as about one-quarter of the total parabronchial diameter (Figure 20.4). The parabronchi are lined with cuboidal and squamous epithelial cells that become thinner moving into the atria and

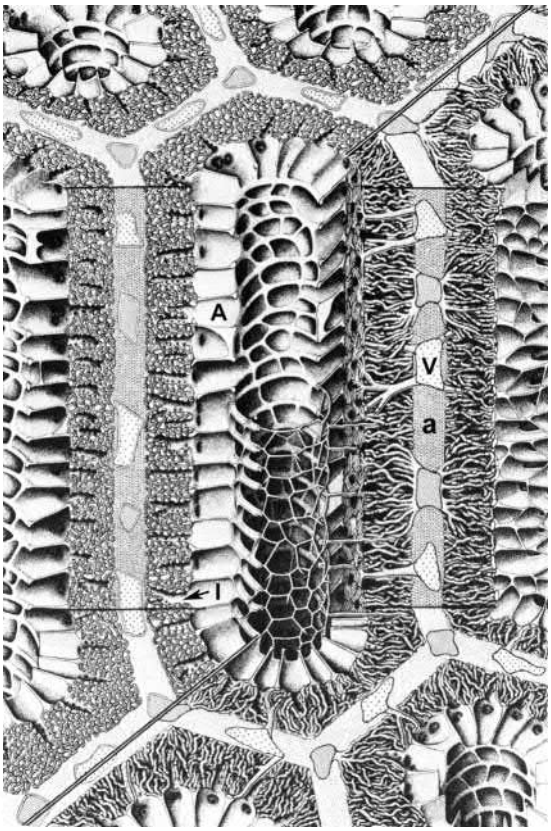

FIGURE 20.4 Cutaway drawing of a typical parabronchus (ca. 1 mm diameter). Left side shows pathway for air from parabronchial lumen into the atria (A), infundibula (I) and air capillaries. Right side shows blood flow from interparabronchial arterioles (a) into blood capillaries that collect in venules near the base of the atria and flow away from the lumen to interparabronchial venules (v). *Modified from Duncker (1974).*

exclusively squamous in the infundibulae and air capillaries (Smith et al., 1986). Air capillaries intertwine with a network of pulmonary blood capillaries in the parabronchial mantle, and the air-blood capillary interface is the site of gas exchange (see below). The gas exchange paryenchyma (air and blood capillaries and tissue) occupies 50 to 60% pf the parabronchial volume, with the balance being the lumen, atria, and large vessels in birds over a large range of sizes from hummingbirds to geese (Dubach, 1981; Powell and Mazzone, 1983).

20.2.2.3 Frontiers: *evolution of the blood-gas barrier*

The evolution of respiratory organs has been guided by at least two principles. First, the area of the blood-gas barrier has to be very large and very thin to support oxygen uptake by diffusion. Subdividing the lungs into smaller compartments increases the surface to volume ratio, so the total surface area in a bird or mammal is over 10-times that in a reptile with a simpler lung (Hsia et al., 2013). (A smaller surface area is adequate in reptiles given their lower levels

of oxygen consumption.) The second principle is keeping the blood-gas barrier extremely thin to facilitate diffusion, but this must be balanced with the need for structural integrity of the blood capillaries. This is particularly important in birds and mammals, which require high rates of blood flow to meet metabolic demands and have evolved separate pulmonary and systemic circulations allowing lower pressures in pulmonary versus systemic capillaries. Even so, pressure can increase during exercise to cause stress failure in mammalian pulmonary capillaries, but this has not been observed in bird lungs (West et al., 2006).

Birds have evolved a unique solution to these challenges that is arguably more adaptive than the mammalian solution, with the total surface area for gas exchange being about 15% greater and 2.5-times thinner in a bird than in the same-sized mammal (Maina et al., 1989; West, 2009). However, this results in air capillaries in the birds that are much smaller than alveoli in mammals. Recent detailed morphological studies reveal some of the factors providing extra strength in the dense air-blood capillary network of the parabronchial mantle, although questions remain. Figure 20.5 shows how the blood capillaries are conspicuous segments of similar dimensions while the air capillaries include larger spaces interconnected by short, narrow passages, with dimensions ranging from 3 to 20 µm in diameter (Maina, 2017). The intimate relationship between the air and blood capillaries strengthens both structures by the property of interdependence (which also is important in alveolar lungs). Further support for both kinds of capillaries is also provided by epithelial-epithelial bridges (shown separating air capillaries in Figure 20.5 upper left panel), thin collagen fibers forming a fibro-skeletal network supporting the exchange tissue, type-IV collagen in the basement membrane of the blood-gas barrier, and accumulation of trilaminar substance (surfactant) in the corners where the epithelial bridges abut blood capillaries (reviewed by Maina, 2017). The lack of volume changes in the air and blood capillaries in birds versus alveoli and capillaries in mammalian lungs must also contribute. The complete biomechanics of this system remain to be determined but the avian solution permits very high levels of oxygen uptake supporting activities such as hard exercise during flight with limited oxygen availability at high altitude (West et al., 2010).

20.2.3 Air sacs

The air sacs are thin membranous structures connected to the primary or secondary bronchi via ostia, and they comprise most of the volume of the respiratory system (Figure 20.2). Air sacs are poorly vascularized by the systemic circulation and do not directly participate in significant gas exchange but act as a bellows to ventilate the lungs. In most species, there are nine air sacs that can be considered in cranial and caudal functional groups (Duncker, 1971; Maina, 1989; McLelland, 1989b). Air sac diverticulae may also penetrate the skeleton, but there are large species differences. There is no evidence for these participating in respiration (Maina, 1989) although in an early experiment investigating the pattern of air flow in the avian respiratory system, Biggs and King (1957) showed that an anesthetized chicken could survive for several minutes breathing through the broken humerus if the trachea was blocked!

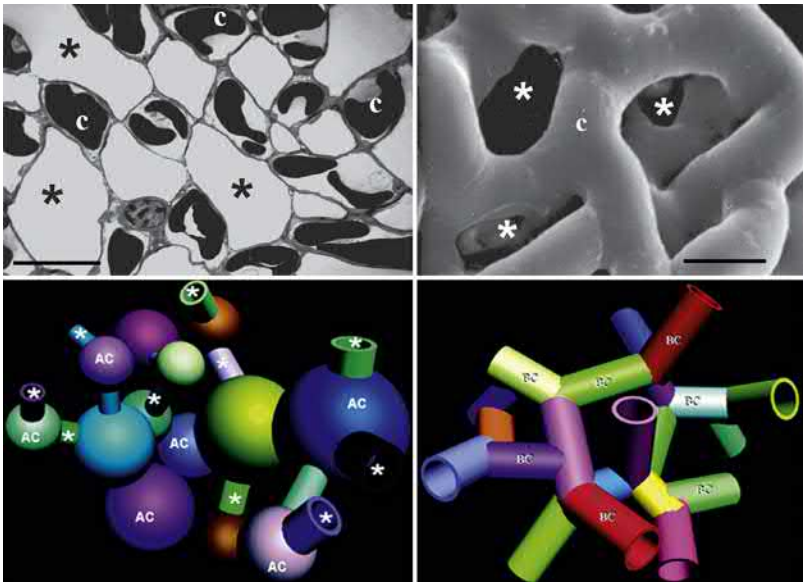

FIGURE 20.5 Top: Air (*)-blood (c) capillary network transmission electron micrograph (left) and scanning electron micrograph of case (right). Scale bar = 10 micron. Bottom: Computer-generated 3-D configuration of the air (left, AC) and blood capillaries (right, BC). AC consist of rotund spaces interconnected by short tubes (*asterisks*) while BC are short interconnected tubes of similar length and diameter. *From Maina (2007).*

The cranial group consists of the paired cervical air sacs, the unpaired clavicular air sac, and the paired cranial thoracic air sacs. The cervical sacs directly connect to the first medioventral secondary bronchus. The clavicular air sac directly connects to the third medioventral secondary bronchus and may also have indirect connections via parabronchi to other cranial (medioventral) secondary bronchi in some species, e.g., chickens. The cranial thoracic air sacs generally connect to the third medioventral secondary bronchi, and also to parabronchi originating from other cranial secondary bronchi in some species.

The caudal group consists of the paired caudal thoracic air sacs and paired abdominal air sacs. The caudal thoracic air sac is directly connected to the lateroventral secondary bronchus, and may have indirect connections to other lateroventral, or even cranial (medioventral) secondary bronchi in species with large amounts of neopulmonic parabronchi, e.g., chickens. The abdominal air sacs connect to the caudal end of the intrapulmonary primary bronchus and may have more indirect connections to parabronchi from laterodorsal secondary bronchi and the last mediodorsal secondary bronchi. Air sac connections with parabronchi are frequently grouped into a funnel-like structure called the saccobronchus.

20.2.4 Respiratory system volumes

The upper airways and bronchial branches proximal to the parabronchi comprise anatomical dead space as described above. Such conducting airways are called "dead space" because they do not participate directly in gas exchange. The intrapulmonary conducting airways make a relatively small contribution to total dead space, but total dead space volume is generally larger than most mammals, consistent with the generally long neck of birds. Physiological measures of dead space are considered below.

The actual volume of air in the avian lung directly involved in gas exchange at any moment is in the air capillaries. This averages about 30% of the lung volume in small birds (Dubach, 1981) compared to 40% in a human [considering the functional residual capacity (FRC) minus dead space]. The unique pattern of airflow in the open-ended parabronchi renews this gas exchanging volume more frequently than does tidal ventilation in dead-end alveolar lungs. This means birds experience larger variations in O_2 and CO_2 levels than mammals within the gas exchange regions of the lung during a breathing cycle.

Most of the respiratory system volume in birds is in the air sacs, and there is no comparable volume in the mammalian lung. Unlike mammalian alveoli, which change volume during ventilation, the air sacs are not important sites of gas exchange. There is tremendous variation in the volumes of air sacs reported in the literature because the value is very sensitive to the method of measurement. For example, the volume of plastic casting material that can be instilled under a pressure head into the air sacs of a dead bird may be much greater than the gas volume in live birds with muscle tone in the thorax and abdominal wall. Also, air sac volume in vivo can vary with posture, digestive, and reproductive states, as different structures in the body (e.g., eggs) displace volume. Casting under controlled pressure conditions (Duncker, 1971), gas dilution in vivo (Scheid et al., 1974) and imaging (Ponganis et al., 2015) are probably the most accurate methods available for determining air sac volume.

20.3 Ventilation and respiratory mechanics

Respiratory muscles generate pressure to move air in and out of the air sacs and through the parabronchial lung. The air sacs follow changes in body volume with respiratory muscle activity, and act as a bellows to ventilate the parabronchial lung that is essentially constant in volume (Jones et al., 1985; Macklem et al., 1979). In contrast to mammals, the avian lung volume is maintained by attachments to the body wall, and not by a subatmospheric pressure in an intrapleural space surrounding it. Also in contrast to mammals, birds have no diaphragm separating the body cavity into separate thoracic and abdominal compartments. Hence, pressures are relatively uniform in the avian thoracoabdominal cavity, which behaves mechanically as a single compartment (Scheid and Piiper, 1989).

Ventilation ($\dot{V}$) is the product of the volume per breath, or tidal volume (V_T) and the respiratory frequency (f_R), so $\dot{V}$ can be increased by breathing faster or deeper. The distribution of gas flow in the avian respiratory system depends upon the magnitude and pattern of respiratory muscle activity, as well as the mechanical properties of the body wall, lungs, and air sacs as described below.

20.3.1 Respiratory muscles

Figure 20.6 shows the changes in thoracic skeleton between normal inspiration and expiration in a bird (King and Molony, 1971; Zimmer, 1935). During inspiration, the sternum rocks cranially and ventrally with the coracoids and furcula rotating at the shoulder. Simultaneously, the vertebral ribs move cranially to expand the sternal ribs and thoracoabdominal cavity laterally.

In small birds (e.g., starlings) during flight, the furcula (wishbone) and sternum are mechanically coupled, such that the wing beat assists ventilation (Jenkins et al., 1988). However, wing movements in flight and ventilation are coordinated even in larger birds like geese so this may involve coupling of neuromuscular circuits as much as

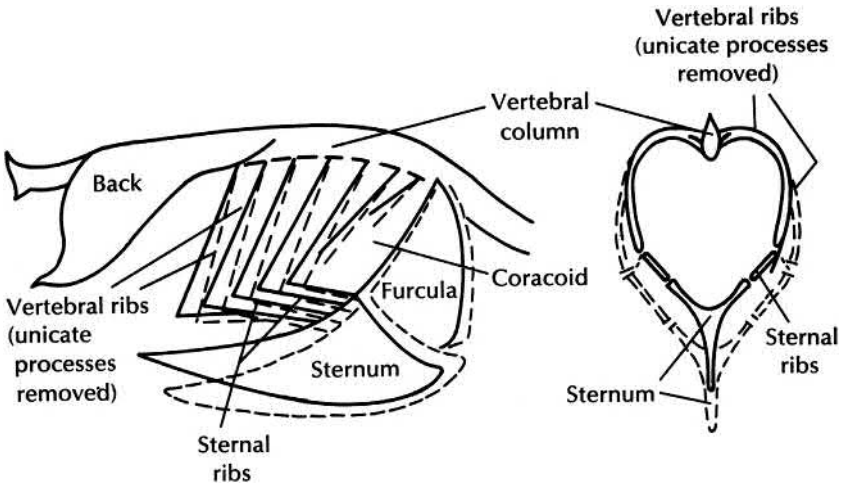

FIGURE 20.6 Changes in the position of the thoracic skeleton during breathing in a standing bird. *Solid lines* show thoracic position at the end of expiration and *dotted lines* show the end of inspiration.

respiratory mechanics (Funk et al., 1992a,b). During rest, both inspiration and expiration require active contraction of the respiratory muscles as listed in Table 20.2. The innervation for these muscles is summarized in deWet et al. (1967). Increases in ventilatory volumes are achieved by recruiting more motor units in active muscles and additional respiratory muscles, and during expiration, the opposite occurs (Fedde et al., 1963, 1964b, 1969; Kadono and Okada, 1962; Kadono et al., 1963). Therefore, the relaxed resting volume of the avian respiratory system is midway between inspiratory and expiratory volumes (Seifert, 1896), in contrast to mammals that relax to FRC at end-expiratory volume. The costoseptal muscles control the tension of the horizontal septum covering the ventral surface of the lung, but unlike the mammalian diaphragm, these are not effective at changing lung volume (Fedde et al., 1964a).

20.3.2 Mechanical properties

20.3.2.1 Compliance

Compliance (C) defines the effectiveness of small pressure changes (ΔP) at inducing volume changes (ΔV):

$$C = \Delta V/\Delta P$$

Because the pressure changes with breathing are essentially uniform throughout the coelom in birds, they can be measured as the difference between pressure in an air sac (P_{AS}) and atmospheric pressure outside the bird. Changes in respiratory system volume (V_{RS}) can be measured with a plethysmograph, which measures changes in whole body volume during breathing, or a pneumotachograph, which quantifies the amount of air inhaled or exhaled at the mouth or trachea. Compliance, measured as the slope of the steepest part of a graph plotting V_{RS} versus

TABLE 20.2 Respiratory muscles of the chicken.

	M. costoseptalis

P_{AS} in an artificially ventilated bird, ranges from 10 mL/cm H_2O in chickens (Scheid and Piiper, 1969) to 30 mL/cm H_2O in ducks (Gillespie et al., 1982b). These values are similar to compliance in mammals when correcting for body size.

Different results are obtained when compliance is measured by applying small oscillations in volume on spontaneously breathing birds. Compliance measured with this forced oscillation technique is only 7.7 mL/cm H_2O in ducks (Gillespie et al., 1982b) or much less than in mammals. In contrast, compliance measured with this technique in pigeons (2.8 mL/cm H_2O, Kampe and Crawford, 1973) is 3.7 times greater than the value predicted for a similar sized mammal (Powell, 1983). The reasons for these differences are not clear, but they suggest that compliance is exquisitely sensitivity to posture and muscular tone. Compliance primarily depends on the viscoelastic properties of the body wall and air sacs in birds, in contrast to the elastic properties of the lung in mammals (Macklem et al., 1979). Therefore, compliance in birds is high when volume changes occur by "unfolding" air sacs and stretching the abdominal wall, but it is low when volume changes are opposed by muscle tone in the body wall.

Birds native to high altitude have higher compliance than comparable species from low altitude, but this does not translate into differences in the work of breathing, which is only 1%−3% of resting metabolic rate and similar to mammals (York et al., 2017).

20.3.2.2 Resistance

Ohm's law defines the relationship between pressure, flow, and resistance (R) for the respiratory system as:

$$R = \Delta P/\dot{V}$$

where ΔP is the pressure gradient between the atmosphere and air sacs driving ventilatory airflow ($\dot{V}$). Expiration decreases air sac volume and creates a small positive pressure, which drives airflow out of the sac across small airway resistances; the opposite occurs during inspiration. Air sac pressure changes during breathing are small and similar in all of the air sacs (+1 cm H_2O), so resistance can be measured by measuring pressure and volume changes during artificial or spontaneous breathing as described above for compliance measurements (Scheid and Piiper, 1989). Airway resistance ranges from 4.8 cm H_2O/(L/s) in ducks (Gillespie et al., 1982a) to 41 cm H_2O/(L/s) in pigeons at the resonant frequency of their respiratory system (Kampe and Crawford, 1973).

Airway geometry is an important determinant of resistance. Poiseuille's law predicts resistance to laminar airflow is directly proportional to the length of an airway and inversely proportional to the fourth power of the airway radius. Therefore, resistance can vary between the different anatomical pathways possible for airflow in the avian respiratory system (see below). Different pathways presumably explain why airway resistance is generally greater during inspiration than during expiration in birds (Brackenbury, 1971, 1972; Cohn and Shannon, 1968). However, measurements using the forced oscillation technique on unanesthetized ducks find similar resistance during inspiration and expiration (Gillespie et al., 1982a). Resistance measured with this technique does not include any contributions from the body wall (Scheid and Piiper, 1989), so some differences between inspiratory and expiratory resistance may reflect muscle tone.

Physiological factors also affect airway resistance. Decreased lung P_{CO_2} increases resistance by a local effect on the openings of the mediodorsal secondary bronchi into the primary bronchus (Molony et al., 1976). However, P_{CO_2} does not affect smooth muscle contraction in the parabronchi (Barnas and Mather, 1978). Turbulent flow, which may occur in large airways at high ventilation rates or at bronchial bifurcations, can increase resistance (Brackenbury, 1972; Molony et al., 1976). Finally, resistance can change with breathing frequency. The pathway for airflow may be different with ventilation at high frequencies and small volumes (Banzett and Lehr, 1982; Hastings and Powell, 1987), and therefore affects resistance as described above. Also, the respiratory system has a resonant frequency, at which the overall impedance to breathing is minimized (e.g., 9.4 breaths/s in pigeons, Kampe and Crawford, 1973).

20.3.2.3 Air capillary surface forces

Surface tension at the gas-liquid interface of the respiratory exchange surface tends to collapse the air capillaries, and this decreases interstitial pressure between the air and blood capillaries. A decrease in interstitial pressure increases capillary filtration and can lead to edema and a thickening of the blood-gas barrier (see below). This tendency toward edema is probably a more important consequence of surface tension than airway collapse in the parabronchial lung because the air-blood capillary network tends to maintain constant volume (Maina, 2007). Similar to alveoli, air capillaries are lined by a surfactant, which lowers surface tension and counteracts these potentially deleterious effects (McLelland, 1989b). Lamellated osmophilic bodies in the parabronchial atria secrete the surfactant, which spreads as a trilaminar substance that is unique to birds over the air capillary surface (Bernhard et al., 2001; King and Molony, 1971; McLelland, 1989b; Pattle, 1978). Surface tension in avian surfactant is about threefold greater than in mammalian surfactant when subject to volume changes, but the maximum surface tension in avian surfactant is lower than in mammals (Bernhard et al., 2001). This is consistent with the chemical composition of avian versus mammalian surfactant and air capillaries not changing change volume

with ventilation, so there is no selective pressure to decrease surface tension to reduce the work of breathing in birds (Bernhard, 2016).

20.3.3 Ventilatory flow patterns

20.3.3.1 Air sac ventilation

The air sacs are ventilated roughly in proportion to their volume, such that the cranial and caudal groups (see above) each receive about 50% of the inspired volume (Scheid et al., 1974). The ventilation/volume ratio affects the O_2 and CO_2 levels in the air sacs (see below). Hence, the increase in air sac volume with changes in body wall muscle tone that may accompany anesthesia can alter air sac composition (Scheid and Piiper, 1969). There is no evidence for air flow between the sacs during normal breathing (Scheid and Piiper, 1989), although this has been postulated as a mechanism to enhance pulmonary gas exchange during breath-hold diving in birds (Boggs et al., 1996) and very complicated patterns of airflow may occur in the system during singing (Schmidt and Wild, 2014).

20.3.3.2 Pulmonary ventilation

Figure 20.7 shows the general pattern of ventilatory airflow during inspiration and expiration in the avian lung. The unidirectional flow in a caudal-to-cranial direction through the paleopulmonic parabronchi during both phases of ventilation has been established by a variety of methods (Scheid and Piiper, 1989). Early researchers noted that soot deposited primarily in the caudal regions of the lungs of pigeons collected in train stations, suggesting that inspired gas entered the lungs from a caudal direction (Dotterweich, 1930). More recently, researchers have confirmed this pattern with direct measurements of airflow (Brackenbury, 1971; Bretz and Schmidt-Nielsen, 1971; Scheid et al., 1972) and respiratory gases (Powell et al., 1981) in different parts of the lung.

Upon inspiration, about half of the tidal volume goes into the caudal air sacs and half goes into the cranial air sacs. Figure 20.7 shows how inspiratory flow bypasses the cranial secondary bronchial openings in the primary bronchus and flows directly into the caudal air sacs and caudal secondary bronchi. When gas enters the caudal secondary bronchi, it continues through the paleopulmonic parabronchi in a caudal-to-cranial direction and enters the cranial air sacs via the cranial secondary bronchi. If tidal volume is large enough, some of the inspired gas may reach the cranial air sacs via the paleopulmonic parabronchi during the same breath.

Upon expiration, the air sacs expel gas that eventually leaves the bird via the primary bronchi and trachea. Figure 20.7 shows how expiratory flow from the cranial air sacs leaves the lung via the cranial secondary bronchi emptying into the primary bronchi. Expiratory flow from the caudal air sacs is routed through the paleopulmonic parabronchi in a caudal-to-cranial direction via caudal secondary bronchi. If the expired volume is large enough, gas from the caudal air sacs will also leave the lung through the cranial secondary bronchi and mix with the gas emptying from the cranial air sacs.

Hence, airflow in the paleopulmonic parabronchi is caudal-to-cranial during both inspiration and expiration. In contrast to the paleopulmonic parabronchi, flow is bidirectional in the neopulmonic parabronchi, which are functionally in series with the caudal air sacs (Figure 20.7). Inspiratory airflow is cranial-to-caudal through neopulmonic parabronchi and into caudal air sacs, and in the caudal-to-cranial direction during expiration (Scheid and Piiper, 1989). The implications of these flow patterns for gas exchange are discussed later.

The pattern of airflow in the avian lung is determined by "aerodynamic valving." Pressure measurements show that branch points, such as the openings of the cranial secondary bronchial into the primary bronchi, are more important than distal airway resistance for determining flow patterns (Kuethe, 1988; Molony et al., 1976). There is no evidence for anatomical valves, for example, closing the primary bronchial openings of the cranial secondary bronchi during inspiration (reviewed by Scheid and Piiper, 1989 and Maina, 2017). As early as 1943, fluid dynamic models of the avian lung were used to show that these branches were critical for unidirectional caudal-to-cranial airflow in the paleopulmonic parabronchi (Hazelhoff, 1951). Modern theoretical models predict decreased effectiveness of aerodynamic valving with reduced gas

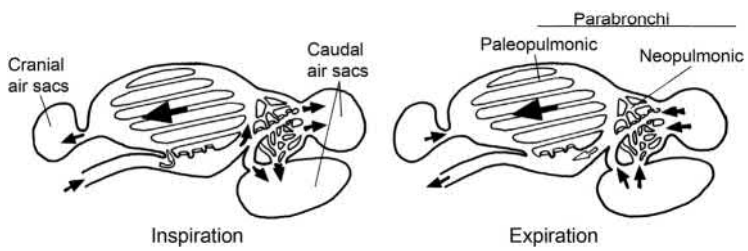

FIGURE 20.7 Pathway of airflow in the avian respiratory system during inspiration and expiration. Flow in paleopulmonic parabronchi is always caudal-to-cranial during both phases of breathing (*large solid arrows*), but neopulmonic flow is bidirectional. *Open arrows* show possible ventilatory shunts.

density, and experiments with low-density gases show valve failure and inspiratory shunts in birds (Banzett et al., 1987, 1991; Butler et al., 1988; Wang et al., 1988, 1992). In contrast, expiratory aerodynamic valving is not sensitive to gas density (Brown et al., 1995). Careful anatomical study has shown a narrowing of the primary bronchus distal to the cranial secondary bronchi that has been termed the *segmentum accelerans* (Maina, 2017). Computational fluid dynamic modeling of air flow in the ostrich lung shows a Bernoulli effect caused by flow through; this narrowing promotes flow past the cranial secondary bronchial openings to support the caudal-to-cranial flow in paleopulmonic parabronchi (Maina et al., 2009). Future experiments are necessary to determine if decreased gas density at high altitude can affect aerodynamic valving of not.

20.3.3.3 Air sac P_{O_2} and P_{CO_2}

The pattern of airflow is an important determinant of P_{O_2} and P_{CO_2} in the air sacs (Table 20.3). Cranial air sacs only receive gas from the parabronchi, so their P_{O_2} and P_{CO_2} levels are very near end-expired values. However, caudal air sacs contain a mixture of re-inhaled dead space gas (also end-expired P_{O_2} and P_{CO_2} levels) and fresh air, which raises their P_{O_2} and lowers their P_{CO_2}. Other factors that decrease P_{O_2} and increase P_{CO_2} in the air sacs include "stratification," gas exchange across the air sac wall, and gas exchange in neopulmonic parabronchi in series with the air sacs (Geiser et al., 1984).

Gas exchange across the air sac walls is less than 5% of the total respiratory gas exchange and a minor factor in determining air sac P_{O_2} and P_{CO_2} (Magnussen et al., 1976). Stratification (i.e., incomplete mixing of freshly inspired gas and resident gas in the air sacs) has been observed in ducks (Torre-Bueno et al., 1980), but its effect on air sac gas concentrations is not clear (Powell and Hempleman, 1985). Gas exchange in neopulmonic parabronchi in series with caudal air sacs seems to be the most important factor causing differences in measured P_{O_2} and P_{CO_2} values, and those predicted from re-inhaled dead space (Piiper, 1978). Bidirectional flow may also occur in a small fraction of parabronchi in the purely paleopulmonic lungs of penguins and affect P_{O_2} and P_{CO_2} in the caudal lungs of these birds too (Powell and Hempleman, 1985).

Considering the determinants of air sac P_{O_2} and P_{CO_2}, air sac sampling can offer valuable insights into respiratory function in birds under physiologically interesting conditions. For example, recent experiments sampling air sac gases in diving emperor penguins have been important for understanding how O_2 stores are utilized differently in diving birds and mammals; these differences result in similar O_2 levels in prolonged dives but the penguins

maintain normal (breathing) levels of arterial saturation during the first 7 min of a deep dive in contrast to dramatic decreases in Weddell and elephant seals (Ponganis et al., 2011).

20.3.3.4 Effective parabronchial ventilation

A quantitative description of gas exchange requires a measure of the effective ventilation of the lung. By analogy with alveolar ventilation in mammals, this is defined as parabronchial ventilation ($\dot{V}_P$) birds, and it differs from inspired ventilation ($\dot{V}_I$) because of dead space ventilation ($\dot{V}_D$). $\dot{V}_D$ in birds includes not only anatomic dead space in the upper airways but also it may result from ventilatory shunts in which airflow bypasses the parabronchi. The open arrows in Figure 20.7 show how gas might bypass the parabronchi during inspiration by directly entering the cranial secondary bronchi and air sacs, or during expiration by flowing back out the primary bronchus (Powell, 1988).

P_{CO_2} measurements in the cranial secondary bronchi show that an "inspiratory shunt", with inspired gas directly entering cranial air sacs from the primary bronchi does not occur (Powell et al., 1981). Some inspiratory flow may enter the fourth medioventral (cranial secondary) bronchus, however, and flow in a cranial-to-caudal direction through some paleopulmonic parabronchi (Powell and Hempleman, 1985), but this would not be a "shunt." In contrast, P_{CO_2} measurements indicate that an "expiratory shunt" with 10% −25% of expired gas from the caudal air sacs gas flowing out through the primary bronchus (Powell, 1988; Powell et al., 1981). Other experiments indicate that the relative proportion of expiratory flow in a mesobronchial shunt may vary from 100 to 75% at the beginning of expiration, to 0% near the midpoint of expiration (Hastings and Powell, 1986a). The magnitude of expiratory mesobronchial shunting depends on the pattern of ventilation, such as tidal volume, flow rate, and thermal panting (Bretz and Schmidt-Nielsen, 1971; Hastings and Powell, 1986a).

20.3.3.5 Artificial ventilation

The flow-through design of the rigid parabronchial lung allows a unique form of artificial ventilation, called unidirectional ventilation (Burger and Lorenz, 1960). Fresh humidified gas can be insufflated through a cannula in the trachea or an air sac, so it flows through the parabronchi before leaving the body through another cannula. This technique can be used clinically to support gas exchange during surgery which opens one of the air sacs (preventing effective spontaneous ventilation), to administer anesthetic gas or nebulized drugs (Fedde, 1978; Whittow and Ossorio, 1970), or for experimental studies (e.g., Burger et al., 1979; Fedde et al., 1974a). Artificial ventilation can also be performed manually by alternately compressing and lifting the sternum, for example, in a bird that may be anesthetized too deeply. It is also important to note that the sternum should not be compressed when holding a bird because this may lead to suffocation.

Inhalation anesthesia results in a higher mortality rate in birds (14%) compared to dogs and cats (Seamon et al., 2017) although experimental studies show that normal gas exchange can be maintained by positive pressure ventilation (e.g., Powell and Wagner, 1982). Inhalation anesthetics can inhibit intrapulmonary chemoreceptors (IPCs) in birds and inhibit CO_2-sensitive ventilatory drive (see below), which may contribute to this high mortality in birds. Further research on administering anesthetics during pressure-supported artificial ventilation in birds is warranted.

20.3.3.6 Frontiers: *lung structure-function in dinosaurs*

There is a rich literature on the evolutionary relationship between birds and dinosaurs and the progress continues in this field with modern experimental physiology. Originally, paleontology was used to generate the hypothesis that the long trachea, voluminous air sacs, and pneumatized bones found in birds evolved to enhance thermoregulation in extremely large dinosaurs (Perry et al., 2009). Subsequently, models were used to demonstrate how air sacs could facilitate the transition from quadrupedal to bipedal locomotion in dinosaurs, and this could ultimately lead to improvements in balance and agility necessary for flight (Farmer, 2006). More recently, physiological studies have demonstrated unidirectional air flow in the lungs of alligators, which have a bronchial tree similar to modern birds but no air sacs (Farmer and Sanders, 2010). This means cross-current gas exchange is possible in animals using a hepatic piston mechanism of breathing, as found in alligators and quadrupedal ancestors of birds, and costal breathing or bipedal locomotion are not prerequisites for cross-current gas exchange. The efficiency of cross-current gas exchange could have given avian ancestors a competitive advantage over synapsids when the basal archosaurs were evolving in times of low environmental oxygen. Such research demonstrates the value of comparative physiology for addressing important questions about evolution that can reach beyond what is possible with fossil skeletons.

20.4 Pulmonary circulation

The circulation is covered in another chapter, but this section highlights details of the pulmonary circulation that are relevant to understanding pulmonary gas exchange. The pulmonary circulation is unique because the lung is the only organ to receive the entire cardiac output. The "series" arrangement of the systemic and pulmonary circulations in

birds and mammals means that the lungs receive the same amount of blood flow as the whole rest of the body. However, the resistance to blood flow in the lungs is lower, and this allows lower perfusion pressure than in the systemic circulation, with the complete separation of the left and right ventricles. This section describes the structural and functional factors that determine pressures, volumes, and flows in the pulmonary capillaries, which are also important determinants of gas exchange.

20.4.1 Anatomy of the pulmonary circulation

The functional anatomy of the pulmonary circulation has been studied in detail for the domestic fowl (Abdalla and King, 1975). Interparabronchial arteries arise from main rami of the pulmonary arteries and run between the parabronchi and may perfuse more than one parabronchus. These vessels give rise to intraparabronchial arteries which perfuse the parabronchial mantle at several points along a parabronchus. The intraparabronchial arteries branch into the pulmonary blood capillaries near the outside edge of the parabronchial mantle which form a meshwork with air capillaries as described above. Pulmonary capillary blood is collected in intraparabronchial veins near the parabronchial lumen. These veins deliver blood flow to interparabronchial veins located near the outside edges of the parabronchus. The interparabronchial veins run between the parabronchi and collect blood from several points along a parabronchus and from several parabronchi. There are no anastomoses between the arterioles and veins in the lung (Abdalla, 1989).

This anatomy has two important consequences for respiratory gas exchange. First, all of the parabronchi are perfused along their entire length by mixed venous blood, and the oxygenated blood returning to the heart in the pulmonary vein (i.e., systemic arterial blood) is a mixture of blood draining the entire length of all the parabronchi. This allows cross-current gas exchange to occur, which is more efficient than alveolar gas exchange as described below. Second, it means that blood flow within the parabronchial mantle is directed from the periphery toward the lumen, which can affect the efficiency of gas exchange in the air capillaries.

20.4.2 Pulmonary capillary volume

Pulmonary capillary blood volume is similar in avian parabronchial lungs and mammalian alveolar lungs. A notable exception is the domestic fowl, which has a pulmonary blood capillary volume about threefold less than predicted for other birds that size (Maina et al., 1989). However, pulmonary blood capillary volume in birds is essentially constant under all conditions, in contrast to mammals that can increase pulmonary capillary volume by recruitment and distention when flow or pressure increases. Recruitment or distention of blood capillaries in a parabronchial lung would collapse the adjacent air capillaries and reduce gas exchange efficiency by causing a shunt (see below).

20.4.3 Pulmonary vascular pressures, resistance, and flow

20.4.3.1 Pulmonary vascular resistance and pressures

By analogy with Ohm's law:

$$PVR = \dot{Q}/\Delta P$$

where $\dot{Q}$ is cardiac output and ΔP is the difference between mean pulmonary artery and left atrial pressure. Pulmonary vascular pressures, cardiac output, and, therefore, pulmonary vascular resistances (PVRs) are similar in resting birds and mammals, but pulmonary arterial pressure changes more with cardiac output in birds. For example, doubling the blood flow through one lung of a duck almost doubles mean pulmonary artery pressure but causes no change in the resistance calculated for that lung, and no change in the capillary dimensions (Powell et al., 1985). Morphometric measurements of pulmonary blood capillaries in chickens with systematic increases in pulmonary artery pressure show no recruitment and very little distention (Watson et al., 2008). The lack of distention and recruitment of avian pulmonary capillaries also implies that the major effects of gravity and pulmonary vascular pressures on determining regional blood flow in mammalian lungs are not important in birds. The so-called Zone-1 and 2 conditions of mammalian lungs, in which alveolar pressure can collapse blood capillaries and stop or determine flow simply do not exist in birds (West et al., 2006). Hence, other mechanisms are responsible for the distribution of pulmonary blood flow in birds, as considered in the next section.

20.4.3.2 Distribution of blood flow

Local and regional changes in vascular resistance are more important than overall PVR for respiratory gas exchange. For example, regional control of blood flow between parabronchi has important effects on the efficiency of gas exchange (see below). Hypoxia has been shown to decrease local parabronchial blood flow, and gradients in P_{O_2} can explain differences in perfusion along parabronchi (Holle et al., 1978; Parry and Yates, 1979). Hypoxia and hypercapnia can also redistribute blood flow between paleopulmonic and neopulmonic parabronchi (Weidner et al., 2012). The physiological mechanism of these responses is not known. It may involve hypoxic pulmonary vasoconstriction, which is a direct effect of alveolar hypoxia on pulmonary arterioles in mammals. Smooth muscle capable of controlling local blood flow has been described for

interparabronchial arteries and veins in chickens, which could be responsible for control of blood flow between and along the lengths of parabronchi (Abdalla, 1989; Black and Tenney, 1980a; Burton et al., 1968).

20.4.3.3 Frontiers: *pulmonary vascular pressures during exercise in birds*

The lack of capillary distension and recruitment with increased cardiac output pose an interesting challenge for the avian lung during exercise. Alveolar capillary recruitment and distention is important for facilitating gas exchange during exercise by increasing the surface area for diffusion and preserving transit time for red blood cells in the capillaries to absorb oxygen by diffusion. In mammals, if pressures increase too much during exercise, for example, with extremely high cardiac outputs in elite human athletes or thoroughbred racehorses, then pulmonary capillaries suffer "stress failure" and blood to leaks into the alveoli (West, 2011). The blood-gas barrier in birds is even thinner than mammals, yet it appears to avoid stress failure on exercise. Cardiac output and therefore pulmonary blood flow increase comparably in birds and mammals, so extremely high pulmonary artery pressures are predicted with limited compliance in avian pulmonary blood capillaries. As considered above, blood capillaries may be supported better by air capillaries in birds than alveoli in mammals. However, there are no actual measurements of pulmonary circulation pressures in naturally exercising birds to date. Experiments simulating exercise, which used drug to increase metabolic rate, did not find large increases in pulmonary artery pressure as predicted for the increase in pulmonary blood flow (West et al., 2010). This is an area for future research.

20.4.4 Fluid balance

Fluid balance in the lungs, as in all organs, depends on the balance of hydrostatic and colloid osmotic pressures across the capillaries, and capillary permeability. These variables are similar in birds and mammals, although lymph drainage from avian lungs has not been measured directly (Weidner et al., 2006). Volume loading increases extravascular water in the lung interstitium, especially in the interparabronchial septum, and can lead to edema (Weidner et al., 1993; Weidner and Kinnison, 2002). The detailed anatomy of lymphatic vessels and rates pulmonary lymph drainage remains to be determined in birds.

A very important problem involving the pulmonary circulation and fluid balance in poultry husbandry is ascites in fast-growing broilers (chickens) bred for meat production (Julian, 1993). Ascites (i.e., fluid accumulation in the peritoneum) is associated with pulmonary arterial hypertension (PAH) and also occurs frequently in chickens raised at high altitude. Hence, early research on the problem focused on abnormal oxygen sensitivity, which could exaggerate increases in cardiac output with fast growth and cause hypoxic pulmonary vasoconstriction (Peacock et al., 1990). However, comparisons of PAH-susceptible and PAH-resistant broilers do not consistently reveal differences in cardiac output, although vascular capacity is limited in PAH susceptible broilers (Wideman et al., 2007). Factors that increase the PVR (e.g., hypoxia, thromboxane, endothelin-1, and serotonin) and reduce vasodilation (e.g., limited L-arginine, which is the substrate for nitric oxide) promote the onset of PAH and ascites and appear to be under genetic control (Wideman et al., 2013). Attempts to reduce deleterious effects of reactive oxygen species with antioxidative supplements to the diet have not worked consistently for ascites in very fast growing broilers. Current attempts to control the problem involve reducing the growth rate (and metabolic demand or cardiac output) and breeding resistant strains (reviewed by Kalmar et al., 2013).

20.5 Gas transport by blood

Equilibrium curves, also called dissociation curves, quantify the amount of O_2 and CO_2 in blood as functions of partial pressure. It is necessary to consider both partial pressure and concentration because partial pressure gradients drive diffusive gas transport in lungs and tissues, but concentration differences determine convective gas transport rates in lungs and the circulation. The concentration of a physically dissolved gas in a liquid is directly, and linearly, proportional to its partial pressure according to Henry's law: $C = \alpha P$, where α = solubility in mM/Torr. This means that inert gases such as nitrogen, and even anesthetic gases, increase in blood in direct proportion to their partial pressure. However, O_2 and CO_2 also enter into chemical reactions with blood. These reactions result in more complex relationships between concentration and partial pressure, but they serve to (*i*) increase O_2 and CO_2 concentrations in blood, (*ii*) allow physiological modulation of O_2 and CO_2 transport in blood, and (*iii*) make respiratory CO_2 exchange an important mechanism of acid-base balance in the body.

20.5.1 Oxygen

Oxygen concentration in normal arterial blood (Ca_{O_2}) of, for example, a pigeon is about 8.3 mM. However, the physical solubility of O_2 in blood (α_{O_2}) is only 0.00124 mM/Torr at 41°C, so only 0.117 mM of arterial O_2 content is dissolved gas with a normal arterial P_{O_2} of 95 Torr in pigeons (Powell, 1983). Most of the O_2 in blood is chemically bound to hemoglobin.

20.5.1.1 Hemoglobin

Hemoglobin is a large molecule consisting of four individual polypeptide chains, each with a heme (iron containing) protein that can bind O_2 when iron is in the *ferrous* (Fe^{2+}) form. Methemoglobin occurs when the iron is in the *ferric* form (Fe^{3+}), and it cannot bind O_2. Small amounts of methemoglobin, which occur under normal conditions, slightly reduce the amount of O_2 that can be bound to hemoglobin. One gram of pure mammalian hemoglobin can bind 0.060 mmol of O_2 when fully saturated, and this value appears similar in birds (Powell, 1983). Hemoglobin is concentrated inside red blood cells or erythrocytes. This cellular packaging is important for the biophysics of the microcirculation, and it provides physiological control of O_2 binding through cellular changes in the hemoglobin microenvironment (see below).

20.5.1.2 O_2-blood equilibrium curves

Figure 20.8 shows the O_2 equilibrium curve for duck blood as saturation (S_{O_2}) versus P_{O_2}, where S_{O_2} is defined as the percentage of the total hemoglobin sites available for binding O_2 which are occupied by O_2. Therefore, the maximum S_{O_2} is 100% and independent of hemoglobin concentration in blood. In contrast, O_2-hemoglobin equilibrium curves plotting concentration versus P_{O_2} quantify the absolute amount of O_2 in blood at a given P_{O_2}, and the maximum O_2 concentration depends on the amount of hemoglobin available. O_2 capacity defines the maximum O_2 concentration in blood when hemoglobin is 100% saturated with O_2. Total O_2 concentration in blood (C_{O_2}), including chemically bound and dissolved O_2, can be calculated as:

$$C_{O_2} = (O_2\text{capacity}[S_{O_2} / 100]) + (\alpha_{O_2} P_{O_2})$$

The sigmoidal (or "S") shape of the blood-O_2 equilibrium curve results from cooperative, *allosteric* interactions between the four subunits of hemoglobin, which determine the three-dimensional shape of the molecule. O_2 equilibrium curves for individual hemoglobin subunits are not sigmoidal, but simple convex curves like the O_2 equilibrium curve for myoglobin (see Section 20.7). The shape of the blood-O_2 hemoglobin equilibrium curve facilitates O_2 loading on blood in the lungs, and O_2 unloading from blood in the tissues.

The cooperativity between functional subunits of hemoglobin is quantified with Hill's coefficient, "n" (Powell and Scheid, 1989). High values of n, exceeding the theoretical limit of 4, have been observed in bird blood and may reflect increased cooperativity between aggregates of multiple hemoglobin molecules, or interactions between different isoforms of hemoglobin within a blood sample (Black and Tenney, 1980b; Lapennas and Reeves, 1983).

The affinity of hemoglobin for O_2 is quantified with P_{50}, which is the P_{O_2} at 50% saturation. For example, a decrease in P_{50}, or a "left shift," indicates an increase in O_2 affinity because S_{O_2} is greater for a given P_{O_2}. In general, P_{50} in avian blood is greater than in mammalian blood. Table 20.4 shows P_{50} values for several common avian species in the 40 Torr range, while P_{50} in comparably sized mammals are nearer 30 Torr. Some studies have used erythrocyte suspensions (Lutz, 1980), and this might explain the low P_{50} values they have found. However, determinations of P_{50} in avian hemoglobin solutions agree well with other published values for whole blood, for example, in pigeons (Powell, 1983). Because the efficiency of O_2 uptake in the avian lung is greater than mammals, birds may have evolved blood with low O_2 affinity to maximize O_2 delivery in tissue.

Developmental changes in hemoglobin-O_2 affinity are explained by differences in the type of hemoglobin expressed in an individual. For example, the dramatic decrease of P_{50} in chickens, from 75 Torr at 8 days to 35 Torr at 14 to 16 days of development, is explained by the replacement fetal hemoglobin with adult hemoglobin expressed in the erythrocytes (Baumann and Baumann, 1978).

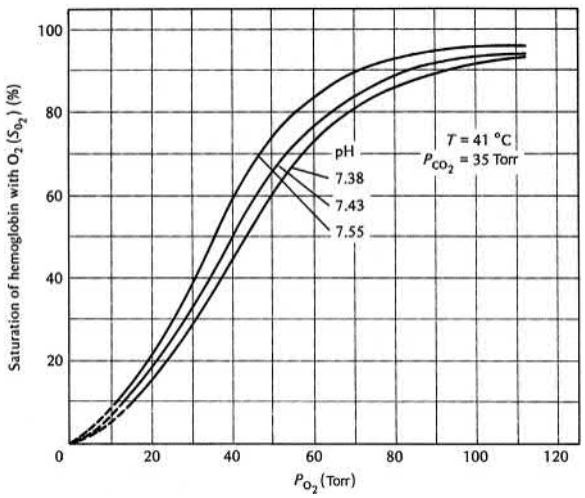

FIGURE 20.8 O_2-blood equilibrium curves for duck. Bohr effect is demonstrated by shifts of the curve as pH changes. *From Scheipers et al. (1975).*

20.5.1.3 Physiological control of O_2-hemoglobin affinity

The most important physiological factors that affect the P_{50} in a given species are (*i*) organic phosphate levels, (*ii*) pH,

and (*iii*) temperature. These factors work by modifying the structure of the hemoglobin tetramer, so it binds O_2 more or less efficiently.

Inositol pentahosphate (IPP) is the primary organic phosphate affecting P_{50} in birds (Weber and Wells, 1989). The effect of IPP binding with hemoglobin inside erythrocytes is considerable, for example, increasing P_{50} from less than 3 Torr in stripped hemoglobin from chickens, to over 40 Torr under in vivo conditions (Weingarten et al., 1978). Physiological changes in organic phosphates have not been studied extensively in birds (Maginniss and Kilgore, 1989; Weber and Wells, 1989). In mammals, acclimatization to conditions such as altitude can modulate P_{50} by altering organic phosphates (2,3 diphosphoglycerate, or 2,3-DPG). However, it is important to note that differences in P_{50} between birds adapted over generations to low or high altitude cannot be explained by different organic phosphate concentrations. Erythrocyte inorganic phosphate levels and the effects of phosphates on P_{50} are similar in the low altitude (Canda and domestic) geese and the high altitude adapted bar-headed goose (Jendroszek et al., 2018; Petschow et al., 1977).

Figure 20.8 shows the effect of pH on the O_2 affinity, which is known as the Bohr effect. Increases in pH cause decreases in P_{50} (i.e., increase O_2-hemoglobin affinity) and vice versa. H^+ binds to histidine residues in hemoglobin, which changes the molecular conformation and ability of heme sites to bind O_2. The physiological advantage of the Bohr effect is that it facilitates O_2 loading in the lungs, where CO_2 is low and pH is high (see below). In muscles, the opposite occurs, and decreased pH facilitates O_2 unloading to the tissues. The Bohr effect is independent of saturation in most birds (Lapennas and Reeves, 1983; Maginniss, 1985; Meyer et al., 1978) and similar to values reported for mammals (Table 20.4).

In most birds, and in contrast to mammals, there is no independent effect of CO_2 on P_{50} (Meyer et al., 1978). CO_2 forms carbamino compounds with hemoglobin in mammals, and these cause small increases in P_{50}. In some birds, such as sparrows and burrowing owls, the Bohr effect is

greater when pH is changed with CO_2 compared to fixed acid (Maginniss, 1985; Maginniss and Kilgore, 1989). Therefore, carbamino formation does occur and can decrease O_2 affinity in stripped avian hemoglobin. However, strong binding of IPP to hemoglobin in most birds prevents an independent CO_2 Bohr effect (Lapennas and Reeves, 1983; Weingarten et al., 1978).

The in vivo physiological O_2 dissociation curve is steeper than the individual in vitro curves in Figure 20.8 because P_{CO_2} increases and pH decreases between arterial and venous blood. This is an advantage for gas exchange because it increases the change in O_2 concentration for a given change in P_{O_2}, thereby increasing O_2 uptake or delivery. The slope of the physiological O_2-blood equilibrium curve, in terms of O_2 concentration, is called βb_{O_2} (mM/Torr) and is used for quantitative descriptions of gas exchange (see below).

Because the combination of O_2 with hemoglobin is a chemical reaction that releases heat, increased temperature reduces the affinity of hemoglobin for O_2. This facilitates O_2 off-loading at exercising muscle with relatively high temperatures. It has also been hypothesized to facilitate O_2 loading in the lungs of birds flying at high altitude, when high rates of ventilation with extremely cold air might cool the respiratory exchange surfaces (Faraci, 1986, 1991). However, experiments to date have not been able to demonstrate decreased temperature of blood in the lungs. The effect of temperature on P_{50} in birds is generally similar to the effect in mammals (Table 20.4) except in the bar-headed goose, described next.

20.5.1.4 Frontiers: *hemoglobin adaptations to high altitude*

Hemoglobin-O_2 affinity is generally greater in birds native to high altitude compared to low altitude species, presumably as an adaptation to hypoxia (Black and Tenney, 1980b; Jessen et al., 1991; Meir and Milsom, 2013; Petschow et al., 1977). For example, P_{50} in the bar-headed goose (discussed above) is 10 Torr less than P_{50} in the closely related greylag goose, which lives on the Indian planes year-round (Petschow et al., 1977). Low P_{50} enhances pulmonary O_2 loading in extreme hypoxia (Bencowitz et al., 1982), and the trend for high O_2-affinity/low P_{50} hemoglobin in high altitude species is observed widely in both birds and mammals (Powell and Hopkins, 2010; Weber, 2007). Despite the universal nature of this adaptation, the molecular underpinnings of a low P_{50} at high altitude are diverse. In 56 pairs of avian taxa with contrasting altitudinal ranges, P_{50} was universally lower in the high altitude taxa but only a few of the amino acid substitutions explaining a low P_{50} were similar (Natarajan et al., 2016). Amino acid sequences from the bar-headed goose and greylag goose revealed a single substitution on one of the four hemoglobin subunits and genetically engineering this substitution into human hemoglobin decreases P_{50} by a similar amount to the difference between the two species of geese (Jessen et al., 1991). In general, a low P_{50} in high altitude compared to low altitude species requires only a few amino acid substitutions, and in birds these occur at contact points between subunits that stabilize hemoglobin in either low or high O_2-affinity conformations (Jendroszek et al., 2018). Effects of phosphates and H^+ on O_2-affinity are similar between low and high altitude avian hemoglobins (Weber, 2007). However, bar-headed goose hemoglobin is more sensitive to temperature than other birds (Table 20.4), and this is hypothesized to confer additional advantages. With differences in temperature and CO_2 between lungs and exercising muscle during high altitude flight, changes in P_{50} are predicted to double O_2 delivery, relative to a fixed P_{50} in bar-headed geese (Meir et al., 2013).

20.5.1.5 *Factors affecting O_2 capacity*

Changes in hemoglobin concentration [Hb] in blood will change the O_2 capacity, and therefore the O_2 concentration at any P_{O_2} as described above. [Hb] depends on both the mean corpuscular hemoglobin concentration (MCHC) and the hematocrit. Typical hematocrit and [Hb] values are given in Table 20.4; [Hb] is expressed as g/100 mL of blood instead of mM because the molecular weight was not known for all hemoglobins when they were originally measured. Typical values for MCHC in birds are 30–40 g Hb/100 mL of erythrocytes (Palomeque et al., 1979) or similar to the MCHC in mammals.

If [Hb] decreases, for example, with decreased hematocrit in anemia, then O_2 capacity and concentration decreases at any given P_{O_2}. The O_2 capacity increases when [Hb] increases, for example, by the stimulation of red blood cell production in bone marrow by the hormone erythropoietin (EPO). EPO is released from cells in the kidneys in response to decreases in arterial O_2 levels (Sturkie, 1986). Significant gender differences in [Hb], for example, in chickens, are explained by the effects of sex hormones on hematocrit (Sturkie, 1986). The functional consequences of changes in [Hb] are not always directly related to oxygen delivery (the product of blood flow and O_2 concentration) but also depend on viscosity, which increases with hematocrit and can limit tissue O_2 exchange. For example, warblers treated with anti-EPO decrease hematocrit and flight performance in a wind-tunnel at sea-level; however, their flight performance increases at 3000 m simulated altitude in a hypobaric wind tunnel (Yap et al., 2018). Optimal hematocrit depends upon the altitude at which an animal is exercising.

20.5.2 Carbon dioxide

CO_2-blood equilibrium (or dissociation) curves are nonlinear, but they have a different shape and position than O_2-blood equilibrium curves (Figure 20.9). CO_2 is carried in three forms by blood, so CO_2 concentrations in blood are generally much higher than O_2 concentrations. This results in a smaller range of P_{CO_2} values in the body, compared to the range P_{O_2} values, although the differences between arterial and venous *concentrations* are similar for CO_2 and O_2. The resulting physiological CO_2 dissociation curve between the arterial and venous points is much more linear than the physiological O_2 dissociation curve (Figure 20.9).

20.5.2.1 Forms of CO_2 in blood

CO_2 solubility in water or plasma is 0.0278 mM/Torr or about 20 times more soluble than O_2. Still, dissolved CO_2 only contributes about 5% of total CO_2 concentration in arterial blood. CO_2 can also combine with terminal amine groups in hemoglobin to form carbamino compounds. Bicarbonate ion (HCO_3^-) is the most important form of CO_2 carriage in blood. CO_2 combines with water to form carbonic acid, and this dissociates to HCO_3^- and H^+:

$$CO_2 + H_2O \; H_2CO_3 \; HCO_3^- + H^+$$

Carbonic anhydrase is the enzyme that catalyzes this reaction, and it occurs mainly in red blood cells (Maren, 1967). The reaction is almost instantaneous with carbonic anhydrase, but the uncatalyzed reaction will occur much more slowly in any aqueous medium (requiring over 4 min for equilibrium). The rapid conversion of CO_2 to bicarbonate results in about 90% of the CO_2 in arterial blood being carried in that form. The H^+ produced from CO_2 reacts with hemoglobin and affects both the O_2 dissociation curve (Bohr effect), and CO_2 dissociation curve as described next.

20.5.2.2 Factors affecting blood-CO_2 equilibrium curves

Hb-O_2 saturation is the major factor affecting the position of the CO_2 equilibrium curve. The Haldane effect increases CO_2 concentration when blood is deoxygenated, or decreases CO_2 concentration when blood is oxygenated, at any given P_{CO_2} (Figure 20.9). The Haldane effect is actually another view of the same molecular mechanism causing the Bohr effect on the O_2 equilibrium curve (see above). H^+ ions and O_2 can be thought of as competing for hemoglobin binding, so increasing O_2 decreases the affinity of hemoglobin for H^+ (Haldane effect) and increased $[H^+]$ decreases the affinity of hemoglobin for O_2 (Bohr effect).

The physiological advantages of the Haldane effect are to promote unloading of CO_2 in the lungs when blood is oxygenated, and CO_2 loading in the blood when O_2 is released to tissues. The Haldane effect also results in a steeper physiological CO_2-blood equilibrium curve (Figure 20.9), which has the physiological advantage of increasing CO_2 concentration differences for a given P_{CO_2} difference. Finally, the Haldane effect can cause apparent negative blood-gas CO_2 gradients when it is amplified by cross-current gas exchange in avian lungs (see below).

20.5.3 Acid-base

The chemical equilibrium between CO_2 and H^+/HCO_3^- ions has tremendous implications for acid-base physiology. Every mole of metabolic CO_2 produced results in 1 mole of acid, and over 95% of this acid is excreted by the lungs (Skadhauge, 1983). The ability to change blood P_{CO_2} levels rapidly by changing ventilation has a powerful effect on blood pH, so acid-base balance depends on the integrated function of respiratory and renal systems.

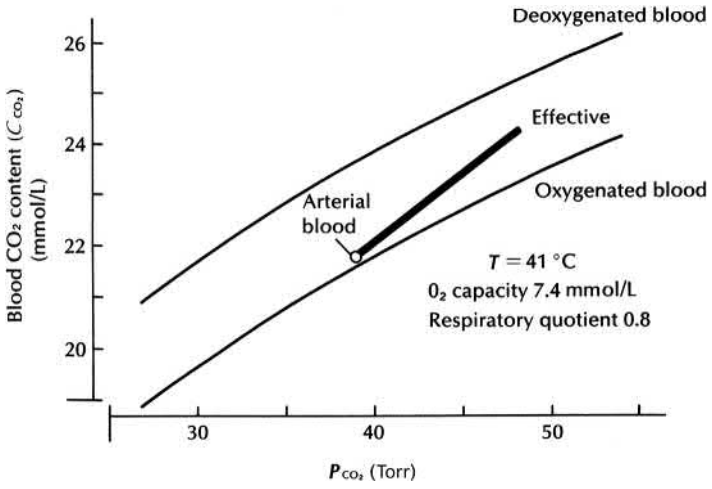

FIGURE 20.9 CO_2-blood equilibrium curves from the duck. Upper (deoxygenated blood) and lower (oxygenated blood) curves are derived from in vitro equilibration of blood samples. Heavy line is the physiological or in vivo dissociation curve from unanesthetized undisturbed birds. It illustrates the changes in CO_2 content (C_{CO_2}) in blood as it changes from arterial blood to venous blood in the tissue capillaries. *From Scheipers et al. (1975).*

20.5.3.1 Henderson-Hasselbalch equation

This equation describes the relationship between P_{CO_2}, pH, and $[HCO_3^-]$ in blood as:

$$pH = pK_a + \log\left([HCO_3^-] / \alpha P_{CO_2}\right)$$

where pK_a is $-\log_{10}$ of K_a, the dissociation constant for carbonic acid, $[HCO_3^-]$ = bicarbonate concentration in mEq/L or mM, and α is the physical solubility for CO_2 in water. A normal value for arterial pH (pHa) in chickens is 7.52 (Table 20.5), which can be calculated from $pK_a = 6.09$ and $\alpha_{CO_2} = 0.03$ mM/Torr in chicken plasma at 41°C (Helbacka et al., 1963), arterial $P_{CO_2} = 33$ Torr (Table 20.5), and arterial $[HCO_3^-] = 27.2$ mM. The buffer value for plasma in ducks is similar to the value for humans (Scheipers et al., 1975) if corrections are made for differences in [Hb]. At pH = 7.5, the $[H^+]$ is only 30 *nano*M, or significantly less than many other important ions in the body, such as Na^+, Cl_3^-, HCO_3^-, which occur in the mM range. Small changes in pH, corresponding to very small changes in $[H^+]$ can lead to dramatic changes in physiological function.

The Henderson-Hasselbalch equation shows how the physiological control of pH depends on the ratio of $[HCO_3^-]$ to $[\alpha P_{CO_2}]$. Notice, that a normal pH can occur with a variety of $[HCO_3^-]$ and P_{CO_2} values, so, for example, pH = 7.52 in a chicken does not necessarily indicate normal acid-base status. The primary cause of a chronic acid-base disturbance cannot be determined from P_{CO_2}, pH, and $[HCO_3^-]$ data alone. Other details of the disease history, pulmonary function, or blood chemistry must be obtained for a proper diagnosis.

The respiratory system controls pH primarily by changing arterial P_{CO_2} ($P_{a_{CO_2}}$). $P_{a_{CO_2}}$ is determined by parabronchial ventilation at any given metabolic rate (see below). Increasing ventilation will decrease $P_{a_{CO_2}}$ and increase pHa, while decreasing ventilation will have the opposite effects. Therefore, ventilation is an extremely effective mechanism for changing pHa quickly, and ventilatory reflex responses to pH are the most important physiological mechanisms for rapid control of pH (see below) The kidneys can also control pH by changing $[HCO_3^-]$ independent of CO_2 changes, as described in another Chapter 12, but renal changes in pH generally take longer than respiratory changes in pH.

20.5.4 Blood gas measurements

Avian blood presents special challenges to the accurate measurement of P_{O_2}, P_{CO_2}, and pH with traditional equipment designed for humans. In contrast to mammals, avian

erythrocytes are nucleated (as are most other vertebrates), and this may be the reason for high rates of O_2 consumption compared to mammals. Therefore, care must be taken to analyze arterial blood gases in birds as soon as possible after the sample is drawn, and to correct for any decreases in P_{O_2} with time if necessary. Storing the samples in ice water may help if immediate analysis is not possible, but the analyzed value can still differ from the in vivo value if any delay occurs, especially in normoxia where the blood-O_2 equilibrium curve is relatively flat and small O_2 content changes cause large changes in P_{O_2} (Kawashiro and Scheid, 1975). Sampling delays may also explain reports of 0 Torr P_{O_2} values in mixed venous blood from pigeons at simulated high altitude (Weinstein et al., 1985).

In addition to sampling delays, care must be taken to perform the analysis at body temperature, which is usually greater than the human value of 37°C, or to apply temperature correction values established for avian blood (Kiley et al., 1979). Also, a blood-gas correction factor needs to be established with a tonometer to account for differences in P_{O_2} measured in the liquid phase after calibrating electrodes with a gas phase (Nightingale et al., 1968). These, and other factors which may affect O_2-hemoglobin saturation measurements, have been discussed in other reviews (e.g., Powell and Scheid, 1989).

Finally, the most important determinant of arterial blood gas values is the physiological state of the bird. Table 20.5 presents arterial blood gases for several species breathing room air, but these may not be "normal" if the bird was excited by the sampling procedure. Remote-controlled sampling devices have been used for resting ducks (Scheid and Slama, 1975), and this technology is being extended to other interesting conditions such as diving penguins (Ponganis et al., 2011) and flying geese (Meir et al., 2013). Recently, a mouse pulse oximeter has been used to measure O_2-hemoglobin saturation in geese, and the results were generally as expected and the measurements are almost noninvasive (Ivy et al., 2018); however, potential errors are physiologically significant (95% confidence limits = +5% S_{O_2} in normoxia), and the device has not been calibrated against validated methods on simultaneous samples.

20.6 Pulmonary gas exchange

Theoretically, the unique anatomy of the avian respiratory system results in a more efficient model of gas exchange than the mammalian model (Piiper and Scheid, 1975). For a given level of ventilation to the gas exchange surfaces ($\dot{V}_P$), cardiac output ($\dot{Q}$), and lung diffusing capacity ($D_{L_{O_2}}$), arterial oxygenation and CO_2 elimination are predicted to be greater in a parabronchial lung, compared to an alveolar lung with the same inspired gases and metabolic demands (Powell and Scheid, 1989). This section explains the structural and functional basis for this most important function of the respiratory system and how avian gas exchange actually performs in nature under physiological conditions.

20.6.1 Basic principles of oxygen transport

20.6.1.1 Convection

Convection, or bulk flow of gas, is used to transport oxygen into the lungs by ventilation, and to the tissues by blood flow. The Fick principle, which is simply conservation of mass applied to respiratory gas transport, can be used to quantify O_2 uptake as:

$$\dot{M}_{O_2} = \dot{V}\beta_{g_{O_2}}\left(P_{I_{O_2}} - P_{\overline{E}O_2}\right)$$

where $\dot{M}_{O_2}$ is O_2 uptake, $\dot{V}$ is ventilation, $\beta_{g_{O_2}}$ is the capacitance coefficient for O_2 in the gas phase (0.512 mM/Torr at 41°C), and $(P_{I_{O_2}} - P_{\overline{E}_{O_2}})$ is the difference between inspired and mixed-expired P_{O_2} (Piiper et al., 1971; Powell and Scheid, 1989). Inspired and expired ventilation are assumed equal in this formulation of the Fick principle, so the amount of O_2 consumed is the difference between the amount of O_2 inspired and the amount expired. Mixed-expired P_{O_2} is used when total ventilation is measured or end-expired P_{O_2} is used if parabronchial ventilation ($\dot{V}_P$) is available (see above). The same principles described for O_2, also apply to CO_2 exchange.

The Fick principle can be written for the cardiovascular transport of O_2 out of the lungs and to the tissues also:

$$\dot{M}_{O_2} = \dot{Q}\beta_{b_{O_2}}\left(P_{a_{O_2}} - P_{\overline{\dot{V}}_{O_2}}\right)$$

where $\dot{Q}$ is cardiac output and $\beta_{b_{O_2}}$ is the physiological slope of the blood-O_2 equilibrium curve. Hence, the amount of O_2 taken up by blood in the lungs is the difference between the amount of O_2 leaving the lungs in arterial blood, and the amount that entered the lungs in mixed-venous blood. In a steady state, $\dot{M}_{O_2}$ is equal at each step of the O_2 cascade, so the Fick principle can be rearranged to calculate $\dot{M}_{O_2}$, $\dot{Q}$, $\dot{V}$, or P_{O_2} from measurements of other variables in the equation. Table 20.5 lists the important variables for quantifying gas exchange in several birds under resting conditions. Changes in these variables under different physiological conditions such as exercise, hypoxia, and thermal stress have been summarized in several reviews (Brackenbury, 1984; Butler, 1991; Faraci, 1991; Powell and Scheid, 1989).

20.6.1.2 Diffusion

O_2 movement over the very short distances across the blood-gas barrier occurs effectively by the "passive" mechanism of diffusion; active transport of O_2 does not occur in the body. Fick's law of diffusion describes O_2 transport from the air capillaries to the blood capillaries as:

$$\dot{M}_{O_2} = \Delta P_{O_2} \cdot D_{L_{O_2}}$$

where ΔP_{O_2} is the average P_{O_2} gradient between the air capillary and blood in the pulmonary capillary and $D_{L_{O_2}}$ is the diffusing capacity of the lung for O_2. The equation shows that a larger $D_{L_{O_2}}$ can transport more O_2 for a given P_{O_2} gradient. Determinants of $D_{L_{O_2}}$ are described in the section on lung diffusing capacity below.

20.6.2 Cross-current gas exchange

20.6.2.1 Cross-current O_2 exchange

Figure 20.10 shows how air flow and blood flow in the parabronchus can be viewed as occurring perpendicular to one another, and this is the basis for describing avian gas exchange with a "cross-current" model (Piiper and Scheid, 1972, 1975). In this idealized model of cross-current exchange, air flow is assumed continuous through the parabronchus which is uniformly perfused along its length by mixed-venous blood. At the inspiratory end of the parabronchus, there is a large P_{O_2} gradient driving diffusion of O_2 into the capillary blood, which raises capillary P_{O_2} and drops parabronchial P_{O_2}. As air flows along the parabronchus, the P_{O_2} gradient driving O_2 diffusion decreases with parabronchial P_{O_2}, while $P_{\bar{V}_{O_2}}$ is constant. At the expiratory end of the parabronchus, P_{O_2} has decreased to end-expired levels, and P_{O_2} in the capillary blood leaving this part of the parabronchus is correspondingly low. However, notice that arterialized blood returning to the heart is a mixture of capillary blood draining the entire length of the parabronchus. Therefore, arterial P_{O_2} is greater than end-expired P_{O_2} in ideal cross-current gas exchange.

A negative expired-arterial P_{O_2} difference, shown in Figure 20.10 as the overlap of P_{O_2} arrows, is not possible in alveolar gas exchange. The best situation that can be achieved in ideal alveolar gas lungs is equilibrium between expired and arterial P_{O_2}, so $(P_{E_{O_2}} - P_{a_{O_2}}) = 0$. However, negative expired-arterial P_{O_2} differences are not always observed in birds, and arterial P_{O_2} is similar in resting, normoxic birds and mammals (Table 20.5). As explained in the following sections, cross-current O_2 exchange is theoretically more efficient than alveolar exchange, but similar amounts of gas exchange limitation have a larger effect in cross-current exchange (see below).

Notice that the efficiency of cross-current exchange should not depend on the direction of ventilatory flow in the parabronchus. This is supported by experiments which reversed the direction of parabronchial flow in ducks and chickens and found no difference in the expired-arterial P_{O_2} differences for O_2 or CO_2 (Powell, 1982; Scheid and Piiper, 1972). It is physiologically significant because airflow is presumably bidirectional in neopulmonic parabronchi (see above).

20.6.2.2 Cross-current CO_2 exchange

Figure 20.10 also shows how expired P_{CO_2} can exceed arterial P_{CO_2} in a parabronchus, which is also impossible in alveolar gas exchange. This occurs similar to the "overlap" of arterial and expired P_{O_2} as explained above. However,

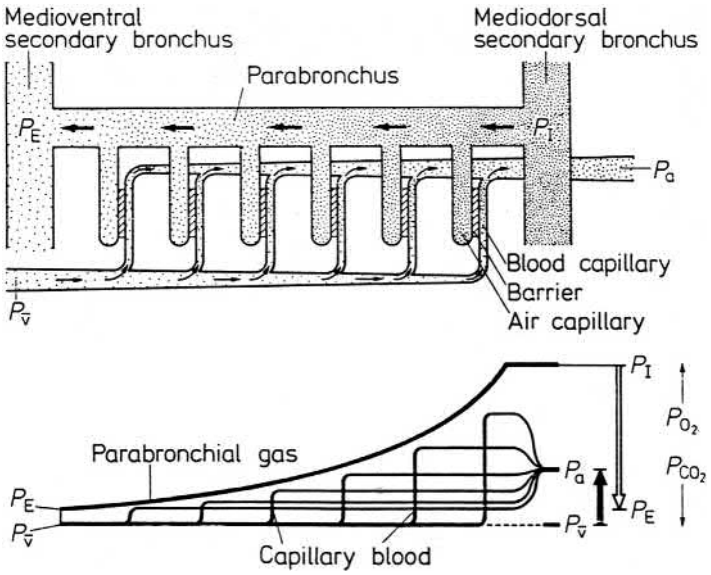

FIGURE 20.10 Cross-current model of gas exchange in the parabronchus. Lower panel shows how $P_{a_{O_2}}$ results from a mixture of blood from capillaries all along the parabronchus, where P_{O_2} ranges from P_I to P_E. Overlap of P_{O_2} in gas (*open arrows*) and blood (*filled arrows*) shows how $P_{a_{O_2}}$ can exceed $P_{E_{O_2}}$ in birds. *From Scheid (1979).*

experimental observations of expired P_{CO_2} exceeding *mixed-venous* P_{CO_2} in birds can only be explained by an interesting interaction of O_2 and CO_2 exchange in the parabronchus. Because of the shape of the O_2 and CO_2 blood equilibrium curves, the ratio of CO_2 elimination to O_2 uptake (R = respiratory exchange ratio) decreases near the expiratory ends of the parabronchus (Meyer et al., 1976). As originally postulated by Zeuthen (1942), this can lead to oxygenation of mixed-venous blood in expiratory ends of the parabronchi and increase P_{CO_2} in capillaries by the Haldane effect. Because P_{CO_2} of oxygenated mixed-venous blood is greater than $P_{\overline{V}_{O_2}}$ (Figure 20.9), P_{CO_2} in gas equilibrating with such blood at the expiratory end of the parabronchus (i.e., $P_{E_{O_2}}$) can exceed true $P_{\overline{V}_{O_2}}$.

Overlap between arterial and expired P_{CO_2} is more commonly observed than overlap for O_2 in birds (Table 20.5). This is because of differences in the O_2 and CO_2 blood equilibrium curves, and the fact that CO_2 is less sensitive than O_2 to some of the factors limiting the efficacy of cross-current gas exchange (Powell and Scheid, 1989).

CO_2 exchange can be affected by the same factors limiting O_2 exchange, which are considered in detail below. However, $P_{a_{CO_2}}$ is most sensitive to changes in ($\dot{V}_{D_{phys}}$) and effective $\dot{V}_P$. CO_2 should not be diffusion limited either because O_2 and CO_2 require similar times for diffusion equilibrium (Wagner, 1977). $\dot{V}/\dot{Q}$ mismatching and shunt increases $P_{a_{CO_2}}$ less than they decrease $P_{a_{O_2}}$ because of differences between the O_2 and CO_2-blood equilibrium curves (Powell and Scheid, 1989).

20.6.3 Lung diffusing capacity

The diffusing capacity of the lung for O_2 ($D_{L_{O_2}}$) is a complex variable that depends on several physiological processes (Powell, 1982; Powell and Scheid, 1989). These include gas-phase diffusion in the air capillaries, diffusion across the blood-gas barrier, and the chemical reaction between O_2 and hemoglobin.

20.6.3.1 Gas transport in air capillaries

Ventilatory flow in the parabronchi prevents significant P_{O_2} gradients from developing in the lumen of the parabronchus. However, the mechanism of gas transport in the air capillaries is not clear, and P_{O_2} gradients could occur between the lumen and the depths of the parabronchial mantle. Originally, it was assumed that diffusion explained gas transport over the small dimensions of the air capillary, considering the small distances involved and effectiveness of diffusive gas transport in the functional gas exchange unit of alveolar lungs. Indeed, measurements show no significant diffusive resistance to gas exchange along the air capillaries (Burger et al., 1979; Crank and Gallagher, 1978; Scheid, 1978). If diffusion is the main gas transport mechanism within air capillaries, then air-blood capillary exchange could be enhanced by an arrangement similar to counter-current exchange (Scheid, 1978). O_2 would diffuse from the lumen toward the periphery in air capillaries, which is opposite to the direction of flow in the blood capillaries (Figures 20.4 and 20.10). Therefore, blood at the end of a capillary would equilibrate with the relatively high P_{O_2} levels in air capillaries near the parabronchial lumen. However, there is no experimental evidence for this, and more recent morophometric studies of the air capillary network (Figure 20.5) shows extensive connections and branching, in contrast to the dead end tubes in Figure 20.10. This could result in convective flow instead of only diffusion in air capillaries (Maina et al., 2010).

20.6.3.2 Blood-gas barrier diffusion

The effect of the blood-gas barrier on diffusion in the lung can be evaluated by the membrane diffusing capacity ($D_{m_{O_2}}$), which can be estimated from morphometric measurements of the lung (Maina, 1989; Powell and Scheid, 1989). $D_{m_{O_2}}$ is directly proportional to the surface area and inversely proportional to the thickness of the blood-gas barrier. These variables have been measured in several species of birds now, using perfusion fixation and rapid freezing to preserve tissue for electron microscopy and stereological analysis (Dubach, 1981; Maina et al., 1982, 1989; Powell and Mazzone, 1983). The values depend on body size, which determines metabolic rate, but in general they show that $D_{m_{O_2}}$ is larger in birds than in comparably sized terrestrial mammals (Maina, 1989). For example, $D_{m_{O_2}}$ in Canada geese is 1.7-times greater than a comparably sized mammal (Powell and Mazzone, 1983). Also, the thickness of the blood-gas barrier is 2.5 times thinner, and of much more uniform thickness, than in mammals (Maina, 1989; West, 2009). Interestingly, $D_{m_{O_2}}$ is similar in birds and bats of the same body size, indicating the importance of favorable diffusion for high O_2 consumption levels during flight (Maina, 1989).

20.6.3.3 O_2-hemoglobin reaction rates

Finite reaction rates between O_2 and hemoglobin behave as an additional resistance to O_2 uptake across the blood-gas barrier. Consequently, $D_{L_{O_2}}$ increases if there is more hemoglobin available with increased capillary volume. Pulmonary capillary blood volume is similar in birds and terrestrial mammals of similar body sizes, except for chickens, which have a relatively low capillary volume (Maina, 1989). Also, estimates of the reaction rates between O_2 and avian hemoglobin in birds and mammals are similar (Phu et al., 1986). Therefore, O_2-hemoglobin reaction rates probably contribute a similar amount to

diffusion resistances in avian and mammalian lungs. In mammals, this is estimated to comprise about half of the diffusive resistance to O_2 diffusion.

20.6.3.4 Physiological estimates of $D_{L_{O_2}}$

$D_{L_{O_2}}$ can be estimated from experimental measurements on birds if certain conditions are met to satisfy the assumptions necessary for an ideal cross-current analysis of the data. For example, measurements should be made in hypoxia, where the O_2-blood equilibrium curve is linear, to satisfy the assumption of constant $\beta_{b_{O_2}}$. Physiological measurements of $D_{L_{O_2}}$ that satisfy these assumptions have been made in ducks and chickens (Burger et al., 1979; Scheid and Piiper, 1970), and they generally agree with morphometric estimates (Maina and King, 1982). Physiological $D_{L_{O_2}}$ in ducks ranges from 38 to 68 μmol/(min Torr kg) (Hempleman and Powell, 1986). Other methods for estimating potential diffusion limitations indicate complete diffusion equilibrium for O_2 in resting birds (Powell and Scheid, 1989).

Exercise and pharmacological stimulation of metabolic rate increases $D_{L_{O_2}}$ in ducks (Geiser et al., 1984; Hempleman and Powell, 1986; Kiley et al., 1985), and the change is correlated closely with increased cardiac output (Hempleman and Powell, 1986). In alveolar lungs, $D_{L_{O_2}}$ increases with cardiac output by recruitment and distention of the pulmonary capillaries, which increases surface area and capillary volume. However, these enhancements can be offset by shorter transit times in the pulmonary capillaries allowing less time for diffusion equilibrium. Recruitment and distention do not occur in avian lungs (see above), so mechanisms of increasing $D_{L_{O_2}}$ in birds during exercise are not known.

20.6.4 Heterogeneity in the lung

The avian lung is a complex structure consisting of hundreds of parabronchi. Mismatching of ventilation, blood flow, or diffusing capacity between these functional units can reduce the efficacy of gas exchange. Temporal variations in flow rates and inspired gas composition can also impair gas exchange. Under normal resting conditions at sea level, such heterogeneity in lung function is the most important factor reducing gas exchange efficacy from ideal levels in birds and in mammals.

20.6.4.1 Physiological dead space

Physiological dead space is defined as the difference between total inspired or expired ventilation ($\dot{V}_E$ or $\dot{V}_I$) and effective parabronchial ventilation ($\dot{V}_P$):

$$\dot{V}_{D_{phys}} = \dot{V}_I - \dot{V}_P$$

$\dot{V}_{D_{phys}}$ includes anatomic dead space ventilation plus any heterogeneity such as inspiratory or expiratory mesobronchial shunts (see Section 20.3.3.4) or ventilation to regions of the lung with high $\dot{V}/\dot{Q}$ ratios (see below). Therefore, $\dot{V}_{D_{phys}}$ considers ventilation "as if" total ventilation was partitioned between a single ideal parabronchus with $\dot{V}_P$ and anatomic dead space (Scheid and Piiper, 1989).

Many of the techniques used to estimate $\dot{V}_{D_{phys}}$ in alveolar lungs are not applicable to birds (Powell, 1988). However, with a computer model of O_2 and CO_2 dissociation curves and cross-current gas exchange, $\dot{V}_P$ can be calculated from measured ventilation, mixed-venous blood, and mixed-expired gas (Hastings and Powell, 1986b). $\dot{V}_{D_{phys}}$ in artificially ventilated ducks was almost 10 mL greater than anatomic plus instrument dead space, and two-thirds of the 15 mL anatomic dead space (Hastings and Powell, 1986b). This large amount of physiological dead space is consistent with relatively large amounts of total ventilation going to regions of the lung with high ventilation/perfusion ratios ($\dot{V}/\dot{Q}$, see below) and indicates that ventilatory heterogeneity within the lung has a significant impact on $\dot{V}_P$ and gas exchange.

20.6.4.2 Shunt

Shunting of pulmonary blood flow past effective gas exchange areas is very small in birds. As described above, there are no arteriovenous anastomoses in the pulmonary circulation. Shunt ranges from less than 1 to 2.7% of cardiac output in anesthetized artificially ventilated geese and ducks, respectively, using inert gas methods to quantify true intrapulmonary shunt (Burger et al., 1979; Powell and Wagner, 1982). Oxygen can be used to quantify intrapulmonary plus extra-pulmonary shunts, such as drainage of systemic venous blood from bronchial or Thebesian veins into pulmonary venous blood. Oxygen shunts average 6.3 to 8% of cardiac output in ducks, which is much greater than would be predicted given the magnitude of Thebesian and bronchial circulations in mammals (Bickler et al., 1986). One possible explanation for this large shunt is the connection between the vertebral venous and pulmonary circulations described for chickens (Burger and Estavillo, 1977), which also occur in ducks (Bickler et al., 1986). The sensitivity of extra-pulmonary shunts to various physiological conditions has not been measured, but $P_{a_{O_2}}$ is greater than predicted in hypoxia if such shunts persisted (see below).

20.6.4.3 $\dot{V}/\dot{Q}$ mismatching

Differences in the ventilation/perfusion ratio ($\dot{V}/\dot{Q}$) between individual parabronchi is the main factor reducing arterial

P_{O_2} from ideal cross-current levels in birds under resting conditions at sea level (Powell and Scheid, 1989). Ventilation and blood flow can differ between parabronchi depending on small differences in resistance or pressure gradients that can occur along the multiple parallel pathways through the lung. Physiological mechanisms, such as smooth muscle tone in the bronchi and parabronchi or interparabronchial arteries may act to reduce such heterogeneity, but matching is never perfect.

It is important to point out that the effect of such spatial $\dot{V}/\dot{Q}$ heterogeneity on gas exchange is different than the effect of changes in the *overall* $\dot{V}/\dot{Q}$ ratio. The overall $\dot{V}/\dot{Q}$ ratio can affect $P_{a_{O_2}}$, so, for example, decreases in ventilation at constant cardiac output cause decreases in $P_{a_{O_2}}$. Also, the overall ($\dot{V}/\dot{Q}$) ratio affects the magnitude of the arterial-expired P_{O_2} difference in a perfectly homogeneous cross-current gas exchanger (Powell and Scheid, 1989). However, spatial mismatching of $\dot{V}/\dot{Q}$ ratios between parabronchi will decrease $P_{a_{O_2}}$ further and make the arterial-expired P_{O_2} difference more positive than predicted for a homogeneous cross-current exchanger with the same overall $\dot{V}/\dot{Q}$ ratio; this is analogous to increasing the ideal alveolar-arterial P_{O_2} difference in mammals.

Several techniques have been used to measure distributions of $\dot{V}/\dot{Q}$ ratios in the avian lung, but they are relatively complicated and have not been applied yet to awake birds under many physiological conditions lung (Burger et al., 1979; Hempleman and Powell, 1986; Powell, 1988; Powell and Wagner, 1982). Significant amounts of ventilation go to high $\dot{V}/\dot{Q}$ regions of the lung in some cases (Powell and Wagner, 1982), and this contributes to physiological dead space. Heterogeneity in $\dot{V}/\dot{Q}$ ratios near the overall parabronchial $\dot{V}/\dot{Q}$ ratio has a large impact on O_2 exchange in birds. Compared to mammals, $\dot{V}/\dot{Q}$ heterogeneity is slightly greater (Powell and Wagner, 1982), and cross-current gas exchange is more sensitive to $\dot{V}/\dot{Q}$ mismatching than alveolar gas exchange (Powell and Hempleman, 1988; Powell and Scheid, 1989). In normoxic artificially ventilated geese, $P_{a_{O_2}}$ is 25 Torr less than the ideal level predicted for homogeneous cross-current gas exchange, which is significantly greater than the ideal-measured (alveolar-arterial) P_{O_2} difference in typical mammals (Powell and Hempleman, 1988). Hence, most of this drop in $P_{a_{O_2}}$ from ideal levels (15 Torr) is explained by $\dot{V}/\dot{Q}$ heterogeneity (Powell, 1993). The remaining 10 Torr difference between measured and ideal $P_{a_{O_2}}$ can be explained by postpulmonary shunts, which are virtually nonexistent in mammals. Pulmonary shunt is small (Bickler et al., 1986; Powell and Wagner, 1982), and there is no evidence for a diffusion limitation in normoxia at rest (Powell and Scheid, 1989).

In addition to parallel $\dot{V}/\dot{Q}$ mismatching between parabronchi, serial $\dot{V}/\dot{Q}$ mismatch can occur along a single parabronchus if the longitudinal distribution of blood flow is not even. Several studies have shown that blood flow is greater at the inspiratory ends of the parabronchi (Holle et al., 1978; Jones, 1982; Parry and Yates, 1979). However, such serial heterogeneity does not affect gas exchange unless there is a diffusion limitation (Holle et al., 1978; Powell and Scheid, 1989), and this does not occur under most conditions.

20.6.4.4 *Temporal heterogeneity*

Changes in instantaneous ventilation of the parabronchi during normal breathing could in temporal variations in the $\dot{V}/\dot{Q}$ ratio. In theory, this could significantly decrease $P_{a_{O_2}}$ relative to the ideal level predicted for continuous ventilation (Powell, 1988; Powell and Scheid, 1989). For example, a ventilatory pause could act like a breath-hold, and rapidly decrease P_{O_2} in the small gas volume of the avian lung (Powell and Scheid, 1989). However, experiments indicate that this does not occur during normal breathing because the effective parabronchial gas volume is increased by mixing with larger bronchi (Scheid et al., 1977). Temporal changes in P_{O_2} entering the parabronchi during breathing could also impact $P_{a_{O_2}}$, but the effects are predicted to be relatively small (Powell, 1988). A time-averaged $P_{I_{O_2}}$ can be calculated for the parabronchi, and it is similar to caudal air sac P_{O_2} (Scheid et al., 1978).

20.6.5 *Frontiers*: pulmonary gas exchange during high altitude flight

How birds manage high levels of O_2 consumption for flight in extreme hypoxia at very high altitudes remains a fascinating and unanswered question. Birds are generally more tolerant of hypoxia than mammals (Tucker, 1972), and radio tracking was used to confirm bar-headed geese flying over the Himalayas at altitude of 7,920 m (Hawkes et al., 2011). The first experiments actually measuring oxygen exchange during hypoxic flight took advantage of hovering flight in hummingbirds using a hypobaric chamber (Berger, 1974). $\dot{M}_{O_2}$ during hovering at sea level was 32 mmol/(kg min), which is less than the maximal $\dot{M}_{O_2}$ for a hummingbird (Wells, 1993); however, this is greater than the maximal $\dot{M}_{O_2}$ for a comparably sized mammal. Furthermore, the hummingbird was able to maintain this high level of $\dot{M}_{O_2}$ at 6,000 m simulated altitude, while maximal $\dot{M}_{O_2}$ is reduced to half the sea level value in mammals that have been studied at this altitude. Other experiments have studied $\dot{M}_{O_2}$ in hummingbirds with graded levels of exercise at different levels

of O_2 (Chai and Dudley, 1996), but maximal $\dot{M}_{O_2}$ at different altitudes has not been determined in any bird to date.

Measuring the relevant physiological variables to understand how gas exchange changes in birds flying at high altitude is a huge experimental challenge. Consequently, most of the earlier studies exposed resting or anesthetized domestic birds to hypoxia. Experiments on resting ducks and bar-headed geese show extremely high levels of ventilation at very high altitudes (Black and Tenny, 1980b; Powell et al., 2004), which are largely predicted to eliminate the advantage of cross-current gas exchange, compared to alveolar exchange (Shams and Scheid, 1989). However, these predictions are extremely sensitive to cardiac output, which varies greatly in the same species studied during hypoxic rest in different laboratories (Black and Tenney, 1980b; Shams and Scheid, 1989). Depending on the cardiac output, the advantage of cross-current compared to alveolar gas exchange could increase $P_{a_{O_2}}$ by 2 Torr in birds at 11 km altitude. But such a small change is physiologically important when the entire P_{O_2} difference between inspired gas and mixed-venous blood is only 20 Torr (Powell, 1993). Hence, cross-current gas exchange may contribute to the increases in O_2 extraction reported for birds at high altitude (reviewed by Parr et al., 2019a).

Measurements of gas exchange limitations in anesthetized ducks during hypoxia show the difference in $P_{a_{O_2}}$ predicted for an ideal cross-current lung versus the measured value is only a few Torr (Powell, 1993), which contrasts with the relatively large difference in normoxia indicating gas exchange limitations (see above). This is because the effects of $\dot{V}/\dot{Q}$ mismatching on $P_{a_{O_2}}$ are decreased in hypoxia, when exchange operates on the steep portion of the O_2-hemoglobin equilibrium curve (Powell and Scheid, 1989). $\dot{V}/\dot{Q}$ distributions do not change with hypoxia versus normoxia in anesthetized ducks (Powell and Hastings, 1983), and the increased efficiency in hypoxia may be decreased postpulmonary shunting that has been measured in normoxia (Bickler et al., 1986). Diffusion limitations are expected to be extremely small or not present in the avian lung with its extremely high-surface area and thin blood-gas barrier (Maina et al., 2017; Parr et al., 2019b; Scott and Milsom, 2006). High altitude pulmonary edema, which could impair alveolar gas exchange even at subclinical levels, does not appear to be a problem in birds apparently because of factors strengthening the blood-gas barrier discussed earlier.

Other experiments measuring all of the variables necessary for a quantitative analysis of gas exchange during exercise in hypoxia have been done in running waterfowl (Kiley et al., 1985) and emus (Schmitt et al., 2002). Such studies revealed unique features of the avian respiratory system that could provide an advantage over alveolar gas exchange, but they are limited in only increasing $\dot{M}_{O_2}$ about threefold from resting levels. Studies on the emu showed no change in $\dot{V}/\dot{Q}$ mismatching in hypoxic versus normoxia, similar to results in anesthetized ducks (Powell and Hastings, 1983). However, $\dot{V}/\dot{Q}$ mismatching did not change with exercise in the emus either, in contrast with increased $\dot{V}/\dot{Q}$ mismatching in exercising mammals and may provide an avian advantage at altitude (Powell and Hopkins, 2010).

With advances in instrumentation, it is becoming possible to measure more of the relevant gas exchange variables in flying birds. For example, hypobaric wind tunnels can be used to study birds exhibiting natural flight behavior (Yap et al., 2018). Metabolic rate measured in bar-headed geese flying in a wind tunnel show decreases in $\dot{M}_{O_2}$ when inspired O_2 is decreased to simulate altitudes of 5,500 m and 8,500 m while flight speed is maintained (Meir et al., 2019). Important for gas exchange efficiency, arterial P_{O_2} was maintained also. This indicates flight becomes more efficient in hypoxia, which might be studied with experimental approaches similar to those used to demonstrate increases in locomotor efficiency during natural diving in penguins and marine mammals (Ponganis et al., 2011). Radio-tracking has already been used to start documenting energy budgets for bar-headed geese migrating over the Himalayas (Parr et al., 2019a), but much work remains to fully investigate potential advantages of the unique structure and function of the avian respiratory system at high altitude.

20.7 Tissue gas exchange

O_2 moves out of systemic capillaries to the mitochondria in cells by diffusion. Therefore, O_2 transport in tissues is described by Fick's first law of diffusion, similar to diffusion across the blood-gas barrier in the lung:

$$\dot{M}_{O_2} = \Delta P_{O_2} \cdot D_{t_{O_2}}$$

where ΔP_{O_2} is the *average* P_{O_2} gradient between capillary blood and the mitochondria, and $D_{t_{O_2}}$ is a tissue diffusing capacity for O_2, analogous to the lung diffusing capacity (see above). The main difference between O_2 diffusion in tissue and in the lung is that diffusion pathways are much greater in tissue. Tissue capillaries may be 50 μm apart, so the distance from a capillary surface to mitochondria can be 50 times longer than the thickness of the blood-gas barrier (<0.5 μm).

20.7.1 Microcirculation

20.7.1.1 Skeletal muscle

Long diffusion distances can lead to significant P_{O_2} gradients in muscle. Also, the P_{O_2} gradient varies along the

length of a capillary as O_2 leaves the blood, and capillary P_{O_2} decreases from arterial to venous levels. However, birds have some unique structural features in the skeletal muscle microcirculation to minimize diffusion distances and enhance tissue gas exchange. For example, the number of capillaries per cross-sectional area of flight muscle fiber in hummingbirds is six times greater than the value for rat soleus muscle, and the value in pigeon flight muscle is three times greater (Mathieu-Costello, 1993; Mathieu-Costello et al., 1992). This clearly decreases radial diffusion distances for O_2 leaving capillaries in birds. This advantage is increased further in high altitude adapted species, such as bar-headed geese that have significantly higher capillary densities and higher capillary to muscle fiber ratios at the surface of flight muscles, compared to low-altitude waterfowl species (Scott et al., 2009).

In addition, skeletal muscle capillaries in birds are very tortuous and have extensive manifolds connecting capillaries running along adjacent muscle fibers (Mathieu-Costello, 1991, 1993). This geometry increases the exchange surface area, so a muscle fiber is functionally surrounded by "sheet" of capillary blood. This provides better tissue oxygenation than the traditional mammalian model of straight capillaries running along a muscle fiber (i.e., the Krogh cylinder); Krogh's model predicts that P_{O_2} at the venous end of the capillary may be zero when O_2 supply decreases or demand increases (Mathieu-Costello, 1991).

20.7.1.2 Cerebral circulation

Most evidence indicates cerebral blood flow increases with hypoxia but does not change with CO_2 in birds (Faraci, 1991). This results in significant improvements in tissue O_2 delivery during hypoxia (Faraci et al., 1984; Grubb et al., 1977). In mammals, hypoxia also increases cerebral blood flow, but this is partially offset by a vasoconstrictor effect of the decrease in $P_{a_{CO_2}}$ that accompanies the reflex increase in ventilation during hypoxia (see below). This difference in cerebral vascular control may help explain how some birds are able to tolerate severe hypoxia better than some mammals (Faraci, 1986).

20.7.2 Myoglobin

Myoglobin is an O_2-binding protein, similar to a single polypeptide chain of the hemoglobin molecule, which has an extremely high affinity for O_2. For example, the P_{50} for hummingbird's myoglobin is 2.5 Torr (Johansen et al., 1987), so myoglobin can readily accept O_2 from capillary blood. Consequently, myoglobin is thought to be important for facilitating O_2 diffusion in muscle, by shuttling O_2 to sites far away from capillaries, or toward the venous end of capillaries. High levels of myoglobin are present in the heart and skeletal muscles of diving birds (Giardina et al., 1985; Weber et al., 1974), birds native to high altitudes (Fedde, 1990), and in hummingbirds with extremely high metabolism (Johansen et al., 1987). Increases in myoglobin with physical training in birds provides further evidence for the physiological significance of myoglobin in tissue gas exchange (Butler and Turner, 1988). Mb is also a significant O_2 store in diving birds, carrying about 1/3 of the total O_2 stores while the respiratory system and blood carry similar amounts (Ponganis et al., 2011).

20.7.3 Effects of hypoxia and exercise

Generally, decreases in O_2 supply (e.g., hypoxia) or increases in O_2 demand (e.g., exercise) are satisfied at the tissue level by increased O_2 extraction from blood or increasing blood flow. This is illustrated by the Fick equation applied to the cardiovascular O_2 delivery:

$$\dot{M}_{O_2} = \dot{Q}\left(C_{a_{O_2}} - C_{\bar{v}_{O_2}}\right)$$

Increased O_2 extraction from the blood decreases $C_{\bar{v}_{O_2}}$ but $P_{\bar{v}_{O_2}}$ does not decrease much because the slope of the blood-O_2 equilibrium curve is steep around the venous point (Figure 20.8). High $P_{\bar{v}_{O_2}}$ levels are advantageous by keeping average capillary P_{O_2} levels high to drive O_2 diffusion into tissue. O_2 consumption is maintained in duck skeletal muscle during hypoxia without any change in blood flow (Grubb, 1981). During severe hypoxia in resting ducks and bar-headed geese, $C_{\bar{v}_{O_2}}$ can be less than 0.5 mM (Black and Tenney, 1980b). This suggests nearly complete O_2 extraction, although such low venous O_2 values could also result from measurement error. O_2 extraction in the cerebral and coronary circulations is not known for birds.

In exercising birds, extraction and blood flow increase to satisfy metabolic demands (Faraci, 1986; Faraci et al., 1984; Fedde, 1990). Increasing blood flow helps maintain high average capillary P_{O_2} because it raises mixed-venous O_2 concentration for any given arterial concentration and O_2 consumption (see equation above). Increases in blood flow are also observed in the ventilatory muscles of resting birds during hypoxia, which presumably reflects increased work in these muscles during increased breathing (Faraci, 1986). Under some extreme conditions of hypoxic exercise, muscle blood flow or tissue O_2 diffusion may actually limit maximal $\dot{M}_{O_2}$ in birds (Fedde et al., 1989).

Capillaries in avian skeletal muscle also show physiological plasticity and apparent genetic adaptations to hypoxia. Chronic hypoxia increases the capillary-fiber surface area contact for aerobic flight muscles in pigeons (Mathieu-Costello and Agey, 1997), and bar-headed geese have more capillaries per muscle fiber than expected for their aerobic capacity, in comparison to other geese native to lower

altitudes (Scott et al., 2009). Capillaries are also denser and more evenly spaced, and mitochondria are located closer to the capillaries in the bar-headed goose compared to other geese, but the respiratory capacities, O_2 kinetics, and phosphorylation efficiencies of isolated mitochondria were not different between species (Scott et al., 2009). Hence, acclimatization and adaptation to limited O_2 appear to involve changes in O_2 delivery versus utilization (i.e., mitochondrial respiration).

20.8 Control of breathing

Breathing originates as rhythmic motor output from the central nervous system (CNS). This basic respiratory rhythm is modulated by several reflexes, in response to changes in activity and the environment. These reflexes are examples of negative feedback control and tend to maintain normal arterial blood gases and pH homeostasis (Table 20.6). For example, if dead space increases, then

TABLE 20.6 Arterial blood gases and pH in unanesthetized birds breathing air.

Bird	P_{O_2} (Torr)	P_{CO_2} (Torr)	pH

$P_{a_{CO_2}}$ will increase if ventilation is constant. However, increased $P_{a_{CO_2}}$ stimulates an increase in tidal volume, which compensates for the increased dead space and returns $P_{a_{CO_2}}$ toward the control value. Like all reflexes, the ventilatory reflexes include (i) a sensory or afferent component, (ii) an integrating component in the CNS, and (iii) a motor or efferent component.

This topic bridges respiratory physiology and neuroscience, but the emphasis here is on respiratory aspects and ventilatory reflex responses to changes in blood gases, often called the "chemical control of ventilation." Several excellent reviews cover more details about the neuroscience of ventilatory control and control of breathing under different physiologic conditions (Bouverot, 1978; Davey and Seller, 1987; Gleeson and Molony, 1989; Jones and Milsom, 1982; Powell, 1983; Scheid and Piiper, 1986; Taylor et al., 1999).

20.8.1 Respiratory rhythm generation

The basic respiratory rhythm is generated by a "central pattern generator," composed of networks of neurons in the brainstem of the (CNS). Respiratory rhythm can be measured in neural outputs from isolated hindbrain of chicks (Fortin et al., 1994), and transecting the brainstem between the XI and XII cranial nerve roots results in apnea and eventual death in pigeons (von Saalfeld, 1936). Reciprocal inhibition between medullary inspiratory and expiratory neurons are a common feature in birds (Peek et al., 1975), but experiments in mammals show that respiratory rhythm generation can occur without inhibitory synaptic interactions, implicating pacemaker processes (Smith et al., 1991). The equivalent of the Pre-Bötzinger Complex, which is the main respiratory pattern generator in mammals (Smith et al., 1991) has not bee identified in birds yet. Other CNS structures important for sending motor outputs to ventilatory muscles in birds (Table 20.2) have been identified with stimulation experiments to study vocalization (e.g., Peek et al., 1975) and panting (e.g., Richards, 1971) in chickens or pigeons (Davey and Seller, 1987). The development of central pattern generators for bird song, which requires respiratory muscles, requires auditory feedback (Konishi, 2010), but such interactions have not been investigated for breathing.

20.8.2 Sensory inputs

20.8.2.1 Central chemoreceptors

In mammals, relatively discrete regions on the ventrolateral surface of the medulla in mammals show chemosensitivity to changes in $P_{a_{CO_2}}$ and local pH. These so-called central chemoreceptors can explain most of the reflex increase in ventilation when $P_{a_{CO_2}}$ increases in mammals (Bouverot, 1978; Guyenet et al., 2010). Central chemoreceptors have not been identified by neurophysiological or anatomic methods in birds. However, conscious ducks increase ventilation when $P_{a_{CO_2}}$ is increased in blood perfusing only the head, indicating an important physiological role for central chemoreceptors in birds (Milsom et al., 1981; Sèbert, 1979).

20.8.2.2 Arterial chemoreceptors

Arterial chemoreceptors are sensitive to changes in $P_{a_{O_2}}$, $P_{a_{CO_2}}$, and pH, and they explain all of the ventilatory response to hypoxia in birds and mammals (Bouverot, 1978). They are also important for the ventilatory response to CO_2 and pH. The carotid bodies are very small (<1 mm diameter) organs located bilaterally in the thorax between the carotid artery and the nodose ganglion of the vagus nerve (Adamson, 1958; Hempleman and Wharburton, 2013; Kameda, 2002). These organs are richly perfused by a branch of the carotid artery, and they are innervated by a branch of the vagus. Carotid bodies are near the parathyroid and ultimobranchial glands in birds and are enveloped within the parathyroid gland in some species (Kobayashi, 1969; Yamatsu and Kameda, 1995); the physiological significance of this association is unknown. Arterial chemoreceptors have also been identified in other regions of the neck, along the carotid artery and aorta by anatomical and physiological methods (reviewed by Gleeson and Molony, 1989).

Figure 20.11 shows the response of carotid body arterial chemoreceptors to changes in $P_{a_{O_2}}$ and $P_{a_{CO_2}}$ in a duck. Afferent information about hypoxia or hypercapnia is transmitted to the CNS via the vagus nerve as increased frequency of action potentials from the carotid body. The pattern of action potential firing can differ in single chemoreceptors depending on the stimulus modality (O_2 vs. CO_2), but the physiological significance of this is not known (Nye and Powell, 1984; Powell and Hempleman, 1990). Avian arterial chemoreceptors can also respond to oscillations in $P_{a_{O_2}}$, $P_{a_{CO_2}}$, and pH that can occur during breathing (Hempleman et al., 1992). The cell types and ultrastructure of the avian and mammalian carotid bodies are similar (reviewed by Gleeson and Molony, 1989), and similar chemoreceptor mechanisms on glomus cells in the carotid body probably explain P_{O_2} and P_{CO_2}/H^+ sensitivity in both classes. However, cellular mechanisms of arterial chemosensitivity are not completely understood (Kumar and Prabhakar, 2012).

20.8.2.2.1 Intrapulmonary chemoreceptors

In contrast to mammals, the lungs of birds (and reptiles) contain IPCs which respond to physiological changes in P_{CO_2} (Burger et al., 1974; Fedde et al., 1974a;

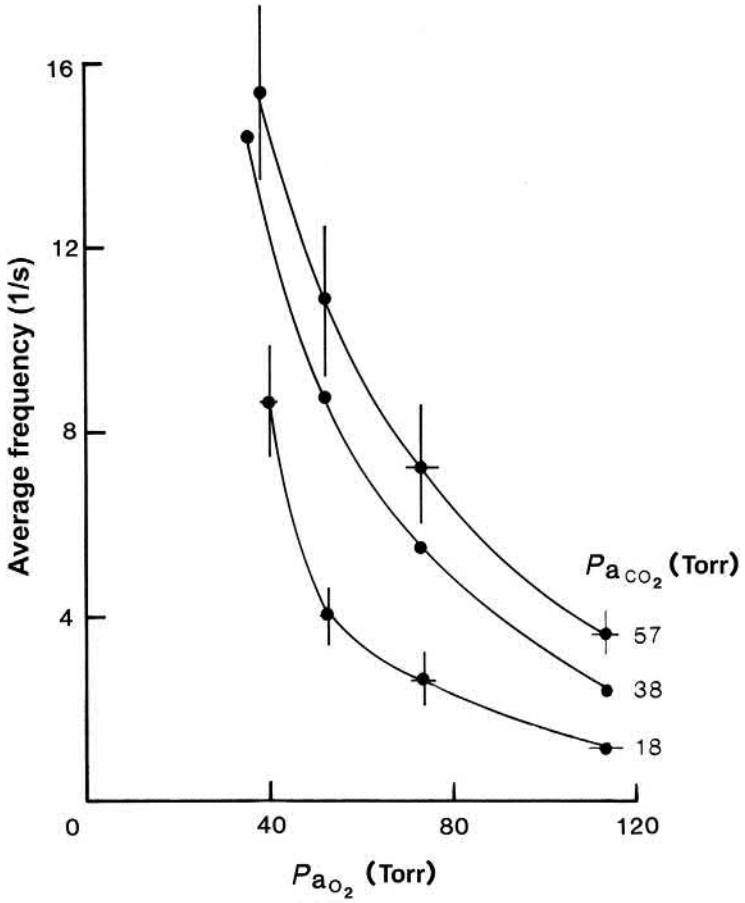

FIGURE 20.11 Average frequency of action potentials (+sem) for arterial chemoreceptors (n = 14) in domestic ducks exposed to different combinations of $P_{a_{O_2}}$ and $P_{a_{CO_2}}$. *From S.C. Hempelman and F.L. Powell, unpublished.*

Peterson and Fedde, 1968). The sensory endings of IPC have not been identified (reviewed by Gleeson and Molony, 1989), but physiological evidence indicates that these vagal afferents have multiple endings in the parabronchial mantle at several points along the length of one or more parabronchi (Hempleman and Burger, 1984). IPC can also respond to changes in CO_2 delivery to the lung by the pulmonary arteries (Banzett and Burger, 1977). Figure 20.12 shows how IPCs are stimulated by *decreases* in P_{CO_2}, in contrast to arterial chemoreceptors that are inhibited by hypocapnia. However, increases in IPC activity cause ventilation to decrease, so the reflex response to CO_2 is similar in direction for central, arterial, and IPC reflexes. The mechanism of chemoreception in IPC depends on intracellular pH (Hempleman and Posner, 2004; Scheid et al., 1978), which is regulated by Na^+/H^+ exchangers (Hempleman et al., 2003), HCO_3^-/Cl^- exchangers (Shoemaker and Hempleman, 2001), and carbonic anhydrase (Hempleman et al., 2000). Calcium and channels also modulate IPC sensitivity (Hempleman et al., 2006) and TREK potassium channels in IPC, which are inhibited by inhalation anesthetics, can explain the

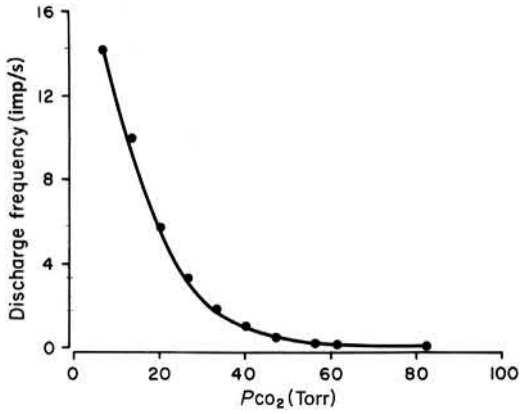

FIGURE 20.12 Average frequency of action potentials for IPC (n = 54) exposed to CO_2 levels ranging from 7 to 82 Torr. *Modified from Nye and Burger (1978).*

inhibitory effects of isoflurane and halothane on ventilation in birds (Bina and Hempleman, 2007).

IPCs are extremely sensitive to *changes* in P_{CO_2} and show large overshoots or undershoots in action potential frequency with the kinds of periodic changes in P_{CO_2} that occur in the lung during normal breathing

(Fedde and Scheid, 1976; Scheid et al., 1978). This makes IPC well suited for fine-tuning the pattern of ventilation, similar to the role of vagal pulmonary stretch receptors in mammals. However, in contrast to mammalian or reptilian pulmonary stretch receptors that are sensitive to mechanical stimuli and P_{CO_2}, avian IPCs are not sensitive to mechanical stretching of the lung (Bouverot, 1978; Fedde et al., 1974b). IPC may be important also in the respiratory transition that occurs during hatching, when gas exchange changes from the chorioallantoic membrane to the lungs (Pilarsky and Hempleman, 2007). IPC activity is not detectable prior to pipping presumably because CO_2 is relatively high. After pipping, IPC respond to CO_2 changes with breathing, but the response is more dynamic and has less sensitivity to static CO_2 levels compared to adult birds, which suggests the IPC show developmental changes similar to chemoreceptors in mammals to support the transition to air breathing.

20.8.2.3 Other receptors affecting breathing

Ventilation also responds to changes in activity from air sac mechanoreceptors, thermal receptors in the spinal cord, proprioceptors in the skin and maybe skeletal muscle, upper airway receptors sensitive to irritants, cold and water, and, perhaps, arterial baroreceptors (reviewed by Gleeson and Molony, 1989).

20.8.3 Ventilatory reflexes

20.8.3.1 CO_2 response

Most birds are not normally exposed to increases in ambient CO_2 levels, except perhaps in specialized nests or burrows. However, ventilatory responses to common stimuli, such as exercise, hot or cold temperatures, and altitude, are influenced by CO_2, so it is important to understand the response to CO_2. Figure 20.13 shows how ventilation increases with increasing inspired CO_2 in conscious ducks. Most species show increased tidal volume, but the frequency response can vary (Bouverot, 1978). At low levels of inspired CO_2, ventilation increases sufficiently to maintain $P_{a_{CO_2}}$ at normal levels (Osborne and Mitchell, 1978).

Decreases in $P_{a_{CO_2}}$ or intrapulmonary P_{CO_2} can decrease ventilation. Hence, when ventilation is increased by another stimulus, such as hypoxia or hyperthermia, the decrease in $P_{a_{CO_2}}$ will act to inhibit ventilatory drive, and ventilation will be the net result of stimulation and inhibition. The hypercapnic ventilatory response scales with size in birds, so smaller birds have reduced CO_2-sensitivity (Williams et al., 1995). It is hypothesized that this may minimize inhibition of a strong hypoxic ventilatory response in small birds, considering the inverse scaling of the hypoxic sensitivity and size in birds (Kilgore et al., 2008 and see below).

Central chemoreceptors contribute to the ventilatory response to $P_{a_{CO_2}}$ as described above. Arterial chemoreceptors play an important role in the response to dynamic changes in $P_{a_{CO_2}}$ (Fedde et al., 1982; Jones and Purves, 1970; Seifert, 1896), such as $P_{a_{CO_2}}$ oscillations which may occur during breathing, and perhaps in the response to static changes in $P_{a_{CO_2}}$ also (Gleeson and Molony, 1989). IPC may contribute to the ventilatory response to changes in $P_{a_{CO_2}}$ also, although their role in this response is controversial (Bouverot, 1978; Gleeson and Molony, 1989). Experimental

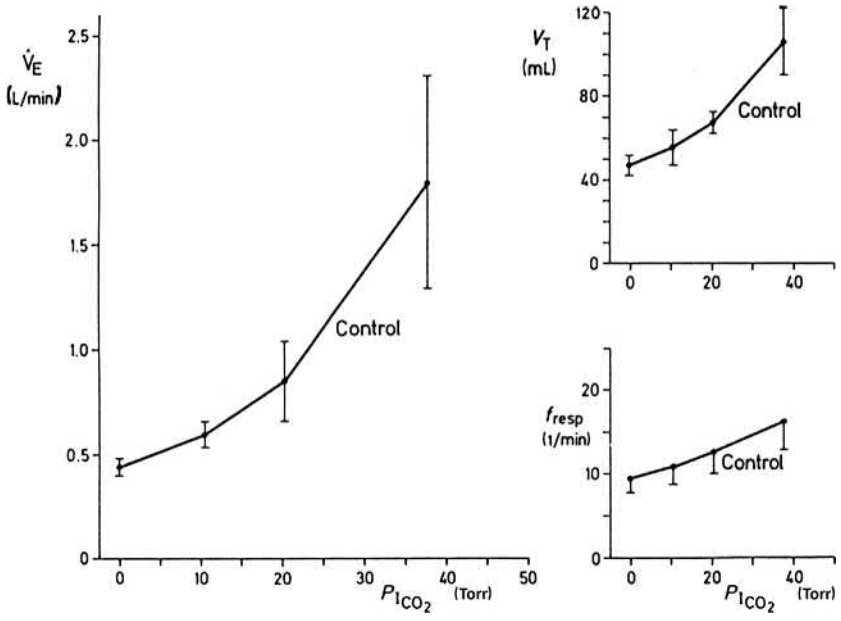

FIGURE 20.13 Ventilatory response to inhaled CO_2 in awake muscovy ducks (*Cairina moschata*), $\dot{V}_E$ = expired ventilation, V_T = tidal volume, f_{resp} = frequency. *Modified from Powell et al. (1978).*

evidence seems to favor a role for IPC in determining the pattern of breathing, but not the overall level of ventilation in conditions where $P_{a_{CO_2}}$ increases (reviewed by Gleeson and Molony, 1989). IPCs are well suited to sense breath-by-breath changes in ventilation as P_{CO_2} changes in the rigid avian lung. Therefore, IPC may play a similar role in the control of breathing to pulmonary stretch receptors in the alveolar lungs, which also sense instantaneous changes in ventilation as changes in lung volume.

20.8.3.2 Hypoxic ventilatory response

The hypoxic ventilatory response (Figure 20.14) is similar in birds and mammals (Black and Tenney, 1980b; Bouverot, 1978). Increasing $P_{a_{O_2}}$ above normal levels does not cause large decreases in ventilation, indicating that normoxic ventilatory drive from arterial chemoreceptors is relatively small (Gleeson and Molony, 1989). Also, ventilation does not change much until $P_{a_{O_2}}$ decreases below about 60 Torr in normal conditions because small increases in ventilation will decrease $P_{a_{CO_2}}$ and ventilatory drive. The hypoxic ventilatory response (Figure 20.14) has a similar shape to the arterial chemoreceptor response to $P_{a_{O_2}}$ (Figure 20.11), and arterial chemoreceptors are responsible for the hypoxic ventilatory response in birds (Jones and Purves, 1970; Seifert, 1896). However, the arterial chemoreceptor response in Figure 20.11 is measured under *isocapnic* conditions, in which $P_{a_{CO_2}}$ was held constant by manipulating CO_2 levels in gas unidirectionally ventilating the lung of anesthetized birds. The hypoxic ventilatory response can be measured under isocapnic conditions also, by manipulating inspired CO_2 in awake birds. However, in contrast to mammals, such an isocapnic hypoxic ventilatory response does not measure of the pure effects of hypoxia on ventilation (independent of CO_2 effects). Changing inspired CO_2 can affect ventilation in birds through effects on IPC independently of $P_{a_{CO_2}}$ (Powell et al., 2000; Scott and Milsom, 2007).

Plasticity is observed in the hypoxic ventilatory response of birds with chronic changes in oxygen level. Chronic sustained hypoxia, as would be experienced during residence at high altitude, causes a time-dependent increase in ventilation above the acute response level (Black and Tenney, 1980b; Bouverot, 1985; Bouverot et al, 1976, 1979; Powell et al., 2004). This is called "ventilatory acclimatization to hypoxia" in mammals and involves changes in both O_2-sensitivity of arterial chemoreceptors and plasticity in respiratory centers in the CNS, which increases respiratory motor output for a given chemoreceptor afferent input (Pamenter and Powell, 2016). In mammals, ventilatory acclimatization to hypoxia causes time-dependent increases in $P_{a_{O_2}}$, but this is not observed in all avian studies. Acclimatizing Pekin ducks to 3,800 m to 5,640 m altitude decreases $P_{a_{CO_2}} > 5$ Torr, indicating increased parabronchial ventilation, yet $P_{a_{O_2}}$ does not increase (Black and Tenny, 1980b; Powell et al., 2004). Apparently, other limitations to oxygen exchange increase during altitude acclimatization and offset the benefits of increased parabronchial ventilation for $P_{a_{O_2}}$.

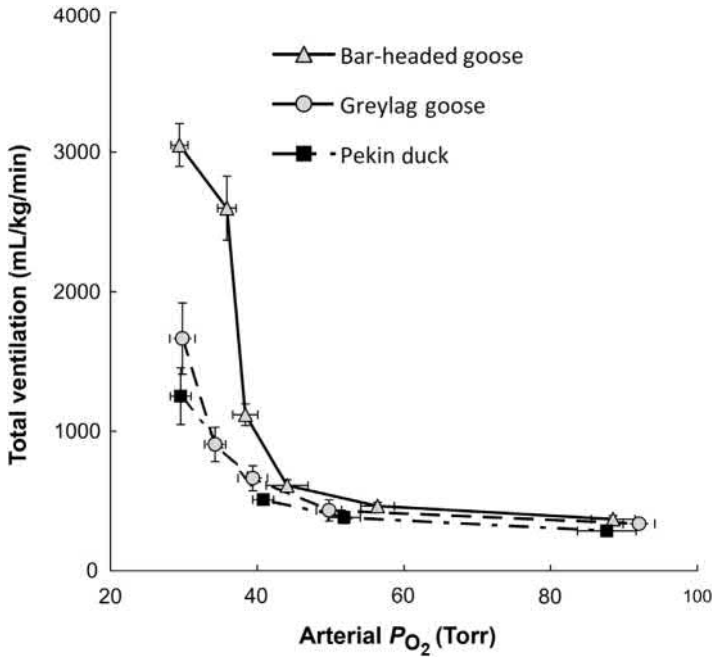

FIGURE 20.14 Hypoxic ventilatory response (isocapnic) for three species of waterfowl. *Modified from Scott and Milson (2007).*

Birds exhibit other forms of plasticity in the hypoxic ventilatory response too (Powell et al., 1998). Similar to mammals, ducks exhibit "long-term facilitation" of ventilation in which breathing remains elevated above control levels following 3−10 brief episodes of hypoxia separated by normoxia (Mitchell et al., 2001). However, inhibitory mechanisms, such as "Hypoxic Ventilatory Decline" or "roll off" are not observed in birds, in contrast to mammals and this bias toward excitatory versus inhibitory effects may provide an advantage at high altitude (Mitchell et al., 2001).

20.8.3.3 *Ventilatory response to exercise*

Exercise is the most common cause of increased ventilation, but the exact physiological mechanism for this is still unknown. The best evidence to date indicates that ventilation increases during exercise through a combination of "feed forward" mechanisms and feedback from chemoreceptors (Dempsey et al., 1995). Feed-forward mechanisms, also called central command, are neural signals from higher centers in the CNS that may stimulate respiratory centers directly. For example, neural signals to locomotor muscles may also stimulate ventilatory muscles and could contribute to some of the phase locking between wing beats and respiration (Funk et al., 1992a,b). Feedback from chemoreceptors prevents ventilation from increasing too much. $P_{a_{CO_2}}$ usually decreases in exercising birds (Kiley et al., 1979), and this hypocapnia would be even worse if ventilatory chemoreflexes did not inhibit ventilation. Other ventilatory stimuli such as body temperature and hypoxia at altitude can modify the response to exercise (reviewed by Gleeson and Molony, 1989).

20.8.3.4 Frontiers: *extreme hyperventilation at high altitude*

Birds hyperventilate more at high altitude than mammals (Powell et al., 2004). Similarly, birds adapted to high altitude, such as the bar-headed goose show a greater hypoxic ventilatory response compared to low-altitude species (Scott and Milsom, 2007). Hyperventilation in hypoxia decreases $P_{a_{CO_2}}$, which increases $P_{a_{O_2}}$ as well as exaggerating the Bohr effect to increase hemoglobin-O_2 affinity. Although $P_{a_{O_2}}$ does not increase further with ventilatory acclimatization to hypoxia in birds (see above), the time-dependent decrease in $P_{a_{CO_2}}$ will further increase arterial O_2 concentration by the Bohr effect. Hence, it appears that many of the advantages birds have at high altitude result from the extreme hyperventilation, hypocapnia, and alkalosis in response to a strong hypoxic ventilatory response. Supporting this are observations of pigeons exposed to 9,000 m simulated altitude showing only minimal stress while arterial pH is 7.85 (Lutz and Schmidt-Nielsen, 1977). Other studies show intracellular pH not changing while venous pH increases from 7.42 to 7.56 in pigeons exposed to 9,000 m (Weinstein et al., 1985). This suggests that tighter regulation of the intracellular milieu may provide an avian advantage at altitude, although the hypothesis remains to be experimentally tested. In any case, the control systems for ventilation and cerebral blood flow that permit such extreme hypocapnia and alkalosis at altitude must have evolved with, or followed from, cellular adaptations preserving function with large pH changes.

Interestingly, both humans and birds show differences in adaptations of the hypoxic ventilatory response between different high-altitude regions. The hypoxic ventilatory response is blunted in human populations in the Andes which who tend to suffer from chronic mountain sickness and other putative maladaptations to hypoxia (Simonson, 2015). In contrast, Tibetans in the Himalayan region include the Sherpa who are recognized as champions of high-altitude performance with a robust hypoxic ventilatory response and chronic mountain sickness is rare. Bird species exhibit similar differences in adaptation to high altitude with bar-headed geese from the Himalayas having a robust hypoxic ventilatory response versus Andean waterfowl having lower levels of ventilation and increased pulmonary O_2 extraction (Lague et al., 2017). Studies on several species of ducks from high altitude in the Andes and closely related species from low altitude found a greater hypoxic ventilatory response in some but not all of the high-altitude species (Ivy et al., 2019). However, increased ventilation did not translate into higher arterial O_2 saturation (as observed in Tibetan compared to Andean humans, Beall et al., 1994), except in yellow-billed pintales that also had a high O_2-hemoglobin affinity (Ivy et al., 2019). The genetic basis for these differences in humans is an intense area of research and may involve relic genes from an extinct species of Hominid (Huerta-Sánchez et al., 2014). Birds may provide an additional animal model to study such genetic adaptations to hypoxia at high altitude, which is one of the most powerful forces of natural selection described to date, at a higher phylogenetic level.

20.9 Defense systems in avian lungs

Infection and disease introduced via the respiratory system is an important problem in poultry husbandry (Maina, 2017). The unique anatomy with relatively few bronchial branches and the large air sacs means that gas exchanging regions of the system may be exposed to microbes, viruses, particulates, and other pathogens with less filtering than occurs in the mammalian respiratory system distal to the blood-gas barrier in the alveoli. Indeed, early research on the pattern of airflow in the avian respiratory system utilized deposition of coal soot in the lungs of pigeons

living in train stations (Dotterweich, 1930). Also, air sac diverticulae have been proposed as a route for infections starting under the skin to enter the respiratory system.

The effectiveness of cellular defense systems by pulmonary macrophages in birds has been questioned also. Pulmonary lavage and histological studies generally find about half the number of free surface macrophages in birds than in mammals with lungs of similar size (reviewed by Maina, 2017). However, the effectiveness of cellular defense appears just as strong in birds because the number of macrophages in pulmonary lavage increases with a challenge; additional cells may include subepithelial and intravascular macrophages, vascular polymorphonuclear neutrophils, and monocyte cells from blood and are found in air sacs as well as parabronchi (reviewed by Maina, 2017). Surfactant proteins A and D, which are important for particle opsonization in alveolar lungs, are absent in birds, which is consistent with sedimentation occurring in extrapulmonary air sacs where flow velocity is low instead of in the air capillaries (Bernhard, 2016). Hence, the most likely causes for susceptibility of poultry to aerosol borne diseases may result from husbandry practices, including overcrowding, force-feeding, and breeding for rapid weight gain and egg production.

T50 50% marker concentration in excreta;
TK thick muscle pair
TK thick muscle pair (dorsal and ventral) of muscular stomach
TJP tight junction protein,
TN thin muscle pair
TRPC transient receptor potential cation channel subfamily C;
TRPM transient receptor potential cation channel subfamily M;
TRPV transient receptor potential cation channel;
U uniport
Ub ubiquitous.
VDR vitamin D receptor;
VFA volatile fatty acid;
Vit vitamin
VIP vasoactive intestinal peptide
WT weightα
βC β-carotene
βC β-cryptoxanthine

21.1 Anatomy of the digestive tract

The gastrointestinal tract (GIT) is not only important for nutrient digestion and absorption, but it is the largest immunological organ in the body protecting against exogenous pathogens. The digestive system (Figure 21.1) has adaptations designed to facilitate flight. The length of the intestinal tract is shorter in most birds relative to mammals (Table 21.1, McWhorter et al., 2009). To compensate for shorter digestive tract, birds generally have higher feed intakes and/or increased intestinal nutrient absorption (McWhorter et al., 2009). In contrast, nonflying birds such as ostrich have heavier organ masses including larger digestive tract (Fritz et al., 2012; Laverty and Skadhauge, 1999). Also, birds lack teeth and heavy jaw muscles, which have been replaced with a lightweight bill or beak. Food particles are swallowed whole and then reduced in size by the *ventriculus* or *gizzard* located within the body cavity.

21.1.1 Beak, mouth, and pharynx

Birds have a bill or beak. This structure shows extensive anatomical variations among species, thus allowing for adaptations for different feeding styles. The upper bill is usually covered with hard keratin. However, in some types

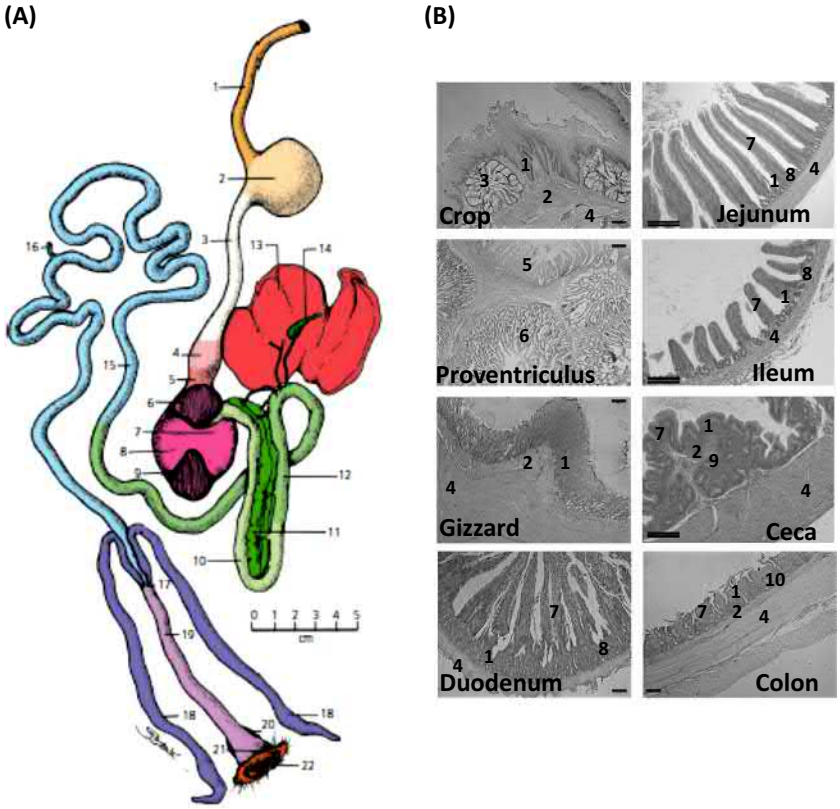

FIGURE 21.1 **Anatomical and histological structure of avian digestive tract.** (A) Digestive tract of a turkey. 1, precrop esophagus; 2, crop; 3, postcrop esophagus; 4, glandular stomach (proventriculus); 5, isthmus; 6–9, muscular stomach (gizzard); 10, proximal duodenum; 11, pancreas; 12, distal duodenum; 13, liver; 14, gallbladder; 15, jejunum; 16, Meckel's diverticulum (remnant of yolk sac); 17, ileocecocolic junction; 18, ceca; 19, colon; 20, bursa of Fabricius; 21, cloaca; 22, vent. Scale is in centimeters. [a]*The length (L), body weight (BW), and weight (WT) of the gastrointestinal tract can change depending on the environment in which the birds are raised.*
Reproduced from Denbow (2015).

of birds, the whole bill is relatively soft (i.e., Charadrii or shorebirds), whereas in others, only the tip is hard (i.e., Anatidae or waterfowl). The culmen, the medial dorsal area of the upper beak, has a pointed protuberance in the embryo, the egg tooth, which drops off after hatching in most birds.

Birds, unlike mammals, do not have a sharp distinction between the pharynx and mouth. Birds lack a soft palate and a pharyngeal isthmus; the combined oral and pharyngeal cavities are referred to as the *oropharynx.* The palate contains a longitudinal fissure, the *choana,* which connects the oral and nasal cavities. Caudal to the choana is the *infundibular cleft,* which is medially located and is the common opening to the auditory tubes (Figure 21.2). The palate generally also has ridges that aid in opening the shell of seeds.

All vertebrates have a hyoid bone, which serves as an attachment site for muscles of the tongue and throat. Birds have a Y-shaped hyoid apparatus that extends to the tip of their tongue. Two long structures, the "horns" of the hyoid, protrude backwards from the fork in the Y and provide insertion sites for protractor muscles originating on the lower jaw. The hyoid horns are modified in different species and can extend to the top of the head, around the eye socket and into the nasal cavity (Short and Sandström, 1982; Wang et al., 2011). Contraction of the muscles attached to the hyoid apparatus pulls the apparatus forward and against the skull, thus thrusting the tongue outward. Lengthening of the hyoid horns and the attached muscles effectively gives the bird a tongue that is able to protrude further out the mouth.

The tongue shows adaptations for collecting, manipulating, and swallowing food (Harrison, 1964). In birds where the tongue is used for collecting food, it can be extended from the mouth during the collection process. Such tongues typically have lateral barbs and may be coated with mucous secreted by the mandibular salivary gland. The tongue may act as either a brush, a spear, or a dynamic tube (Rico-Guevara and Rubega, 2011), sometimes extending four times the length of the beak.

Tongues used to manipulate food, such as in piscivorous species, are nonprotruding and covered with stiff, sharp, caudally directed papillae. In birds of prey, the tongue is a rasp-like structure, with the rostral portion frequently being very hard and rough (McLelland, 1979). On tongues of birds that typically strain food particles (e.g., ducks), the rostral portion forms a scoop-like structure, with the lateral borders having a double row of overlapping bristles. The bristles work in conjunction with the lamellae of the bill to filter particles.

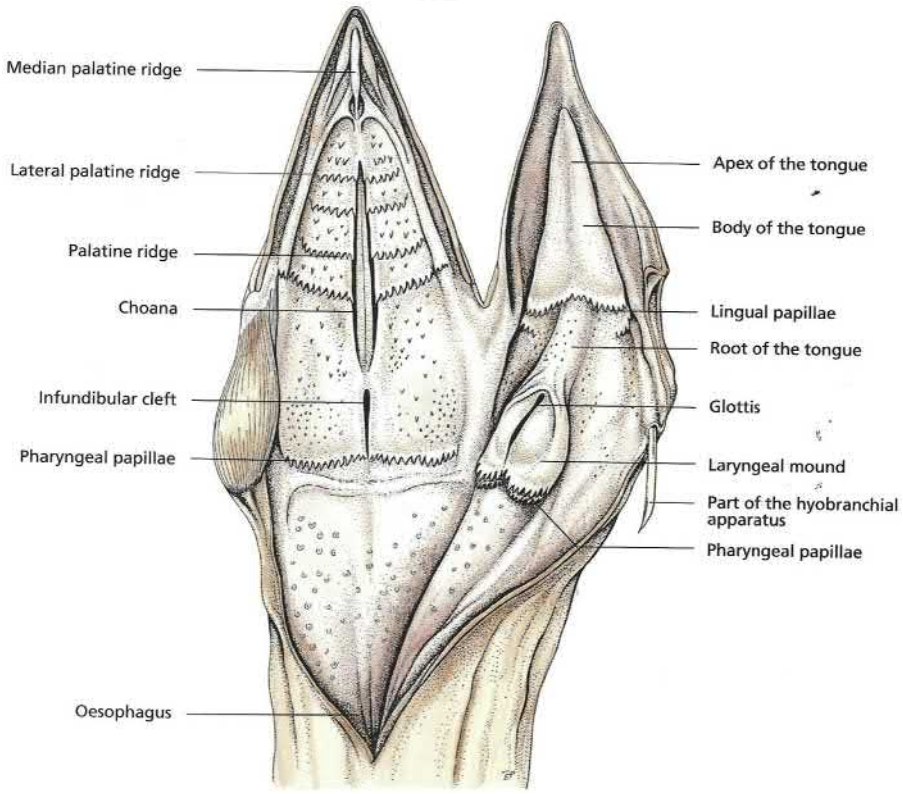

FIGURE 21.2 Oral cavity and pharynx of the chicken (opened and reflected; schematic). *Reprinted from Koenig, Liebich, Korbel and Klupiec (Koenig et al., 2016). Avian Anatomy. Copyright 2016 by HE. Koenig, R. Korbel, H-G. Liebich, p. 95. Used by permission of the copyright holders.*

In birds where the tongue is utilized to aid in swallowing food, caudally directed papillae tend to be located near the root of the tongue. These papillae function to propel food caudally. Tongues specialized for swallowing are nonprotruding.

Avian salivary glands also show considerable species variation. Although salivary glands are generally well developed in granivorous species; they are less developed in birds of prey, poorly developed in piscivores, and absent in the Anhinga and Great Cormorant (Antony, 1920). As a generalization, the *maxillary, palatine*, and *sphenopterygoid* glands are located in the roof of the mouth. The buccal gland is located in the cheeks whereas the *mandibular, lingual,* and *cricoarytenoid* glands are in the floor of the mouth. Although the salivary glands of *Gallus* and *Meleagris* are reported to secrete little amylase, the house sparrow secretes considerable amounts of amylase (Jerrett and Goodge, 1973).

Location of taste buds are variable, on the upper beak epithelium, in the anterior mandible, and the mandibular epithelium posterior to the tongue. There are also small number of taste buds located ventrolaterally on the anterior tongue. In contrast to mammals, chickens have relatively low number of taste buds (Liu et al., 2018). It is believed that chickens can have as many as 240−360 taste buds on average, with the number in broiler being higher than in layer-type chickens (Ganchrow and Ganchrow, 1985; Kudo et al., 2008). Additionally, the number of taste buds can vary among lines in the same type of chicken (Rajapaksha et al., 2016). Molecular staining of the buds showed that the number of taste buds differs between females and males and changes with age (Rajapaksha et al., 2016). In comparison to rodents, chicken taste buds develop and mature before hatch (Ganchrow et al., 1990), and the total number of taste buds is positively correlated with the sensitivity of the taste in chickens (Kudo et al., 2010). In comparison to mammals, chicken have fewer genes coding for taste receptors and are able to detect only taste of sour, umami, salt, and bitter, but not taste of sweet (Cheled-Shoval et al., 2015; Lagerstrom et al., 2006; Liu et al., 2018).

In some species of birds, the floor of the mouth contains sac-like diverticuli called *oral sacs.* These can function in carrying food or as a display apparatus during the breeding season.

Immediately behind the tongue is the *laryngeal mound.* It contains a narrow slit-like opening into the *glottis* of the larynx. The laryngeal mound generally contains rows of caudally directed cornified papillae, which aid in moving food toward the esophagus during swallowing.

21.1.2 Esophagus and crop

The esophagus is a thin-walled, distendable tube that transports food from the pharynx to the stomach, allowing birds to swallow their food whole. Thus, it contains a number of longitudinal folds that provide distensibility. The avian esophageal wall consists of four layers: mucosal, submucosal, muscle tunic, and the serosal layer; it generally contains only smooth muscle cells, with a circular muscle layer predominating (McLelland, 1979).

Unlike mammals, the avian esophagus is divided into a cervical and a thoracic region. In addition, the esophagus of birds lacks both upper and lower esophageal sphincters, which are present in mammals (Mulé, 1991).

In many, but not all (e.g., gulls, penguins, and ostriches) species of birds, the cervical esophagus is expanded to form a *crop.* The crop functions to store food and may be spindle-shaped, bilobed, or unilobed. In the chicken, the crop is a ventral diverticulum of the esophagus and contains longitudinal folds on the inner surface, thus making it distensible (Figure 21.1B). Beyond the crop, the esophagus continues as the thoracic esophagus to connect with the proventriculus.

A small number of species have a diverticulum or a bilaterally symmetrical expansion of the cervical esophagus, the *esophageal sac.* In most species that have this structure, it is present only in males and functions as a sexual display used during the breeding season, and for producing mating calls.

The esophagus and crop are lined with incompletely keratinized stratified squamous epithelia which open into numerous mucous glands. These glands are generally more numerous in the thoracic esophagus and may even be absent in the cervical region. Mucous glands are located in the crop only near its junction with the esophagus.

The cervical esophagus is innervated by parasympathetic nerves while the thoracic esophagus is innervated by the vagus and the celiac plexus. The esophagus is innervated by a few adrenergic fibers, which synapse with the myenteric plexus rather than the muscles (McLelland, 1975; Mulé, 1991).

21.1.3 Stomach

In most mammals, the stomach consists of a single chamber. However, in birds, the stomach consists of two chambers, the proventriculus and the gizzard, with the former being analogous to the mammalian stomach. The proventriculus or glandular stomach is located orad to the gizzard or muscular stomach. The proventriculus is a fusiform organ varying in size and shape among species, being relatively large and distensible in aquatic carnivores while being relatively small in granivorous species. In ostriches, which lack a crop, the proventriculus is especially large. The proventriculus secretes mucus, hydrochloric acid, and pepsinogen, whereas the gizzard functions in mechanical digestion and is the site of gastric proteolysis. The pyloric region connects the gizzard to the duodenum.

Two extremes of gastric anatomy exists in birds (McLelland, 1979). The first type, characteristic of carnivorous and piscivorous species, is adapted for storage and the digestion of a relatively soft diet. The two stomach chambers contain little separation, although one chamber may be more developed than the other, depending on the species. The second stomach type, characteristic of omnivores, insectivores, herbivores, and granivores, is adapted for very hard diets. The proventriculus and gizzard are separated by an isthmus termed the *zona intermedia gastric*. The proventriculus is relatively small, while the gizzard is large and powerful. The gizzard consists of two pairs of opposing muscles, termed thick and thin pairs (Figure 21.3), which are composed of circular muscle. These pairs of muscles are lacking in some species (e.g., herons, hawks, and owls).

The proventriculus, which generally lacks ridges except in fish- and meat-eating species, is lined with a mucous membrane. Projecting into the lumen are papillae located on the surface, from which the openings of the compound glands that secrete gastric juices can be seen. These glands generally contain only oxynticopeptic cells and secrete hydrochloric acid, pepsin, and mucous. The proventriculus contains both a myenteric and a submucosal plexus (Martínez et al., 2000).

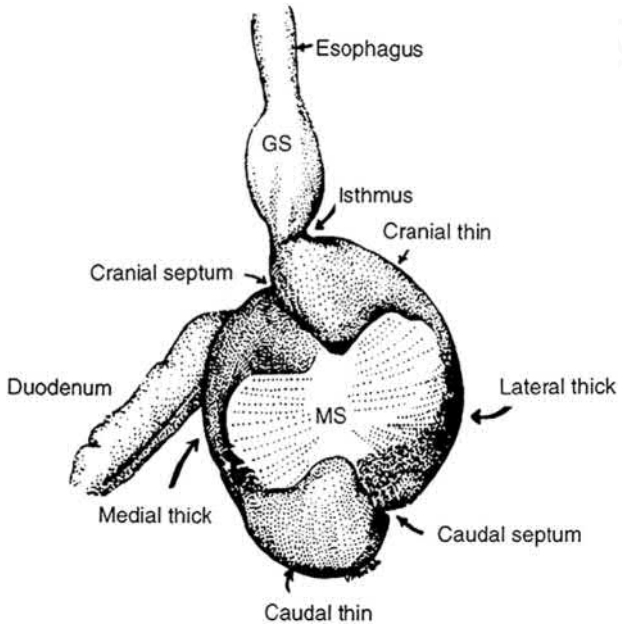

FIGURE 21.3 Anatomical features of muscular stomach of domestic turkeys. *GS*, glandular stomach; *MS*, muscular stomach. Note that cranial thin muscle of MS is continuous with lateral thick muscle and separated from caudal thin muscle at caudal septum. Similarly, the caudal thin muscle in continuous with the medial thick muscle and separated from cranial thin muscle by cranial septum. *Reprinted from Chaplin and Duke. Copyrights 1990 by American Physiological Society. Used by permission of the publisher.*

The interior surface of the gizzard is lined with a cuticle, sometimes called *koilin,* which is produced by the mucosal glands. The cuticle protects the gizzard from acid and proteolytic enzymes secreted by the proventriculus and from injury during grinding of hard food items. The greenish or brownish color of the cuticle is due to the reflux of bile pigments from the duodenum. Although in most birds the cuticle is continuously worn away and replaced, in some species, it is shed.

The pyloric portion of the stomach shows a considerable range in development. In *Gallus,* it is only 0.5 cm long. Its mucosal glands secrete mucous instead of a cuticle. In other species, the pyloric portion is enlarged and contains a cuticle. Although the function of this region is unknown, it is believed that it may slow the movement of large particles into the duodenum (Vergara et al., 1989).

The stomach is innervated by the vagus and perivascular nerve fibers from the celiac and mesenteric plexii. The muscle cells are innervated by cholinergic fibers, while noradrenergic fibers primarily innervate blood vessels. The myenteric nerve plexus lies just under the serosa, while the submucosal plexus is lacking. Because the longitudinal muscle layer is absent, the myenteric nerve plexus is normally visible through the transparent serosa.

21.1.4 Small intestine

The small intestine is divided into the duodenum, jejunum, and ileum. Although there is a distinct duodenal loop, the yolk stalk (i.e., Meckel's diverticulum) is often used as a landmark to separate the jejunum and ileum. Intestinal length varies considerably between species, being relatively shorter in frugivores, carnivores, and insectivores and long in granivores, herbivores, and piscivores. However, the length of the small intestine is relatively shorter than that of mammals in most birds.

Depending on the species, the intestinal wall can contain either folds or villi. The type of mucosal projections is not necessarily consistent between the small and large intestine. *Gallus* species have villi, which decrease in length from 1.5 mm in the duodenum to 0.4−0.6 mm in the ileum and rectum. The number of villi decreases from 1-10 days of age, but thereafter remains constant. Genetic selection for growth has altered villi morphology (Yamauchi and Isshiki, 1991). Compared to white leghorns, the villi of broilers are larger and have more epithelial cell protrusions located between the apical surface of the duodenal villi. Nevertheless, the villi of both types of chickens form a zigzag arrangement, which is thought to slow ingesta flow. Detailed description of intestinal villi and crypt organization, and function is presented in Chapter 21A.

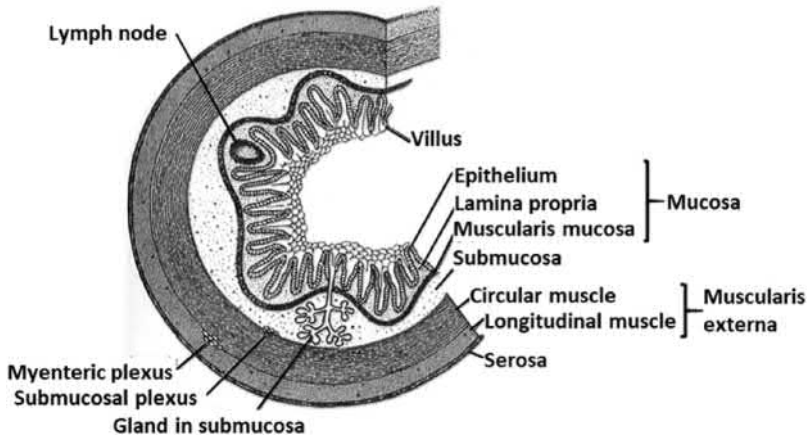

FIGURE 21.4 The general organization of layers of the gastrointestinal tract. *Reprinted from Argenzio. General function of the gastrointestinal tract and their control. In: Reece, W.O. (Ed.), Duke's Physiology of Domestic Animals, 12th ed. Copyright 2004 by Cornell University Press, Ithaca and London p. 383. Used by permission of the publisher.*

The intestinal wall contains the mucosa, submucosa, muscularis externa, and serosa layers. The mucosal layer consists of the muscularis mucosa, lamina propria, and epithelium (Figure 21.4). However, the muscularis mucosa and lamina propria are poorly developed in birds, possibly because the villi lack a central lacteal (blindly ending lymphatic capillary in the center of an intestinal villi). Although Brunner's glands, common to mammals, are absent (Calhoun, 1954), *tubular* glands (possibly homologous to Brunner's glands) are present in some species (Ziswiler and Farner, 1972). The epithelium contains chief cells, goblet cells (GCs), and endocrine cells. The crypts of Lieberkuhn are the source of epithelial cells that line the villi. The crypts contain undifferentiated cells, GCs, endocrine cells, and lymphocytes. Globular leukocytes and Paneth cells appear near the base of the crypts. The submucosa located beneath the lamina propria and muscularis mucosa, contains nerve cell bodies and blood vessels. The innercircular and longitudinal muscle layers are located underneath the submucosa. The serosa makes up the outermost layer of the intestinal wall (Argenzio, 2004).

The intestines contain extensive innervation from both the sympathetic and the parasympathetic nervous systems. As described by Bennett (1974), innervation is both cholinergic and adrenergic. The enteric nerve plexuses were described by Ali and McLelland (1978). Except in the rectum, the longitudinal muscle is sparsely innervated.

The *intestinal nerve* (nerve of Remak), which runs the length of the small and large intestine, is unique to birds. Although it has no mammalian homolog, it may be analogous to the prevertebral ganglion (Hodgkiss, 1984a). This nerve is thought to be a mixed nerve containing both sympathetic and parasympathetic autonomic fibers (Hodgkiss, 1986).

21.1.5 Ceca

Arising at the junction of the ileum and rectum are the ceca. In some species, the ceca may be absent (e.g., Psittaciformes, Apodiformes, and Piciformes) or rudimentary (e.g., Columbiformes and Piciformes). In other species, they are either paired (e.g., herbivores, most granivores, and owls), singular (Ardeidae), or consist of a double pair (secretary bird). McLelland (1979) has grouped ceca into four types based on morphology: (1) intestinal, which resemble the remainder of the intestine; (2) glandular, which are long and contain many actively secreting crypts; (3) lymphoid, which are reduced in size, containing many lymphocytes and occasional nonsecreting crypts; and (4) vestigial, which are small with a reduced lumen (Figure 21.5). A correlation between diet and cecal development, or the size of the ceca and the length and width of the rectum have not been discovered (McLelland, 1989).

In chickens, a cecum can be morphologically divided into three regions (Ferrer et al., 1991). Near the ileocecal junction is the *basis ceci,* where the villi are well developed. The medial region (*corpus ceci*) has longitudinal folds with small villi, while the distal region (*apex ceci*), similarly to *corpus ceci*, has small villi and contains both longitudinal and transverse folds. The combination of villi and musculature near the ileocecal junction effectively prevents even very small particles from entering the ceca (Ferrando et al., 1987), although fluid contents are able to enter.

The ceca are the primary fermentation site of undigested carbohydrates into short chain fatty acids (SCFAs) that serve as energy source for gut cells (Goldstein, 1989; Jamroz et al., 2002; Svihus et al., 2013). Beside its role as a fermentation chamber, the ceca is also responsible for

partial digestion of crude fiber and proteins, microbial synthesis of vitamins, and absorption of electrolytes, sodium, and water (Jozefiak et al., 2004), monosaccharide absorption against a concentration gradient (Planas et al., 1987), cholesterol digestion and absorption (Tortuero et al., 1975), and degradation of nitrogen compounds (Goldstein, 1989).

There is growing understanding of the importance of the ceca. Cecectomy results in decrease in metabolism of food, greater loss of amino acids, and lower digestibility of crude fiber (Chaplin, 1989). The role of the ceca in absorption is discussed later in this chapter.

21.1.6 Colon (rectum) and cloaca

The colon, sometimes called the rectum, is relatively short in most birds, linking the ileum with the *coprodeal* compartment of the cloaca. In contrast, the ostrich is characterized by very long and partly sacculated colon (Skadhauge et al., 1984). Although the colon of mammals has no villi and many GCs, the colon of birds has numerous flat villi and relatively few GCs (Clauss et al., 1991). In addition, the avian rectum has relatively few crypts, which are shorter than those of mammalian species. The simple columnar epithelium lining the colon and the ceca has a well-developed brush border. As discussed in Section 21.6, the cloaca and colon have an important role in water reabsorption.

The cloaca serves as a common pathway for excretory, reproductive, and digestive wastes. It contains three chambers: *coprodeum, urodeum,* and *proctodeum.* The colon empties into coprodeum, which is the most cranial portion of the cloaca. The coprodeum lacks villi, but has mucosal folds or rugae. The urodeum is the middle and smallest compartment of the cloaca, separated from the coprodeum and proctodeum by the coprourodeal fold and the uroproctodeal fold, respectively. The urinary and reproductive tracts empty into the urodeum. The final chamber, the proctodeum, opens externally through the anus. The bursa of Fabricius, involved in immune function, projects dorsally into the proctodeum. Also, projecting into the dorsal portion of the proctodeum is the dorsal proctodeal gland, sometimes called the foam gland, which secretes a white, frothy fluid. Birds lack a urinary bladder, and it has been shown that urine enters the distal lower intestine and is forced back into the colon, ceca, and possibly the small intestine (Goldstein and Braun, 1986).

21.2 Anatomy of the accessory organs

21.2.1 Pancreas

The pancreas is a pale yellow or red organ located within the duodenal loop, although in some species, such as the budgerigar, part of it may be found outside the loop. The gland has both an endocrine function, which will be discussed later, and an exocrine function. It is relatively small in carnivores and granivores but large in piscivores and insectivores. The pancreas is generally divided into three lobes: dorsal, ventral, and splenic, but their function in unknown (Paik et al., 1974).

The exocrine pancreas consists of compound tubuloacinar glands, which are divided into lobules. The number of pancreatic ducts varies from one to three (three in the domestic fowl). The pancreatic ducts generally drain into the distal part of the ascending duodenum and rarely drain into the descending loop of the duodenum. In domestic birds, the pancreatic and bile ducts drain into the ascending loop of the duodenum by a common papilla (Figure 21.1). The pancreas secretes amylase, lipase, proteolytic enzymes, and sodium bicarbonate.

21.2.2 Liver

The liver also functions as both an endocrine and an exocrine gland. It is divided into right and left lobes, which are joined cranially at the midline. The right lobe is larger, and, in the domestic fowl and turkey, the left lobe is subdivided into the dorsal and ventral parts. The bile canaliculi drain into the interlobular ducts. The lobular ducts then combine to form the right and left hepatic ducts. In birds, unlike in mammals, bile is transported to the duodenum via two ducts. The right and left hepatic duct combine to form the common hepatoenteric duct, which then proceeds to the duodenum. However, a hepatocystic duct branches from the right hepatic duct and connects to the gallbladder which, in turn, is drained by the cysticoenteric duct into the duodenum. In species without a gallbladder (e.g., pigeons, some parrots, and ostrich), the branch of the right hepatic duct, called the right hepatoenteric duct, drains directly into the duodenum. The bile ducts generally drain into the duodenum at a site very near the pancreatic ducts. This generally occurs on the ascending loop of the duodenum. However, in some species, including the ostrich and *Columba,* the ducts empty into the descending loop of the duodenum.

21.3 Motility

As food is broken down, it not only needs to be transported along the length of the GIT (i.e., peristalsis), but there is also local, nonpropagating motility that mixes food with gastric juices and brings particles in closer proximity to the enterocytes. Motility not only occurs while an animal is eating but also while the animal is fasting (migrating motor complexes, MMCs). The latter type of motility probably helps keep the digestive tract free from indigestible particles and dead enterocytes, among others. The enteric nervous system, part of the autonomic nervous system, controls GIT function, including motility.

21.3.1 Esophagus

Deglutition (swallowing) has been studied in *Gallus* by White (1969, 1970) and Suzuki and Nomura (1975). For prehension, the head is first lowered, after which food is grasped with the beak and then moved toward the oropharynx with the tongue. The choana reflexively closes. The oral phase of swallowing involves the rapid rostrocaudal movements of the tongue for 1−3 s, which moves the food particles caudally (Suzuki and Nomura, 1975). This movement is assisted by the caudally directed papillae.

During the next phase, the pharyngeal phase, the infundibular mound and glottis close, the hyoid apparatus becomes concave, the tongue is moved backward, and the esophagus is moved forward, thus decreasing the distance between the oral cavity and the esophagus. The head is raised and further tongue movements, assisted by the rostrocaudal movements of the infundibular mound, propel the food particles from the tongue to the esophagus.

Primary peristalsis within the esophagus moves the bolus toward the stomach (esophageal phase). Contractions are more rapid in the cranial esophagus than in the thoracic esophagus. In a fasted bird, the longitudinal muscle layer obliterates the esophago-ingluvial fissura, thus preventing a bolus from entering the crop (Ashcraft, 1930). After partial gizzard filling, the esophago-ingluvial fissura is relaxed and food can either enter the crop or stomach depending on the contractile state of the gizzard. The crop acts as a temporary food storage site (Hill, 1971). The destination of food appears to be controlled by the contractile state of the gizzard, with food entering or bypassing the crop when the gizzard is contracting or relaxing, respectively. In 6- to 10-week-old turkeys fasted overnight, almost no ingested food enters the crop during the first four−six h after dawn. During each meal, the GIT fills cephalic to the upper one-third of ileum. In late afternoon meals, the crop also fills (Denbow, 2015).

Food is evacuated from the crop as a result of contractions by the crop wall. Such contractions last about 6 s with a force of approximately 20 cm H_2O (Fileccia et al., 1984). During primary peristalsis, there is a cessation of spontaneous electrical activity, which is associated with relaxation of the muscular wall. This is followed by a propagated, long-lasting spike burst of high amplitude. As the peristaltic wave moves aborad, it is preceded by inhibition of the muscles directly in front of the wave. The rate of emptying of the crop is not influenced by particle size or

whether the compounds are soluble or insoluble (Vergara et al., 1989).

Unlike mammals, spontaneous electrical activity and contractions have been recorded in the esophagi of birds (Mulé, 1991). This activity is myogenic in origin. It occurs independent of slow waves, which are absent in the esophagi of birds. Although the function of these spontaneous contractions is unknown, they may act to clear contents from the esophagus.

Primary peristalsis is mediated entirely by the extrinsic nervous system (Mulé, 1991). The enteric nervous system of birds is not responsible for propagating peristalsis, at least beyond short distances. Sectioning the glossopharyngeal or vagus nerve can disrupt peristalsis in the cervical and thoracic esophagus, respectively. Denervation of the esophagus prevents the propagation of electrical wave activity, indicating that the muscle cells act similar to multiunit smooth muscle cells.

21.3.2 Gastrointestinal cycle

Motility of the mammalian stomach is regulated by slow waves thought to arise from the interstitial cells of Cajal, which lie adjacent to the myenteric plexus (Sanders et al., 2006). These slow waves pace the "phasic muscles" increasing the probability that voltage-gated Ca^{2+} channels will open, thus exciting the muscles. Slow waves arise from distinct pacemaker regions within different parts of the GIT, thus producing regional differences in slow-wave frequency. In the stomach, the pacemaker cells reside in the greater curvature of the stomach. The slow waves do not propagate from the stomach to the small intestine, but instead the small intestine has its own pacemaker cells. The stomachs of most birds lack longitudinal smooth muscle and do not display slow waves. As a result, gastric motility is more complex in birds than in mammals (Dziuk and Duke, 1972).

During the gastrointestinal cycle of birds, the thin muscles of the muscular stomach contract and the isthmus closes, after which the pylorus opens and gastric contents flow into the duodenum (Figure 21.6). Next, the duodenum contracts, followed by relaxation of the isthmus and a contraction of the thick muscles of the muscular stomach. This precipitates a refluxing of the contents of the muscular stomach into the glandular stomach. The cycle is completed with contraction of the glandular stomach. A gastroduodenal cycle occurs with a frequency of 3.3 cycles/min in turkey (Duke, 1982). As might be expected, the largest change in intraluminal pressure is associated with contraction of the thick muscles (Figure 21.7).

As stated earlier, the pyloric region appears to control the movement of materials from the gizzard to the duodenum. Whereas soluble material is readily transported from the gizzard to the duodenum, larger particles are retained longer within the muscular stomach (Vergara et al., 1989).

Initiation of the gastrointestinal cycle is not dependent on extrinsic innervation in sated birds, suggesting that there is an intrinsic pacemaker controlling the cycle (Chaplin and Duke, 1988). Denervation of the stomach slows the rate of the gastrointestinal cycle in fasted birds and disrupts its normal synchronization (Figure 21.8), indicating that the gastrointestinal cycle is not independent of external neural input.

The pacemaker for the gastrointestinal cycle appears to reside in the isthmus (Chaplin and Duke, 1990). Destruction of the myenteric plexus in this area reduced contractions of the muscular stomach and duodenum by 50%, while simultaneously abolishing glandular stomach contractions.

The muscular stomach of raptors lacks the two pairs of opposing muscles characteristic of other types of birds; as a result, the gastroduodenal cycle is simplified. It is described as having three phases, including mechanical, chemical, and pellet formation and egestion (Kostuch and Duke, 1975). A peristaltic wave originating in the proventriculus moves aborad through the gizzard and into the small

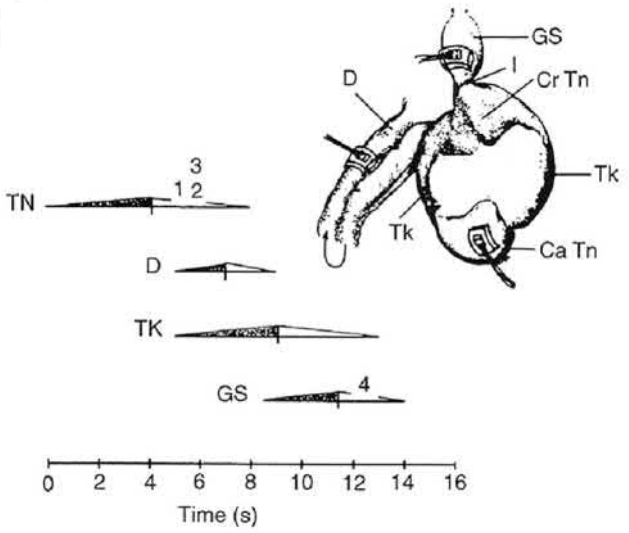

FIGURE 21.6 Top right: illustration of gastroduodenal apparatus of turkeys showing anatomical relationships of organs and placement of strain gauge transducers. Letters refer to organs as follows: *CaTN*, caudal thin muscle of muscular stomach; *CrTN*, cranial thin muscle of muscular stomach; D, duodenum; *GS*, glandular stomach; *I*, isthmus; *TK*, thick muscle pair (dorsal and ventral) of muscular stomach. Bottom left; triangles graphically represent sequence and duration of events in gastroduodenal cycle. Stippled areas indicate duration of contraction and clear areas indicate duration of relaxation of thin muscle pair (TN) and thick muscle pair (TK) of the muscular stomach, duodenum (D), and glandular stomach (GS). Numbers refer to noncontractile events in gastroduodenal cycle; 1, pylorus open; 2, isthmus open; 3, pylorus closed; 4, isthmus closed. *Reprinted from Chaplin and Duke. FIGURE 21.7 Tracings of typical records of electrical potential and intraluminal pressure changes from the stomach and duodenum of turkeys. (A), (B), and (C) are tracings of electrical potential changes recorded from the proventriculus, thick cranioventral muscle of the gizzard, and proximal duodenum, respectively. Slow waves with spikes are evident in the duodenum; only spikes associated with contractions are evident in the proventriculus and gizzard. (D), (E), and (F) are tracings of the corresponding intraluminal pressure changes recorded from these same organs, respectively. Time constant for electrical recordings was I.Is. *Reprinted from Duke et al. (1975) Copyrights 1975 by Springer Nature. Used by permission of the publisher.*

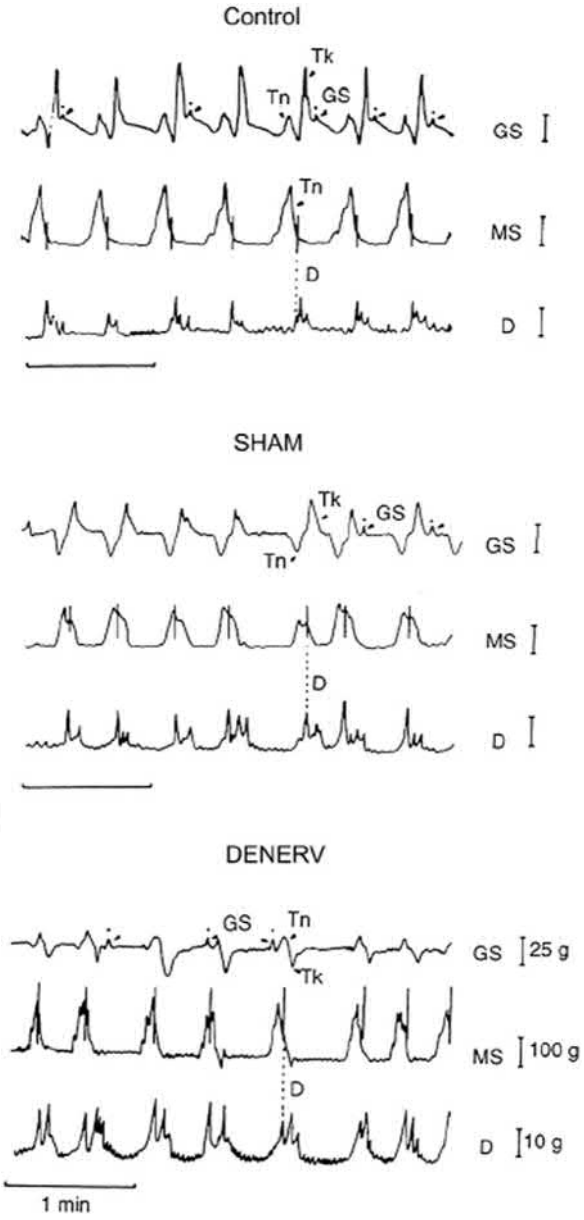

FIGURE 21.8 Tracings of recordings of glandular stomach (GS), muscular stomach (MS), and duodenal (D) contractions detected by implanted strain gauge transducers. Recordings were obtained on day 3 after surgery in three treatment groups used. Arrows and lettering identify contractions of each organ during one gastroduodenal cycle. Glandular stomach contractions are marked with an arrow and a closed circle; duodenal synchronization is identified with a dashed line. Note normal synchronization of contractions in the control tracings. *Reprinted from Chaplin and Duke. Copyrights 1988 by American Physiological Society. Used by permission of the publisher.*

intestine. Although the sequence of motility in the stomach of raptors resembles that in mammals, slow waves have not been recorded in these species.

Egestion is another gastrointestinal function unique to birds (Rea, 1973). This process, which involves the oral expulsion of nondigestible material, is more common in carnivores. Whenever bone, fur, or feathers are ingested, these materials are compacted and orally egested. This process is unlike regurgitation in ruminants or vomiting in mammals (Duke and Evanson, 1976; Duke et al., 1976a,b). Beginning approximately 12 min prior to egestion, gizzard contractions increase in frequency and amplitude. This process both compacts the material into a pellet and moves it into the lower esophagus. Beginning 8–10 s prior to egestion, the pellet is moved orad by esophageal antiperistalsis. Neither the abdominal nor duodenal muscles are involved.

Enterogastric reflexes control gastric emptying. Simply increasing intraduodenal pressure, or administering intraduodenal injections of HCl, hypertonic NaCl, or amino acid solutions, inhibits gastric motility (Duke et al., 1977, 1989; Duke and Evanson, 1972). Inhibition is related to dose and volume; it generally occurs within 3–30 s, and it persists for 2–35 min. Following an intraduodenal injection of a lipid solution, gastric motility decreases after 4–6 min and remains inhibited for 24–45 min. This latter response appears to involve hormonal regulation, presumably by an enterogastrone.

In addition, the presence of bile acids increases in the gizzard in proportion to the amount of wood shavings retained in the gizzard (Hetland et al., 2003). Because bile acids arrive in the intestine in the ascending loop of the duodenal duodenum, there is retrograde transport into the gizzard.

Reverse peristalsis occurs in three areas of the GIT, including proventriculus. The first retrograde movements occurs when digesta are moved from gizzard to proventriculus due to contraction of thick muscle of gizzard (Duke, 1994).

21.3.3 Small intestine

The MMCs are characterized by electrical potential changes known as slow waves, which travel aborad and are associated with periodic spike potentials and smooth muscle contraction (Figure 21.9). Although the MMC has not been extensively studied in birds, available data suggest that the MMC is similar in birds and mammals (Clench et al., 1989). The MMC has three phases: quiescence (phase l); irregularly spaced spike activity superimposed on slow waves (phase 2); and high-amplitude, regular spike activity superimposed on slow waves (phase 3). In chickens, the MMC has a periodicity of 77−122 min, whereas in owls it is only 21 min. The duration of phase 3 lasts approximately 5−8 min (Figure 21.10). These values are similar to those in mammals. Nevertheless, the propagation speed in birds is relatively slow, ranging from 0.48 to 0.62 cm/min. Although the MMC has been observed in the duodenum of chickens, quail, and owls, it has only been observed aborad of the duodenum in turkeys (Mueller et al., 1990).

Intestinal refluxes appear unique to birds (Duke et al., 1973). Increases in intraluminal pressure of the duodenum normally follow increased pressure in the muscular stomach. However, approximately every 15−20 min in the turkey, large pressure changes are observed in the duodenum, which are associated with an inhibition of gastric motility and a reflux of intestinal contents (Figure 21.11). This has been observed in a number of other species as well, and appears more frequently as dietary fat levels increase (Duke et al., 1989).

21.3.4 Ceca

Motility in the ceca is not well understood. The ceca are filled as a result of the convergence of rectal antiperistaltic waves and ileal peristaltic waves. Due to the morphology of the ileocecal junction, only fluids or very small particles are allowed entrance to the ceca. In fact, 87−97% of cecal fluid originates from urine (Bjornhag and Sperber, 1977). The importance of the movement of urine to the ceca is discussed below.

While MMC-like bursts of electrical activity have been observed within the cecum, this activity does not migrate

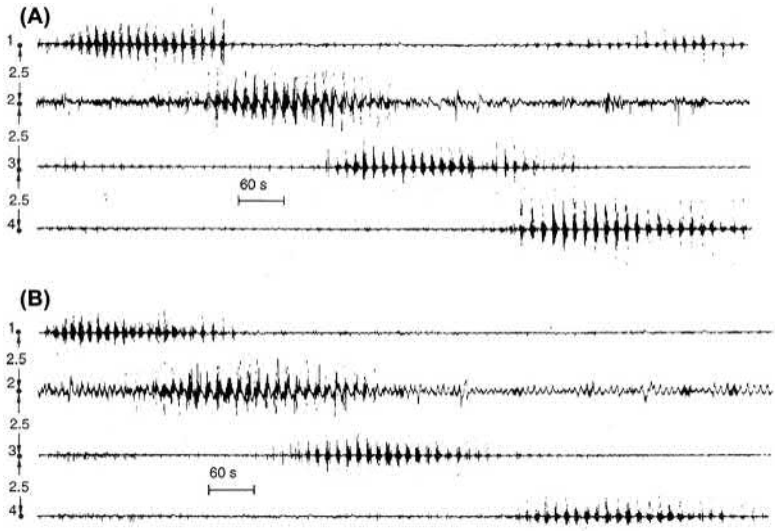

FIGURE 21.10 **Representative myoelectric recording of a migrating myoelectric complex (MMC) in strix.** The electrodes were placed on the proximal ileum 2.5 cm apart. (A): bird in fed state. (B): bird in fasted state. High frequency of MMCs in this owl species in indicated in (A), with a second regular spike activity beginning on lead one before previous complex has propagated through lead 4. *Reprinted from Clench et al. FIGURE 21.11 Tracings of typical records of pressure changes obtained from the proventriculus (A), gizzard (B), and upper proximal duodenum (C) of a turkey, showing pressure events occurring during a duodenal reflux. Positions of open-tipped tubes within gastrointestinal tract are indicated by letters (A), (B), and (C) (*circled*) on the diagram of a sagittal section of the stomach. The biphasic patter (B) of the tracing representing the contraction of the gizzard is quite variable; two phases of one cycle are (a) pressure wave due to contraction of thin muscle pair; and (b) of thick muscle pair. *Reprinted from Duke et al. (1972), Copyrights 1972 by American Physiological Society. Used by permission of the publisher.*

and thus does not constitute an MMC (Clench et al., 1989). Two types of contractions have been recorded in the ceca of turkeys (Duke et al., 1989). One type has a low amplitude, occurring at a rate of 2.6/min, while the other has a higher amplitude and occurs at a rate of 1.2/min. Low-amplitude contractions are associated with mixing, whereas high-amplitude contractions are propulsive. While aborad contractions are more common than orad contractions, the latter contractions have a greater amplitude and thus prevent the collection of digesta in the distal ceca. Peristalsis in a cecum appears to be myogenically mediated, with inhibitory neural input apparently able to suppress such contractions (Hodgkiss, 1984b). In mammals, distention causes an ascending stimulation and a descending inhibition, which is neurogenically mediated by the enteric nervous system and can be blocked by tetrodotoxin. By contrast, in birds, distention causes contraction of the circular muscle, which is unaffected by tetrodotoxin and thus apparently not controlled by the enteric nervous system.

The contents of the ceca are much different in consistency than that of the rectum and can therefore be easily distinguished from rectal feces. The ceca evacuate relatively infrequently compared to the rectum, with rectal evacuations preceding cecal evacuations (Duke et al., 1980). Cecal evacuations in young turkeys typically occur within 1−5 min of lights-on and again in late afternoon. There is an increase in the frequency of high-amplitude contractions, with four to seven such contractions occurring during the 2 min preceding cecal evacuation. These contractions are associated with high-amplitude electrical spiking. One high-amplitude contraction also occurs in the ileum and rectum at the time of cecal evacuation. The ratio of cecal to rectal evacuations is also influenced by diet, ranging from 1:7.3 when feeding barley to 1:11.5 when feeding corn (Röseler, 1929). As discussed in Section 21.6, the extended time that digesta spends in the ceca provides a unique role for this organ.

21.3.5 Colon

The rectum displays almost continuous antiperistalsis. Such motility is responsible for carrying urine from the urodeum. Contraction of the rectum appears to be mediated by noncholinergic, nonadrenergic nerves (Bartlet, 1974; Takewaki et al., 1977) into the colon and ceca (Akester et al., 1967; Goldstein and Braun, 1986; Polin et al., 1967). Two types of colonic slow waves have been recorded (Lai and Duke, 1978). These include small, short duration (sSW) and large, long duration (lSW) slow waves (Figure 21.12). The sSW are associated with small contractions and, as shown with radiography, are antiperistaltic. The lSW are associated with large contractions but, radiographically, could not be associated with movements of rectal contents.

The frequencies of sSW and lSW are shown in Table 21.2 The frequency of sSW is highest in the distal colon. In contrast, the frequency of lSW is highest in the proximal colon and cannot be recorded from the distal colon. This pattern of slow waves, when compared to the

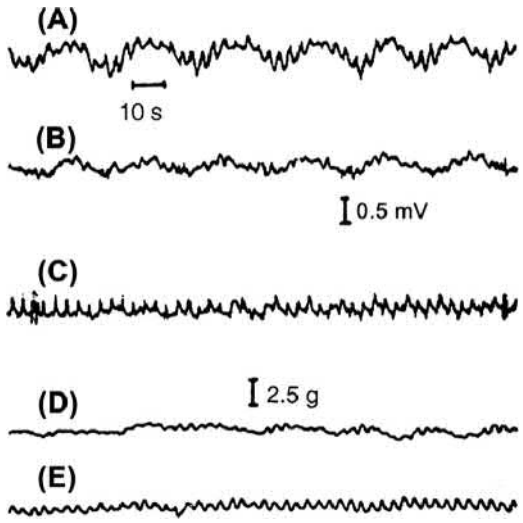

FIGURE 21.12 Electrical potential changes and contractile forces recorded from three bipolar electrodes ((A), (B), (C)) and two strain gauges ((D), (E)) in the colon of a turkey. Electrodes and strain gauges were implanted at 10, 6, and 1, and 8 and 3 cm from the cloaca, respectively. Both large and small slow waves are evident in tracings (A) and (B); only small slow waves are evident in tracing (C). Small contractions (antiperistalsis are evident in tracings (D) and (E)) but large contractions (peristalsis) can be seen only in tracings (D). *Reprinted from Lai et al. Copyrights 1978 by Springer nature. Used by permission of the publisher.*

TABLE 21.2 Mean frequency and amplitude of small and large contraction and of small and large slow waves in the rectum of Turkeys.

	Contractions				Slow waves			
	Small		Large		Small		Large	
	Frequency (cycles/min)	Amplitude (g)	Frequency (cycles/min)	Amplitude (g)	Frequency (per min)	Amplitude (mV)	Frequency (per min)	Amplitude (mV)
Proximal	14.6 ± 0.85	0.45 ± 0.24	2.66 ± 0.26	0.54 ± 0.20	15.4 ± 1.07	0.17 ± 0.08	2.83 ± 0.26	0.21 ± 0.09
Middle	–	–	–	–	15.8 ± 1.12	0.16 ± 0.09	2.76 ± 0.24	0.12 ± 0.06
Distal	15.4 ± 0.69	<0.70 ± 0.33	–	–	16.4 ± 2.16	0.25 ± 0.12	–	–

Proximal, middle, and distal refer to electrode implant sites on the colon 10, 6, and 1 cm from the cloaca, respectively, or the strain gauge transducer implants at 8 (proximal) and 3.5 (distal) cm from the cloaca. (Large contractions were not recorded from the distal strain gauge nor were large slow waves recorded from the distal electrode.)
Reproduced from Denbow (2015).

motility pattern, suggests that sSW arise at the distal colon and are responsible for antiperistaltic movement, whereas the lSW begin in the proximal colon and are responsible for peristaltic movement of rectal contents.

The nearly continuous antiperistaltic activity of the colon is interrupted only near the time of defecation (Duke, 1982). Beginning approximately 10 min prior to defecation, the amplitude of the sSW begins to decrease while the frequency gradient of lSW increases. These conditions favor inhibition of antiperistalsis and stimulation of peristalsis. Defecation is associated with a strong contraction beginning at the proximal colon, moving aborad and carrying the contents the length of the colon in less than 4 s.

21.3.6 Other influences on motility

Motility of the GIT shows diurnal variations. In turkeys, the frequency and amplitude of muscular stomach contractions increased during light periods relative to dark periods (Duke et al., 1976a,b). The increased and decreased gastric contractions coincided with just prior to "lights-on" and "lights-off," respectively. Although less pronounced, this diurnal rhythm of gastric activity continued when birds were fasted.

Birds also display cephalic, gastric, and intestinal phases of motility. In 24 h fasted great horned owls, turkeys, and red-tailed hawks, the sight of food stimulated gastric contractions (Duke et al., 1976a,b). When allowed to eat, gastric activity increased further, indicative of the gastric phase. During the intestinal phase, entrance of food into the duodenum slows the frequency of gastric contractions to allow time for digestion (Duke et al., 1973). While the cephalic phase is mediated largely by the nervous system, there appears to also be an as yet unidentified endocrine component that increases motility.

Motility is influenced by many factors. For example, anesthetics, including nembutal and methoxyflurane, reduce gastroduodenal motility as well as decrease gastric secretion (Duke et al., 1977; Kessler et al., 1972). High-environmental temperatures decrease gastrointestinal motility, whereas cold temperatures differentially affect motility in various parts of the digestive system but appear to have an overall effect of decreasing transit time (Tur and Rial, 1985).

21.4 Neural and hormonal control of motility

Extrinsic and intrinsic innervations of the avian GIT appear similar to mammals (Olsson and Holmgren, 2011). Extrinsic innervations are largely from the vagus nerve, nerve of Remak (ganglionic nerve running along the gut), and fibers from the splanchnic and pelvic nerves (Nilsson, 2011). Nitric oxide synthase (NOS) is found in many neurons associated with the gut. Many of these neurons also contain vasoactive intestinal peptide (VIP) and pituitary adenylate cyclase-activating polypeptide. In pigeons, these nerves also contain galanin. In addition, most regions of the gut have nerves containing tachykinin-immunoreactivity, and the intestines have neurons containing gamma amino butyric acid. The myenteric plexus of the gizzard has aminergic neurons, although it has been reported that catecholamines are not present in the chicken intestine (Aisa et al., 1997).

Contractions of the esophagus are increased by acetylcholine (ACh) and vagal stimulation and unaffected by sympathetic nerve stimulation (Bowman and Everett, 1964; ŌHashi and Ohga, 1967; Taneike et al., 1988). However, there is evidence for nonadrenergic, noncholinergic

TABLE 21.3 Age of chicks embryos (days of incubation) at first appearance of endocrine cells showing immunoreactivity for various regulatory peptides, chromogranin, and serotonin in the gut.

	Pyloric				Upper	Lower		Large

(NANC) inhibition of esophageal smooth muscles (Postorino et al., 1985; Sato et al., 1970). Serotonin also causes contractions of the esophagus (Mule et al., 1987), and this effect appears to be mediated indirectly by activation of both cholinergic and NANC excitatory neurons (Fileccia et al., 1987). In addition, tachykinins cause contraction of the gut (Liu and Burcher, 2001). In contrast, epinephrine induces relaxation of the chicken rectum via α-adrenergic receptors (Ojewole, 1980).

The proventriculus has been shown to contain gastric inhibitory peptide, VIP, and neuronal NOS (nNOS), but not somatostatin, peptide histidine-isoleucine, peptide tyrosine-tyrosine, neuropeptide tyrosine, bombesin, met-enkephalin, serotonin, substance P, galanin, or calcitonin gene-related peptide (Martínez et al., 2000), VIP and nNOS. VIP and nitric oxide (NO) probably cause relaxation of smooth muscle. The proventricular secretions are controlled by parasympathetic nerves and a diffuse endocrine system.

As shown in Table 21.3, many peptides have been identified within the GIT of birds. The function of these peptides remains to be elucidated. Although the identity of the NANC excitatory neurotransmitter was not identified, it has been shown that neurotensin can induce contraction of crop smooth muscle (Denac and Scharrer, 1987). This latter effect is a postjunctional response not mediated by ACh, prostaglandins, or opioids.

Histamine interacts with cholinergic neurotransmission to control esophageal contractions (Taneike et al., 1988). Histamine dose-dependently induces esophageal contractions, but this effect is blocked by tetrodotoxin, suggesting that its effect is mediated by the release of ACh. Contractions induced by vagal stimulation are increased by the presence of histamine, whereas histamine-induced contractions were enhanced by acetylcholinesterase inhibitors. It appears, therefore, that histamine modulates, via H_1 receptors, the release of ACh to control the contraction of esophageal smooth muscle. As indicated in Figure 21.13, enkephalins also cause contraction of the esophagus, but their effect is mediated by serotonergic neurons.

The crop appears to be controlled similarly to the esophagus. Electrical stimulation of the crop causes contraction that is largely, but not completely, due to ACh release because it can be significantly blocked by atropine (Denac et al., 1990). While it is unclear as to which neurotransmitters are responsible for the contraction not blocked by atropine (i.e., NANC-induced), neurotensin, bombesin, and substance P have been shown to cause atropine-resistant contractions following electrical stimulation of the crop (Denac and Scharrer, 1987, 1988). Norepinephrine caused crop muscle relaxation that was mediated by B-adrenoceptors. It appears that the crop and esophagus are controlled by three types of nerves:

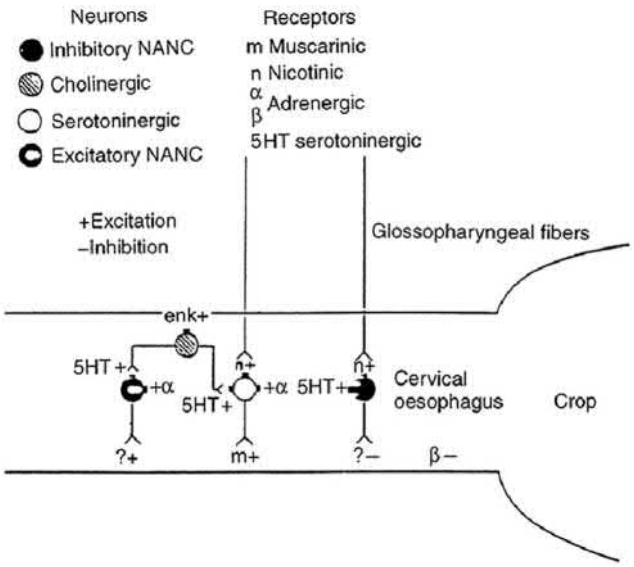

FIGURE 21.13 Schematic diagram illustrating the putative pattern of the intrinsic innervation of the pigeon cervical esophagus. FIGURE 21.14 Recording of gastroduodenal electrical activity showing effect of cholecystokinin octapeptide (CCK-8; 10^{-9} mol/kg) infusion. Studied gastric areas are as follows: *DD*, distal duodenum; *GI*, proventriculus; *G2*, craniodorsal thin muscle; *G3*, caudodorsal thick muscle; *PD*, proximal duodenum. Similar responses were observed in all animals. *Reprinted from Martinez et al. Copyrights 1993 by American Physiological Society. Used by permission of the publisher.*

stimulatory cholinergic neurons, stimulatory NANC neurons (probably peptides), and inhibitory noradrenergic nerves.

Cholecystokinin octapeptide (CCK-8) is the most studied regulator of intestinal motility. Intravenous infusion of CCK-8 inhibited gastric and duodenal motility (Savory et al., 1981). CCK-8 and CCK-tetrapeptide (CCK-4) inhibited gastric electrical activity (Martinez et al., 1993). Whereas CCK-4 inhibited duodenal electrical activity, CCK-8 stimulated such activity (Figure 21.14]. CCK-A and CCK-B receptor antagonists were unable to block the effects of CCK. It appears that the action of CCK on gastric and duodenal motility is similar in birds and mammals. CCK inhibits stomach motility, and the increase in duodenal activity is suggested to cause segmental contractions, and, thus, also delay gastric emptying (Martinez et al., 1993).

Vagotomy and hexamethonium blocked the response to CCK-8 in the chicken stomach (i.e., proventriculus and gizzard) but had no effect on the duodenal response (Martinez et al., 1993). Furthermore, the action of CCK-8 in the duodenum was not altered by atropine or methysergide. Phentolamine and propranolol had no effect on the gastric or duodenal response to CCK-8. It appears, therefore, that the action of CCK-8 on the stomach is mediated via the vagus, whereas the action in the duodenum probably involved a direct effect on smooth muscle cells. The action of CCK-8 on the stomach was blocked by N-nitro-L-arginine methyl ester (L-NAME), suggesting that the inhibitory effect of CCK involves the release of NO. Because L-NAME did not completely block the CCK effect on the caudodorsal thick muscle, it is likely that another neurotransmitter, possibly VIP, is involved in this latter response. Interestingly, CCK-8 caused an excitatory action in the stomach of vagotomized chickens, indicating that CCK-8 may, in addition to acting via the vagus, have a direct action on gastric muscles. The increase in electrical activity caused by CCK-8 in the duodenum was enhanced by L-NAME, indicating that nitric oxide may be a tonic inhibitor of duodenal electrical activity.

Chicken gastrin (cG), which belongs to the gastrin/CCK family, has been isolated from the chicken antrum (Dimaline et al., 1986). Intravenous infusions of cG caused effects similar to CCK-4 (Martinez et al., 1993). This suggests the existence of one receptor subtype in the stomach recognizing both CCK and cG, but possibly two receptors in the duodenum, one recognizing CCK-8 and the other CCK-4 and cG.

Opioid peptides appear to be involved in the MMC. Infusion of met-enkephalin, morphine, and casomorphin (5×10^{-7} mol/kg) induced intense electrical activity, similar to phase 3 of the MMC, in the distal duodenum which migrated through the small intestine (Jiménez et al., 1992). The effect of morphine was blocked by naloxone (5×10^{-7} mol/kg), while higher doses of naloxone reduced gastroduodenal motility. Simultaneous to increasing duodenal electrical activity, activity in the stomach is inhibited.

21.4.1 Rate of passage

The rate of passage in the GIT influences the exposure time of feed to the digestion and absorption processes. The rate of passage of material through the digestive tract has been measured in many ways. Because digesta consists of both solid and liquid components, different types of markers have been used. Insoluble markers such as chromium-mordanted rice, cerium-mordanted rice, Cr_2O_3 (chromium (III) oxide), or radiopaque plastic pellets (Branch and Cummings, 1978; Ferrando et al., 1987; Udén et al., 1980) have been used as indicators of solid transit time, whereas a soluble marker such as Cr-EDTA (chromium ethylenediaminetetraacetic acid salt) (Vergara et al., 1989) or phenol red (Gonalons et al., 1982) has been used to measure liquid transit time. In general, it was found that larger particles are retained longer in the digestive tract.

The rate of passage is determined by measuring the time of 1% marker concentration in excreta (T1), time of 50% marker concentration in excreta (T50), or mean retention time (MRT) (Rochell et al., 2012). In broiler chickens, T1, T50, and MRT depends on the diet and ranges from 0.87 to 1.36 h, 4.47 to 4.97 h, and 5.13 to 5.62 h, respectively (Rochell et al., 2012). The MRT in laying hens fed corn and soybean meal diet is estimated for 5 h and 59 min (Shires et al., 1987). In Japanese quail, the T1 and T50 is lower while the MRT is higher than in broiler chickens (Nobrega et al., 2020).

Transit time of digesta is influenced by genetics. When comparing broiler and Leghorn-type chickens, the overall MRT is similar, but the time food spent in various parts of the digestive tract is different (Table 21.4).

The rate of food passage is affected by many factors. Feed transit time through the small and large intestine increases with age (Shires et al., 1987). This may account for increases in metabolizable energy values of feedstuffs noted in older birds. Adding lipid (Sell et al., 1983) or protein (Sibbald, 1979) to the diet can increase passage time. Increases in environmental temperature also slows transit time. Transit time depends also on the digestive capacity of the birds. In birds with digestive capacity, particles, regardless of the size, spent 10 times less time in gizzard in comparison to birds characterized by high-digestive capacity (Rougiere and Carre, 2010).

TABLE 21.4 Mean retention time (min) of solid phase markers in various segments of the digestive system of broilers and leghorns.

Gastrointestinal tract segments	Broilers[a]	Leghorns	Broilers[a]

21.5 Secretion and digestion

At hatch, the chick has to make a transition from dependence on a lipid-rich endogenous diet coming from the yolk to an exogenous diet rich in carbohydrate and protein (Sklan, 2001). Access to feed at hatch results in an approximately twofold increase in small intestine length of chicks, but only a 60% increase if birds remain fasted (Sklan and Noy, 2000). The increase in intestinal weight is correlated with increases in trypsin, amylase, and lipase activities, which remain unchanged in the absence of feed. Functional genomics of the digestive tract has been recently characterized in broiler chickens (Juanchich et al., 2018). Genes upregulated upstream and downstream of the gizzard junction were related to motility and trophicity, while in the gizzard and jejunum, upregulated genes were related to physical breakdown of the feed, absorption, and body defense, respectively (Juanchich et al., 2018, Figure 21.15).

21.5.1 Mouth

The salivary glands secrete mucous, and depending on the species, amylase. Although amylase is not present in the saliva of *Gallus* and *Meleagris,* it is found in the saliva of the house sparrow (Jerrett and Goodge, 1973) and other species (Bhattacharya and Ghose, 1971). The volume of daily salivary secretion in *Gallus* ranges from 7 to 25 mL (Leasure and Link, 1940).

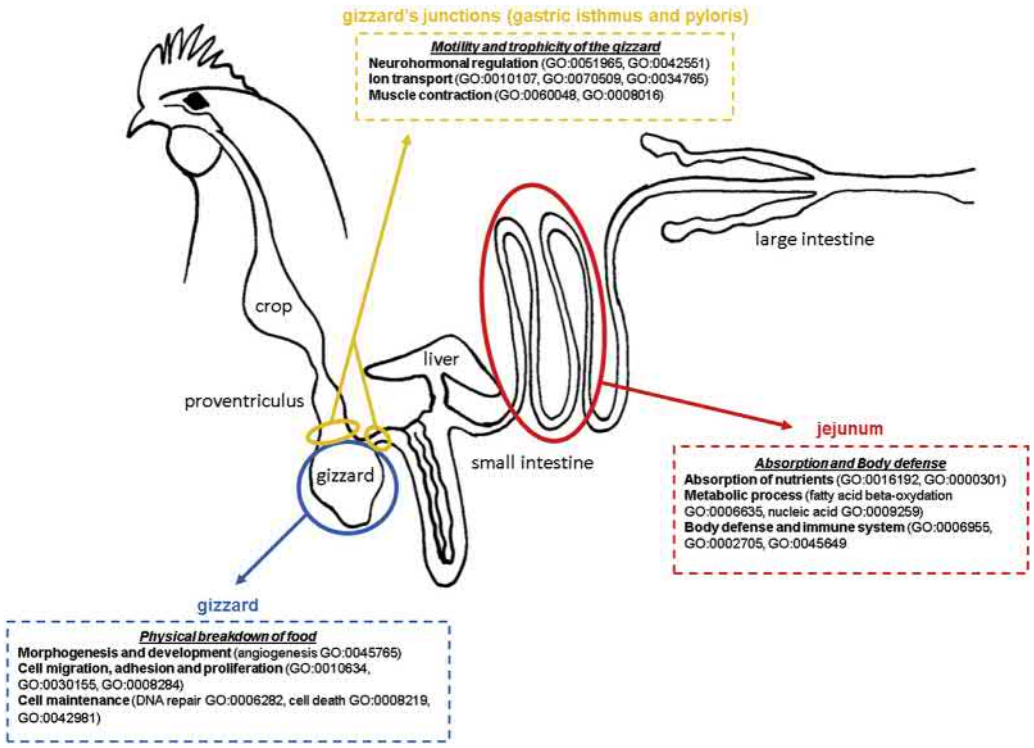

FIGURE 21.15 Representation of the molecular portrait of the digestive tract in broilers from results of this study. *Reprinted from Juanchich et al. Copyrights 2018 Springer Nature. Used under Creative Commons Attribution license (CC BY).*

Mucous functions to lubricate food and allow it to move down the esophagus. However, in some species, mucous also functions as an adhesive coating on the tongue to aid in capturing insects or as a material that cements components during the construction of nests.

21.5.2 Esophagus and crop

The esophagus is not important in chemical digestion, as its major secretion is mucous. The secretion of esophageal mucous is nevertheless important because it is necessary to supplement the limited secretion of saliva. However, in some species, including the greater flamingo and male emperor penguin, a nutritive merocrine-type secretion is produced by the wall of the esophagus, which is fed to the young.

Some carbohydrate digestion may occur in the crop due to the presence of amylase activity (Philips and Fuller, 1983). Amylase activity at this site comes from either salivary secretions, intestinal reflux, or plant and/or bacterial sources. Bolton (1965) reported that starch is hydrolyzed within the crop where it can either be absorbed; converted to either alcohol, lactic acid, or other acids; or transported down the GIT. Pinchasov and Noy (1994) showed that substantial amylolysis occurs in the crop. Sucrose is also hydrolyzed within the crop. While absorption of sugars from the crop appears possible, it is probably minimal.

The crop is not essential for normal growth when access to food is sufficient. Cropectomy has no effect on growth rate of ad libitum fed chickens, but it does decrease growth rate when food intake is limited. This supports the view that the primary function of the crop is food storage, and it is not essential for digestion.

In pigeons and doves, "crop-milk" is produced during the breeding season under the influence of prolactin. Crop milk contains 12.4% protein, 8.6% lipids, 1.37% ash, and 74% water (Vandeputte-Poma, 1968). Therefore, while rich in protein and essential fatty acids (Desmeth, 1980), it is devoid of carbohydrates and calcium.

21.5.3 Stomach

The oxynticopeptic cells found in birds secrete both HCI and pepsinogen. Pepsinogen, under the influence of acid or pepsin that is already present in the stomach, is converted to pepsin. While lipase has been found in gastric secretions, this is probably due to reflux from the duodenum. The basal gastric secretory rate is 15.4 mL/h and contains 93 mEq/L of acid and 247 Pu/mL of pepsin (Long, 1967) with a pH of 2.6 (Joyner and Kokas, 1971). The pH of gastric contents, however, is normally above 2.6 due to the presence of ingesta. The pH has been determined in several species immediately after sacrifice (Table 21.5). Higher pH values have been reported when measurements were made on live

birds. For example, Winget et al. (1962) reported the following values for chickens: mouth, 6.7; crop, 6.4; ileum, 6.7; rectum, 7.1. Age has no effect on pH of the digestive tract (Herpol, 1966). Acid secretion of chickens is high relative to mammals, possibly because of the rapid digestive transit time (Table 21.6).

While amylolysis occurs in the crop, it is not evident in the ventriculus. This is the result of the low pH of the stomach, which is unfavorable for amylase activity (Pinchasov and Noy, 1994).

There are three phases to gastric secretion: the cephalic phase, the gastric phase, and the intestinal phase. All three phases are present in birds (Burhol, 1982). The cephalic phase entails an increase in hydrogen ion (H^+) and pepsin secretion caused by the sight, smell, or expectation of food. This phase is under vagal control. As summarized by Duke (1986), vagal stimulation increases both gastric secretion rate and pepsin secretion. Vagal stimulation causes a greater increase in gastric secretion than do cholinergic agents (Gibson et al., 1974). This suggests, as discussed below, that gastric secretion is stimulated by other neurotransmitters acting together with ACh. In birds, vagal stimulation causes greater pepsin than H^+ accumulation (Burhol, 1982). In contrast, insulin injection inhibits gastric H^+ secretion without affecting pepsin secretion. Therefore, H^+ and pepsin secretion may be under different control.

Pepsin from chicken and duck has been well characterized (Bohak, 1969; Pichová and Kostka, 1990). Chicken pepsinogen and pepsin have 367 and 325 amino acids, respectively. Chicken pepsin stability is temperature dependent with stability up to pH 8 at 24°C and inactivation above pH 8.5 (Bohak, 1969). Duck pepsinogen and pepsin have 374 and 324 amino acids, respectively. Duck pepsin has a pH-optimum of 4, is stable up to pH 7.5, and is inactivated at pH 9.6 (Pichová and Kostka, 1990).

Many hormones are involved in gastric secretion (Table 21.7). Gastrin plays a role in the gastric phase of secretion. cG has been isolated from the chicken pylorus, which is equivalent to the mammalian antrum (Dimaline et al., 1986). While structurally similar to CCK, cG has markedly different secretory functions (Dimaline and Lee, 1990). Infusion of cG increases both acid and pepsin

TABLE 21.6 Basal acid secretion in various species.

TABLE 21.7 Gastrointestinal hormones in the domestic fowl.

Hormone	Site of orgin	Biological action
Gastrin	Proventriculus	Stimulates gastric acid and pepsin secretion
Cholecystokinin	Duodenum and jejunum	Stimulates gallbladder contraction and pancreatic enzyme secretion and gastric acid secretion; inhibits gastric emptying; potentiates secretin-induced stimulation of pancreatic electrolyte secretion
Secretin	Duodenum and jejunum	Stimulates bicarbonate secretion by pancreas
Vasoactive intestinal peptide	Duodenum and jejunum	May be a more potent stimulator of pancreatic electrolyte secretion than secretin; inhibit smooth muscle contraction
Pancreatic polypeptide	Pancreas, proventriculus, and duodenum	Stimulates gastric acid and pepsin secretion
Gastrin-releasing peptide (bombesin)	Proventriculus	Stimulates pancreatic enzyme secretion; stimulates crop contraction
Somatostatin	Pancreas, gizzard, proventriculus, duodenum, and ileum	Inhibits secretion of other gut hormones

Reproduced from Denbow (2015).

secretion. Unlike CCK, gastrin has no effect on gallbladder contractions or pancreatic secretion. Another peptide, GRP, also induces acid secretion, but it is not known whether it acts via gastrin release (Campbell et al., 1991).

The intestinal phase of gastric secretion is controlled by several hormones including CCK, secretin, and avian pancreatic polypeptide (APP). APP, originally discovered in chickens (Kimmel et al., 1968; Larsson et al., 1974), is released from the pancreas postprandially in response to amino acids and HCl (Duke et al., 1982; Hazelwood et al., 1973). APP does not appear to act during the cephalic phase of gastric secretion because it is not released during sham feeding (Kimmel and Pollock, 1975). APP increases gastric acid and pepsin secretion, and this effect is independent of the vagus nerve (Hazelwood et al., 1973).

CCK (Dockray, 1977) and secretin (Nilsson, 1974) have been isolated from the duodenum and jejunum of birds. CCK stimulates gastric acid secretion while having no effect on pepsin secretion. Contrary to its effects in mammals, in which secretin inhibits acid and stimulates pepsin secretion, in chickens, secretin stimulates both acid and pepsin secretion (Burhol, 1974).

As in mammals, histamine is involved in gastric acid release. Injection of cimetidine, an H_2-receptor blocker, raises the pH of the proventriculus and duodenal contents (Ward et al., 1984). The increase in gastric acid secretion induces by the intravenous injection of 2-deoxy-D-glucose is also blocked by metiamide, an H_2-receptor blocker (Nakagawa et al., 1983).

21.5.4 Intestines

Intestinal digestion includes both luminal and brush-border digestion. The brush border contains sucrase-isomaltase, peptidases, and phosphatases. Chicks can hydrolyze disaccharides beginning prehatch, and sucrase-isomaltase expression increases posthatch. Glucose is transported across the enterocyte membrane via a Na-glucose transporter (SGLT-1), which increases in expression beginning two days prehatch and involves a secondary active transport system driven by the active removal of Na from the basolateral membrane of the enterocytes. Absorptive capacity of the intestines increases proportionally to body weight, but the absorption rate for glucose is greatest during the first week and then declines, as does brush border SGLT-1 density (Barfull et al., 2002).

Amylase is produced by both the pancreas and intestine (Osman, 1982). While found in all parts of the small intestine, it is present in particularly high concentrations in the jejunum, with 80% of the activity found there. The high levels found in the jejunum are presumably due to the fact that the openings of the pancreatic ducts discharge near the anterior jejunum. Amylase is found in only trace amounts

TABLE 21.8 Enzymes secreted by the intestines.

Enzyme	Substrate	Product of function
Maltase	Maltose	Glucose
Isomaltase	Dextrins	Glucose
Sucrase	Sucrose	Glucose and fructose
Enterokinase	Trypsinogen	Trypsin
Lipase	Monoglicerides	Glycerol and fatty acids
Peptidases	Di- and tripeptides	Amino acids

in the ceca. The optimum pH of the pancreatic and intestinal amylase is 7.5 and 6.9, respectively.

Intestinal enzymes provide the last step in digestion. These secretions are responsible for digesting starch, sucrose, fats, and protein (Table 21.8). The small intestine of birds contains maltase, sucrase, palatinase, but does not trehalase (Siddons, 1969). Whether lactase is present appears to be debatable. However, it has been reported that lactase is not present in germ-free chicks, and that the rate of mortality of germ-free chicks fed lactose as the sole energy source is very high (Siddons, 1972). Enzyme activity is the highest in the jejunum and decreases both proximally and distally. These enzymes are located in the epithelial cells of the villi. The maltase, sucrase, and palatinase activity found in the large intestine comes from the small intestine, whereas the lactase activity present in the large intestine probably originates from cecal bacteria.

Relatively little is known about the control of intestinal secretions in birds. Intestinal secretion is increased by duodenal distention, vagal stimulation, and secretin. Vagal stimulation has a greater effect on stimulating mucous secretion than enzyme secretion.

21.5.5 Colon

Chloride (Cl^-) ions are secreted in the rectum, ceca, and coprodeum. This is discussed in Section 21.6.

21.5.6 Pancreas

As mentioned previously, pancreatic and bile secretions enter the GIT near the anterior jejunum. Pancreatic secretions have a pH of 6.4–6.8 in chickens (Hulan and Bird, 1972) and 7.4–7.8 in turkeys (Duke, 1986). Secretions include an aqueous phase containing water and bicarbonate ions, as well as an enzymatic phase.

Digestive enzymes found in the pancreas of broiler type chickens are listed in Table 21.9. Although not shown, the pancreas is also reported to secrete ribonuclease and deoxyribonuclease (Borgo et al., 1968). Amylase is found in the duodenum, jejunum, ileum, and colon. Both trypsin and amylase are present in highest concentrations in the jejunum (Bird, 1971; Osman, 1982), presumably because the pancreatic ducts enter near the end of the duodenum. Both pancreatic and intestinal amylase have a requirement for chloride ion. Characterization of these enzymes suggests that pancreatic amylase is similar to mammalian α-amylase, while intestinal amylase is similar to glucoamylase.

Pancreatic secretion is controlled by both nervous and hormonal mechanisms. The secretion rate is higher in birds than in mammals (Table 21.10). Secretion has both a cephalic and an intestinal phase. When fasted birds are allowed to eat, pancreatic secretion increases immediately (Kokue and Hayama, 1972). This response is blocked by vagotomy or atropine and can be augmented by cholinergic agents (Hokin and Hokin, 1953).

Secretin-like activity is released in response to diluted HCl placed in the duodenum (Nilsson, 1974). Secretin, when injected intravenously, increases the aqueous

TABLE 21.10 Pancreatic secretory rate and influence of fasting in the chicken, dog, rat, and sheep.

Species	Starvation time (h)	Pancreatic secretory volume (mL/kg/h)
Chicken	24	0.70
	48	0.68
	72	0.65
Dog	24	0.1–0.3
	48	Negligible
Rat	24	0.6–0.7
Sheep	24	0.13

component of pancreatic secretion. However, in contrast to mammals, VIP stimulates the secretion of pancreatic fluids more strongly (Vaillant et al., 1980). VIP is found in the neurons of both the GIT and pancreas. It is believed that VIP, rather than secretin, is the primary regulator of pancreatic juice secretion and that this response may be either neuronally or hormonally mediated (Dockray, 1988). VIP does not stimulate pancreatic enzyme secretion.

CCK is released in response to lipids and amino acids. The administration of CCK has been shown to increase pancreatic secretion in pigeons (Sahba et al., 1970) and to increase the flow rate and protein secretion rate in turkeys (Dockray, 1975). Two GRPs, which are structurally related to bombesin, have been isolated from the proventriculus (Campbell et al., 1991). These peptides are found in endocrine cells and contain either 27 or 6 amino acids. Distension of the proventriculus with peptone stimulates pancreatic juice and enzyme secretion. This effect appears to be mediated by GRP-27, with GRP-6 being ineffective. Distension with saline is less effective.

Diet can influence the secretory rate of pancreatic enzymes. Increasing the carbohydrate and fat content of the diet increases amylase and lipase activity in pancreatic secretions (Hulan and Bird, 1972).

21.5.7 Bile

Bile, produced and secreted by the liver, is essential for fat digestion. It acts to emulsify lipids so that they can be more efficiently digested by lipase. In addition, amylase begins to appear in chicken bile at four to eight weeks of age (Farner, 1943). Therefore, bile is also involved in carbohydrate digestion.

Relatively little is known about biliary secretion in birds possibly because of the complex anatomy in which bile enters the small intestine via both the hepato-enteric duct and the cysticoenteric duct. The biliary secretion rate is 24.2 μL/min in fasted broilers (Lisbona et al., 1981). Chemodeoxycholyltaurine and cholyltaurine are the predominant bile acids in chickens and turkeys, while chenodeoxycholyltaurine and phocaecholyltaurine predominate in ducks (Elkin et al., 1990). These are secreted by an active transport system.

The bile salts glycocholate and taurocholate are readily absorbed through the intestinal wall. The absorption rate is higher near the distal end of the small intestine (Lindsay and March, 1967). This allows for recirculation of bile acids, thus allowing for their reuse in lipid digestion. It is estimated that 90% of bile salts are reabsorbed in the jejunum and ileum (Hurwitz et al., 1973).

Since chickens have low levels of liver glucuronyl transferase and little or no biliverdin reductase, the secretion rate of biliverdin is high relative to that of bilirubin (14.7 vs. 0.9 μg/kg/min). The green color observed in coprodeal droppings is likely due to biliverdin. The reason for the brown color associated with cecal droppings is unknown, but it may be due to bacterial reduction of biliverdin to bilirubin and subsequent dehydrogenation (Hill, 1983).

21.6 Absorption

21.6.1 Carbohydrates

Absorption of carbohydrates in birds occurs by mechanisms similar to those found in mammals. Absorption occurs more rapidly from the small intestine compared to the cecum with carbohydrates being absorbed by both active and passive mechanisms. Absorption of sugars from the distal regions of the intestinal tract may account for as much as 5% of the total capacity. Those sugars containing a six-membered ring with a hydroxyl group in the number three position oriented similarly to glucose are actively transported. Active transport accounts for at least 80% of glucose absorption. D-Glucose and D-galactose are absorbed faster than D-xylose and D-fructose and D-arabinose. These sugars are absorbed faster than L-arabinose, L-xylose, D-ribose, D-mannose, and D-cellobiose.

Glucose is absorbed via the apically located Na-dependent SGLT-1 system found in both the small and large intestine. Fructose is transported by the apical GLUT5-type system (Garriga et al., 2004). Once inside the epithelial cells, these sugars are transported into the interstitial space by the basolateral GLUT2 transporter. Absorption rates appear greatest during the first week of life, and decline thereafter (Barfull et al., 2002). SGLT-1 expression is regulated by the rennin-antiotensin-aldosterone system (Garriga et al., 2004).

The absorption of sugars against a concentration gradient involves an apically located Na-dependent, phloridzin-sensitive transport. This system is coupled to Na^+-K^+-ATPase located on the basolateral membrane. Contrary to what is believed to occur in mammals, the active transport of one molecule of carbohydrate in birds is coupled to the movement of two molecules of Na (Kimmich and Randles, 1984). Sugars leave the enterocytes on their way to the bloodstream crossing the basolateral membrane by either simple diffusion or facilitated by a Na-independent mechanism.

Within the small intestine, the greatest absorption of glucose occurs in the duodenum (Figure 21.16). Cumulatively, up to 65, 85, and 97% of ingested starch is digested through the duodenum, jejunum, and the terminal ileum, respectively (Riesenfeld et al., 1980). Virtually all of the glucose released from starch digestion is absorbed within the small intestine.

Significant absorption of glucose also occurs in the cecum (Savory and Mitchell, 1991). While the entire cecum

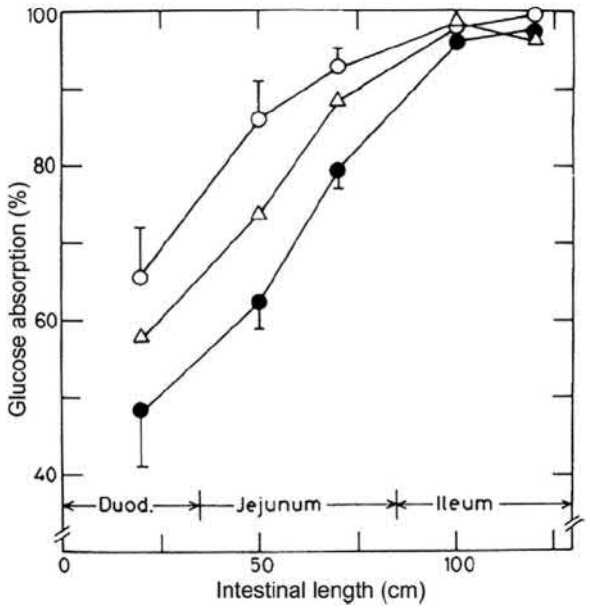

FIGURE 21.16 Cumulative percentage of glucose and starch disappearance from the intestine of seven-week-old chicks. Glucose absorption from glucose monohydrate as the sole dietary carbohydrate source (○), starch digestion (Δ), and absorption (●) in chicks fed starch as the sole dietary carbohydrate source. Values given in the figure are means of six chickens ± standard error. *Reprinted from Riesenfeld et al. Copyrights 1980 by Oxford University Press. Used by permission of the publisher.*

is able to transport sugars at hatch, this ability is soon limited to the proximal region (Planas et al., 1986). The ability of the cecum to actively absorb sugars at low concentrations appears higher than that of the jejunum (Vinardell and Lopera, 1987).

There is a greater affinity for active transport of glucose in the ileum (Levin et al., 1983). The ileum appears well suited for transporting glucose which may not be absorbed within the jejunum.

The GIT also has a role in glucose homeostasis (Riesenfeld et al., 1982). Plasma glucose levels are maintained relatively constant in chickens when fed semi-purified diets in which glucose is replaced with either fructose, soybean oil, or cellulose. While this is partially the result of varying glucose turnover rates, it is largely a result of varying rates of conversion of glucose to lactate by the intestine.

21.6.2 Amino acid and peptides

Amino acid and peptide absorption in birds (Gilbert et al., 2008) is similar to that in mammals. Amino acid transport occurs via a secondary active transport system. This process is saturable, coupled to Na + transport, and uses adenosine triphosphate for energy. The amino acid transport systems can be classified in four groups based on their ability to transport: (1) neutral amino acids; (2) proline, B-alanine, and related amino acids; (3) basic amino acids; and (4) acidic amino acids. This classification, however, is not rigid because many amino acids can be transported by more than one group of transport molecules. For example, leucine, a neutral amino acid, can inhibit the uptake of proline and arginine, a basic amino acid. Glycine transport is partially inhibited by both proline and β-alanine.

The primary site for amino acid absorption is the small intestine. It is still unclear as to which section of the small intestine has the greatest capacity for absorption because there is a lack of agreement among studies. The rectum of hens is also capable of absorbing methionine via a saturable process. As with glucose transport, the K_m for various amino acids is lower in the ileum than in the duodenum (Table 21.11).

Peptide (i.e., di- and tripeptides) absorption can occur via paracellular movement and specific transport systems (Figure 21.17). Many amino acid transporters have been characterized. These include the neutral amino acid transporters with preference for leucine and other large hydrophobic neutral amino acids (system L), system A with preference for alanine and other small and polar neutral amino acids, and system ASC with preference for alanine, serine, and cysteine (Table 21.12). In addition, separate nomenclature (x for anionic, y for cationic, z for neutral) has been applied to systems mediating transport of cationic amino acids (system y+) and anionic amino acids (system X^-_{AG}). With some exceptions (system L, system T), lowercase acronyms indicate Na^+-independent transporters, whereas uppercase acronyms are used for Na + -dependent transporters.

For the absorption of di- and tripeptides, only one transport system, designated as PepTl (SLC15Al), is known. This is a low-affinity, high-capacity transport system and handles essentially all possible protein-derived di-

TABLE 21.11 K_m (mM) and J_{max} (Pmol $Cm^{-2}d^{-1}$) for saturable amino acid absorption in the chicken small intestine.

Amino acid	Jejunum		Ileum	
	K_m	J_{max}	K_m	J_{max}

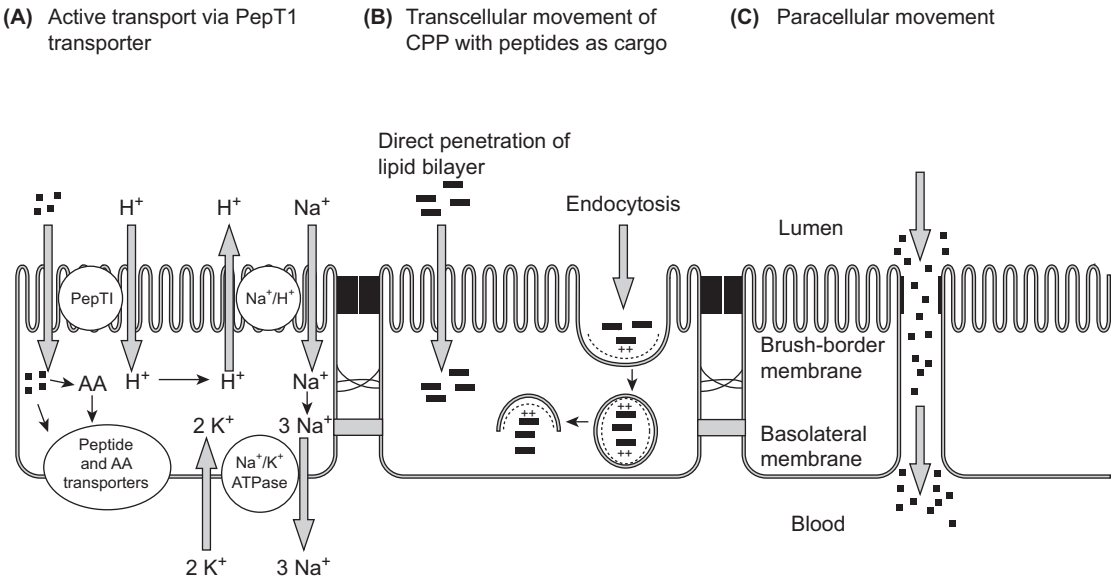

FIGURE 21.17 Potential routes of peptide uptake in enterocytes. (A) The primary route of di- and tripeptide absorption is through cotransport with H+ by the peptide transporter, PepTl. (B) Cell-penetrating peptides (CPP) are capable of carrying cargo such as peptides to the inside of cells. (C) Increased permeability of tight junctions permits uptake of peptides via the paracellular route. *Reprinted from Gilbert et al. Copyrights 2008 by Oxford University Press. Used by permission of the publisher.*

and tripeptides as well as various peptidomimetics, such as aminocephalosporins and various prodrugs. PepTl utilizes the cotransport of protons. It has been well characterized in many species, including chickens and turkeys (Gilbert et al., 2008). Peptides appear to be absorbed more rapidly than amino acids. Absorption of peptides acts to eliminate competition between amino acids for uptake and thus helps increase the speed of absorption. PepTl expression is upregulated during feed restriction. This may be a mechanism to compensate for decreased mucosal surface area caused by reduced villi height and crypt depth observed in broilers given delayed access to feed at hatch. Increased expression of PepTl may be mediated by peroxisome-proliferator-activated receptor alpha (Shimakura et al., 2006).

The ceca are also important in amino acid absorption. Proline is absorbed in the cecum via a Na-dependent carrier-mediated transport system, with transport rates being higher in the proximal than distal cecum (Obst and Diamond, 1989). In addition, leucine, phenylalanine, proline, and glycylsarcosine are absorbed against a concentration gradient (Calonge et al., 1990; Gasaway, 1976; Moreto et al., 1991). Proline and methionine have also been shown to be transported by a Na-independent system (Moreto et al., 1991).

The ceca have a greater ability to transport amino acids than sugars (Moreto et al., 1991). This may be functionally important when considering the following: (1) uric acid, which is retrogradely carried to the ceca from the coprodeum, may be microbially converted to amino acids; and (2) proteases are in high concentration within the ceca and may release amino acids from proteins. Therefore, the ceca may be important in amino acid absorption.

21.6.3 Fatty acids and bile acids

Fatty acid absorption occurs in the distal half of the jejunum and, to a lesser extent, in the ileum. Because the bile duct enters the GIT of birds near the distal duodenum, emulsification of fats is delayed in birds relative to mammals.

In mammals, fatty acids enter the enterocytes where they are esterified to triglycerides and packaged into chylomicrons which enter the lymphatic system. However, in birds, after being re-esterified, lipids are packaged into portomicrons, which pass directly into the hepatic portal blood supply.

21.6.4 Volatile fatty acids

The concentration of volatile fatty acids (VFAs), mainly acetate, but some propionate and butyrate, in the ceca is high (Table 21.13). It can reach 107 mM/kg in the chicken and 20−151 mM/kg in the goose (Goldstein, 1989). VFAs are one of the byproducts of microbial decomposition of uric acid (Braun and Campbell, 1989). Levels of VFAs are higher in the portal blood of conventionally raised compared to germ-free birds, suggesting that VFAs produced by bacteria are absorbed by the GIT. VFAs can be absorbed from both the small intestine and the ceca by passive transport (Sudo and Duke, 1980). Recently, the role

of VFA transporters has been characterized in mammalian species. Monocarboxylates linked with H^+ can be transported by Na co-transporters (SMCT1 and 2) (Halestrap and Meredith, 2004; Poole and Halestrap, 1993) as well as electroneutral co-transporters (MCT1-4) (Halestrap, 2012; Halestrap and Meredith, 2004; Halestrap and Wilson, 2012). MCT1 is involved in SCFA transport at the brush border membrane while MCT4 functions at the basolateral membrane (Gill et al., 2005; Rajendran and Binder, 1994). Presence of mRNA level for both transporters, SMCT1 and MCT1 in ceca of chickens has been confirmed in broilers during posthatch development (Qu et al., 2021). Microbial fermentation within the ceca of birds can provide enough VFAs to meet between 8% (chicken) to 75% (ostrich) of the energy needs for basal metabolic rate (Jozefiak et al., 2004).

21.6.5 Calcium and phosphorus

The major site of calcium and phosphate absorption is the upper jejunum (Levin et al., 1983). Calcium can be transported through active, transcellular, or passive, paracellular transport mechanisms (Dimke et al., 2011).

Transcellular transport involves entry across the cell wall via transient receptor potential vanilloid (TRPV) 5 or TRPV6 transporters, diffusion through the cytoplasm by binding to Calbindin D_{28k}, and extrusion at the basolateral membrane via plasma membrane calcium ATPase 1b (PMCA1b, ATP2B1) and sodium/calcium exchanger 1 (NCX1, SLC8A) (Dimke et al., 2011; Hoenderop et al., 2005). In laying hens, new candidates have been identified for transcellular Ca transport, including TRPV2, TRPC1, and TRPM7 located on the brush border membrane, and two additional plasma membrane Ca ATPases: ATP2B2 and ATP2B4 located at the basolateral membrane (Gloux et al., 2019). The presence of TRPV6 as Ca entry point is controversial in GITs of chickens (Gloux et al., 2019; Proszkowiec-Weglarz and Angel, 2013; Rousseau et al., 2016; Yang et al., 2011).

Paracellular transport is characterized by ion movement from the intestine to the blood along the chemical gradient through tight junctions (Dimke et al., 2011). Tight junction proteins (TJP)1, 2, and 3, claudin 1, 2, 10, and 12, occludin, and junctional adhesion molecule 2 have been suggested to play a role in paracellular Ca transport in laying hens (Gloux et al., 2019).

Similarly to Ca, P transport involves uptake of the mineral through the apical brush border membrane by Na-dependent transporter, translocation across the cells and exit at the basolateral membrane (Tenenhouse et al., 1998). In contrast to the well-known Ca transporter system, little is known about P diffusion through cells and extrusion into blood (Marks et al., 2010; Tenenhouse, 2005).

TABLE 21.13 Composition of volatile fatty acids, pH, and water in cecal content of domestic and wild birds.

Species	Water (%)	pH	Lactic acid	Volatile fatty acids			
				Acetic	Propionic	Butyric	Total

Adapted from Goldstain (1989) and Jozefiak et al. (2004).

In mammals, three classes of Na-dependent P transporters have been identified with class one (Na/PI) being predominantly expressed in the brush border membrane of kidneys, type two (Na/PII) expressed in both renal (IIa and IIc) and intestinal (IIb) epithelium, and type III (PIT1 and PIT2) expressed in most tissues in mammals with predominant presence in kidney (PIT2) and intestine (PIT1) (Marks et al., 2010; Miyamoto et al., 1997; Murer et al., 2000; Tenenhouse, 2007; Tenenhouse et al., 1998). Presence and changes in expression of Na/PIIb (SLC34A2) and PIT1 (SLC20A1) during development and in response to dietary factors in the small intestine of chickens has been characterized (Ashwell and Angel, 2010; Nie et al., 2013; Olukosi et al., 2011; Proszkowiec-Weglarz et al., 2019; Yan et al., 2007). However, the exact role of PIT1 has not been well defined in birds. A hypothetical model of transcellular and paracellular Ca and P transport in poultry is shown in Figure 21.18.

Calcium absorption is influenced by the vitamin D hormone 1,25-dihydroxyvitamin **D_3** ($1,25(0H)_2D_3$) interacting with either cytoplasmic or nuclear vitamin D receptor. It is believed that stimulation of Ca absorption requires active vitamin D synthesis, an increase in gene expression of intestinal Ca transporters, and increase in Calbindin D_{28K} synthesis. Feeding chickens a Ca− or P-deficient diet, repleting vitamin D-deficient chickens with vitamin D, or injecting $1,25(0H)_2D_3$ causes an increase in plasma membrane calcium pump mRNA in the duodenum, jejunum, ileum, and rectum (Cai et al., 1993). A study in white leghorn chicks showed that vitamin D can significantly affect P transfer in all segments of small intestine (Wasserman and Taylor, 1973).

21.6.6 Potassium and magnesium

The absorption and secretion of potassium (K) and magnesium (Mg) in the GIT of broilers has been characterized by Van Der Klis et al. (1990). K and Mg are secreted in the duodenum. In addition, there is some secretion of Mg in the ileum and rectum. The major site of absorption for these minerals is the proximal jejunum, with some absorption of Mg occurring in the gizzard. This coincides with the fact that dry matter spends approximately 25% of its time in the jejunum. There is little absorption of these minerals beyond the jejunum.

21.6.7 Water, sodium, and chloride

Water is absorbed throughout the small and large intestine and the ceca. Absorption of water occurs as a secondary response to the active absorption of other compounds such as glucose, Na, and amino acids.

Birds generally secrete a very dilute urine. Urine can travel into the coprodeum and, via antiperistalsis, continue orad into the ceca. Note that there are exceptions, such as the ostrich, which can concentrate urine and has no movement of urine back into the colon (Elbrønd et al., 2009). The excreta of cecectomized chickens are higher in water, indicating that the lower part of the intestinal tract has an important role in water and salt balance.

Sodium is secreted in the proximal portion of the intestinal tract (Van Der Klis et al., 1990). The major sites for Na absorption are the proximal jejunum followed by the colon. The ileum also has a small capacity for Na absorption.

(2019).*

The coprodeum, colon, and ceca serve an important role in Na, chloride (Cl), and water balance (Laverty et al., 2006). When birds are fed a low-NaCl diet, there is a net absorption of Na from the coprodeum, colon, and ceca. Na^+ absorption occurs by active transport mediated by apical electrogenic and amiloride-sensitive Na^+ channels and basolateral Na^+ pumps (Na^+/K^+-ATPase) (Figure 21.19). The mucosal lining of the colon and coprodeum consists of simple, columnar epithelium with absorptive epithelial cells, GCs, and mitochondria-rich cells. On a low-salt diet, there is an extensive microvillous brush border present. When fed a high-NaCl diet, absorption of Na^+ from the coprodeum nearly ceases, while in the colon absorption remains high provided a low concentration of hexoses and amino acids is maintained on the mucosal side. There is an increased expression of SGLT in the colon which is associated with increased dietary salt. This represents a dramatic change from electrogenic, channel-mediated Na + transport to organic substrate Na^+ - cotransport consistent with what is observed in the small intestine but not in the mammalian large intestine. When fed a high-salt diet, the colon morphology remains the same, but that of the coprodeum shows a decrease in density and length of microvilli. The adaptation to a low-salt diet is mediated by circulating aldosterone and maximizes Na + transport (absorption). Aldosterone suppresses SGLT expression (Laverty et al., 2001).

In addition, there is also a net secretion of Cl from the coprodeum and rectum, but the secretory ability of the coprodeum disappears in birds fed a high-NaCl diet (Skadhauge, 1989). The secretion of Cl is induced by serotonin (Hansen and Bindslev, 1989). Receptor antagonists for 5-HT_{1A}, 5-HT_{1B}, 5-HT_{1C}, 5-HT_{1D}, 5-HT_{2}, 5-HT_{3}, adrenergic, cholinergic, and histaminergic receptors were unable to block the response. However, the second messenger for serotonin-induced chloride secretion is cAMP (Hansen and Bindslev, 1989).

The absorption of Na and secretion of Cl within the lower gut is regulated by plasma aldosterone (Clauss et al., 1991). Increases in plasma aldosterone stimulate amiloride-sensitive Na uptake in the coprodeum, rectum, and ceca. Feeding high-NaCl diets causes a decrease in plasma aldosterone, and a decrease in amiloride-dependent Na absorption. Furthermore, there is a switch to amiloride-independent hexose/amino acid stimulated Na-transport within the rectum and cecum, but a cessation of Na-transport in the coprodeum. The hexose/amino acid stimulated Na-transport in the rectum functions to counteract the osmotic water loss due to feeding a high-NaCl diet (Skadhauge et al., 1985), and is stimulated by increases in plasma arginine vasotocin and/or prolactin (Arnason and Skadhauge, 1991).

21.6.8 Vitamins

Vitamin A and carotenoid metabolism in chickens is very similar to that of humans (Diaz-Gomez et al., 2017). Fat-soluble vitamin A and carotenoids follow the fate of lipids in the upper GIT, and their absorption occurs in the upper half of the small intestine (Borel, 2003). It has been long assumed that carotenoids are absorbed by a passive diffusion process while vitamin A absorption occurred via energy dependent transport (Reboul, 2013). During the

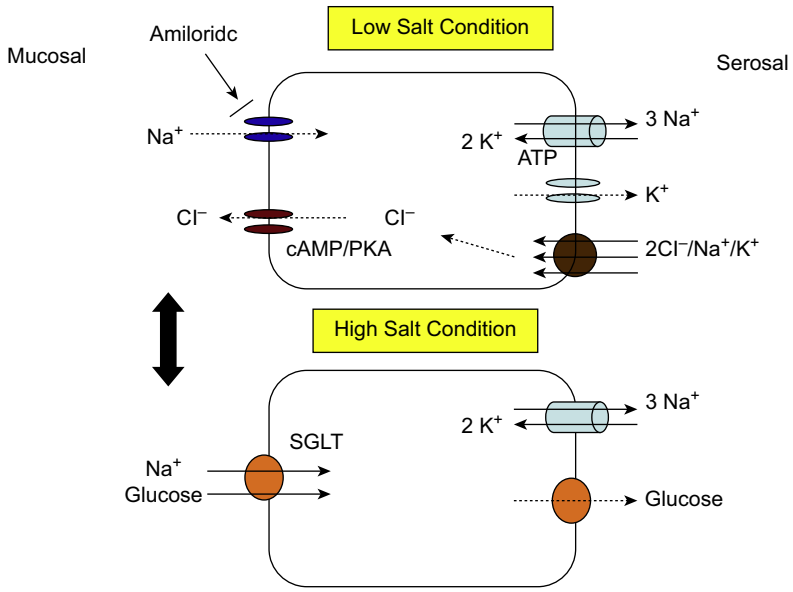

FIGURE 21.19 Working model for transport pathways in the hen lower intestine. The two panels show the different Na + absorptive pathways for tissues from low and high salt-acclimated hens. Example shown is for colon and would represent the extreme conditions of salt intake, in which there is a complete transition in transport pattern. SGLT-mediated glucose uptake and basolateral release via GLUT transporters is representative of several organic substrate cotransporter systems (amino acids and hexoses) expressed in the high salt-acclimated tissues. The diuretic amiloride blocks low salt ENaC channels at concentrations of 10^{-5} M. Potassium channels, shown on the basolateral or serosal side, may also be present on the apical surface and mediate K^+ secretion. For simplicity, the CJ-secretory pathway is shown only in the low salt condition, even though it is also observed under high salt. *Reprinted from Laverty et al. Copyrights 2006 by Elsevier.*

digestion process, carotenoids and fat-soluble vitamins are incorporated with lipids into mixed micelles (Borel, 2003). Retinol (vitamin A) is believed to be transported at the brush border membrane by stimulated by retinoic acid 6 protein and RBP4-receptor 2 while carotenoids are transported by scavenger receptor class B type I, cluster determinant 36 (CD36), and NPC1L1 (cholesterol membrane transporters) in the intestine (Figure 21.20, Reboul, 2013). In the enterocytes, transport of retinol and its metabolites involves retinoid-binding proteins while a carotenoid-binding protein has not yet been identified (Reboul, 2013). Major fractions of vitamin A and carotenoids are incorporated into chylomicrons and secreted into the lymph on the basolateral side of enterocytes.

Absorption of vitamin B-6 occurs throughout the small intestine, but primarily in the duodenum (Heard and Annison, 1986). Absorption can also occur in the crop and cecum, but this is minimal. The mechanism of absorption is passive diffusion. Although microbial synthesis of vitamin B-6 does occur, this is not important in meeting a bird's vitamin requirement.

Members of the vitamin E family, such as dietary alpha tocopherol, nonalpha-tocopherols, and tocotrienols, are absorbed by intestinal cells by passive diffusion and receptor-mediated transport, and are delivered to the lymph via chylomicrons (Schmolz et al., 2016).

Transport of folic acid in the intestine is carried out by a specific folate transporter under acidic conditions. Three major folate transporters have been identified in the intestinal cells including folate receptor, the reduced folate carrier, and the proton-coupled folate transporter (Steinberg, 1984). The reduced folate carrier and proton-coupled folate transporter are widely expressed in the small and large intestine of laying hens (Jing et al., 2009, 2010). Functional studies have shown that folic acid is absorbed in all regions of the intestine with greater transport activity in the upper half of the small intestine while transport of folic acid in the ceca is reduced, indicating the role for bacterially derived folate as an alternative source of folate (Tactacan et al., 2011).

21.7 Age-related effects on gastrointestinal function

The small intestine grows rapidly during the later days of incubation, increasing from 1% of body weight at day 17 to 3.5% at hatch (day 21), followed by a two- to four-fold increase in intestine length through 12 days posthatch (Uni, 2006). Villi grow in length near the end of incubation and increase in size and number following hatch. Duodenal villus growth is nearly complete by day seven, whereas in the jejunum and ileum, growth continues beyond 14 days of age. Unlike in mammals, in which most enterocyte proliferation occurs within the crypts, in poultry, proliferation occurs along the length of the villi. Enterocyte migration to the tip of the villi takes three days in four-day-old chicks and four days in older birds.

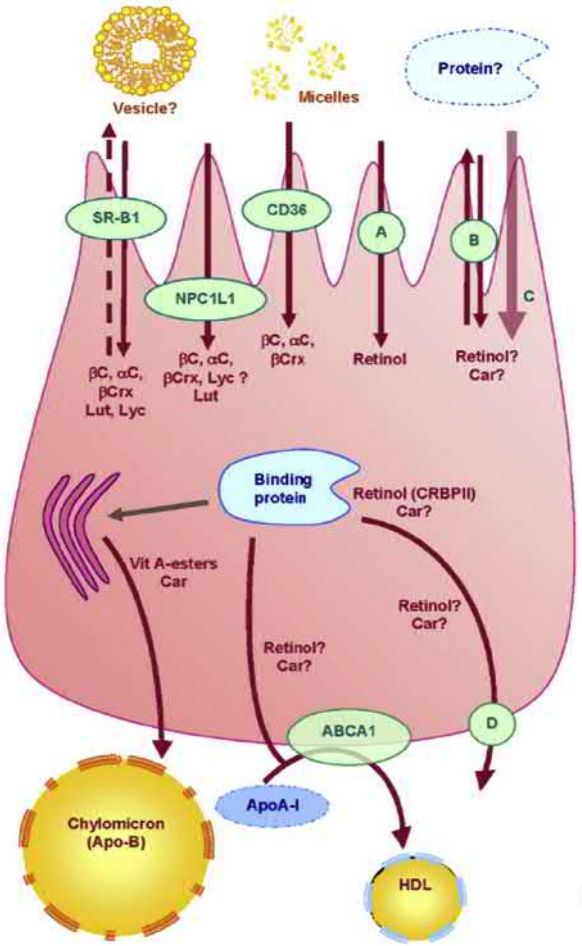

FIGURE 21.20 Proteins involved in uptake, transport, and secretion pathways of vitamin A and carotenoids across the enterocyte. *A*, retinol putative specific transporter; *B*, unidentified apical transporter; *C*, passive diffusion; *Car*, carotenoids; *D*, unidentified basolateral efflux transporter; *Lut*, lutein; *Lyc*, lycopene; *Vit*, vitamin; *αC*, α-carotene; *βC*, β-carotene; *βC*, β-cryptoxanthine; ? = putative pathway. Carotenoids are captured from mixed micelles by apical membrane transporters: SR-BI, CD36, and NPC1L1. Apical membrane proteins involved in apical uptake of retinol have not yet been identified. A fraction of vitamin A and carotenoids may then be effluxed back to the intestinal lumen via apical membrane transporters (SR-BI and possibly other transporters). Another fraction is transported to the site where they are incorporated into chylomicrons. Some proteins may be involved in intracellular transport of carotenoids, but none has been clearly identified. Conversely, CRBPII has clearly been described as involved in intracellular transport retinol. Retinyl esters and carotenoids are secreted in the lymph into chylomicrons, while a part of the more polar metabolites may be secreted by the portal route. It is suggested that free retinol can also be secreted at the basolateral side via ABCA1 (apoAI pathway). *Reprinted from Reboul et al. Copyrights 2013 by the authors. It was hypothesized that the postnatal growth rate is at least partially determined by the differential growth of various organs (Lilja, 1983). The intestinal tract grows rapidly following hatch, with small intestine length increasing by 2.5 cm/d in modern broilers (Schmidt et al., 2009). The most of the posthatch growth (70% of the total length) occurs between day two and seven with plateau phase between day 7 and 14, and second elongation period between day 14 and 28 in broiler chickens (Schmidt et al., 2009).

With regards to pancreatic enzyme activity within the intestines, trypsin, protease, and amylase activity increases rapidly during the first 21 days posthatch in turkey poults (Krogdahl and Sell, 1989) and during the first 14 days posthatch in broiler chickens (Nitsan et al., 1991). However, lipase activity does not begin to increase until after 21 days of age. Feeding a high-fat diet did not significantly increase lipase activity until after 21 days of age. At least during the first few weeks posthatch, it appeared that lipase activity may be a limiting factor in digestion.

Several notable changes have been found in the development of nutrient transport systems during ontogeny in broilers (Obst and Diamond, 1989). During the first week posthatch, proline uptake by the small intestine is high relative to glucose uptake. Because the relative growth rate of broilers is greatest during the first week, it appears that amino acid uptake may parallel this growth pattern. The uptake of glucose displays a transitory increase during week two. This increase is hypothesized to be a result of a switch from lipid metabolism to carbohydrate metabolism due to depletion of the yolk reserves. Because of the allometric growth of the intestine, during the second week posthatch, the intestine displays a decrease in size relative to body weight. This may be a second reason for the increase in uptake of glucose occurring at this time. There is a transitory increase in proline uptake during week six. This increase parallels the first postjuvenile molt and a rise in absolute growth rate.

Interestingly, the intestinal uptake capacity of broilers closely matches a bird's nutrient needs. This contrasts with results in mammals, where uptake far exceeds the animal's needs. It remains to be determined whether this may indicate that nutrient uptake represents a potential constraint for increased growth in broilers, or whether it means that broilers are better allocating resources.

Feeding immediately posthatch stimulates intestinal development. Delaying feed for 24–48 h decreased villi length, enterocyte migration rate (Geyra et al., 2001), and enterocyte number but increased GCs producing acid and neutral mucin (Uni et al., 2003).

21.8 Gastrointestinal microbiota

Most information about avian microbiota comes from studies using broiler chickens and to a lesser extent, laying hens. The GIT of chickens harbors complex microbial communities (bacteria, fungi, archaea, protozoa, and viruses) dominated by diverse bacterial populations (Wei et al., 2013). Due to anatomical differences between birds

and mammals (with a few exemptions, a shorter GIT and faster digesta transit), the microbiota is different in comparison to mammals (Pan and Yu, 2014). Most of the bacteria in the GIT are considered commensal with benefits but also a cost to the host (Dibner and Richards, 2005; Gaskins et al., 2002). Microbiota of the GIT plays an important role in health, nutrition, host physiology regulation, GIT development, and growth. It is also involved in competitive exclusion of pathogens and nonindigenous microbes, immune stimulation and programming, contribution to host nutrition by producing energy and nutrients such as vitamins, amino acids, SCFAs, and in metabolism of host nitrogen compounds (Clavijo and Florez, 2018; Rehman et al., 2007; Shang et al., 2018). The cost to the host of harboring commensal microbiota is related to increased mucus production and secretion, increase in epithelial cell turnover, a more developed immune system, and increased production of IgA. These processes increase the demand for energy and protein from the host (Shang et al., 2018). Chicken microbiota can also be a source of pathogens such as *Salmonella enterica*, *Campylobacter jejuni or coli*, *Escherichia coli*, and *Clostridium perfringens* that pose a threat to public health (Kumar et al., 2018; Mancabelli et al., 2016; Oakley et al., 2014).

The gastrointestinal microbiota can also be classified as the luminal microbiota residing in the lumen and the mucosal microbiota attached to the epithelial cells. The microbiota present in the lumen is influenced by available nutrients, physical properties of the digesta, presence of antimicrobial factors and feed passage rate, while mucosal microbiota is restricted by host factors, such as expression of specific adhesion sites, secretion of immunoglobulin, and mucin production rate (Borda-Molina et al., 2018; Jeurissen et al., 2002; Shang et al., 2018). Both microbiota populations influence each other and can be altered by diet (Jeurissen et al., 2002; Shang et al., 2018).

The composition of the gut microbiota can be affected by various factors such as age of birds, chicken type and breed, anatomical location, maternal factors, sex of the birds, diet and feeding regime, environment (housing, hygiene, temperature, litter quality and age, as well as climate and geographical location), stress, or medication (Clavijo and Florez, 2018; Kers et al., 2018, Figure 21.21). Moreover, the gastrointestinal microbiota can be modulated by many factors including probiotics, prebiotics, synbiotics, organic acids, phytogenics, bacteriophages, and antimicrobial peptides (Clavijo and Florez, 2018; Gadde et al., 2017; Pourabedin and Zhao, 2015, Figure 21.22). All of which are also considered as alternatives to antibiotic growth promoters (Gadde et al., 2017).

The GIT of chickens has been considered to be sterile at hatch. However, recent data indicate that one-day old chicks carry a community of microorganisms in their intestinal tract (Ballou et al., 2016; Kumar et al., 2018)

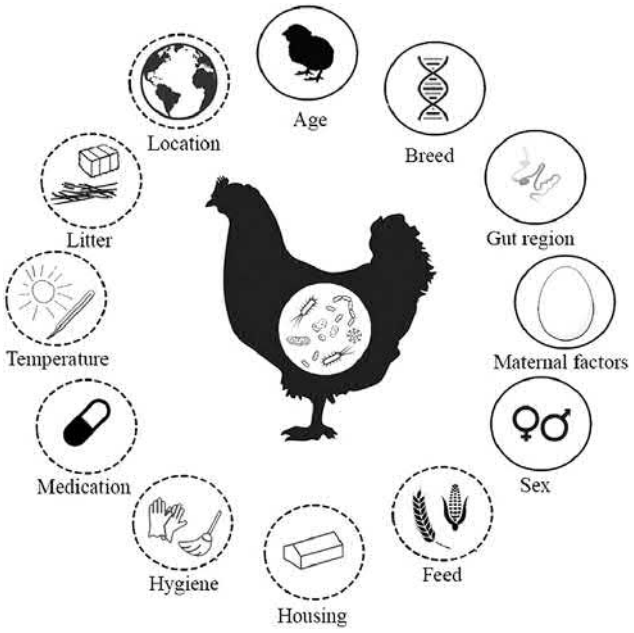

FIGURE 21.21 Factors that affect the intestinal microbiota composition of chickens. Factors found in the literature that determine the development of the intestinal microbiota in broiler chickens. *Solid line* indicates host characteristics, *dashed line* indicates environmental factors. The gut regions comprise the crop, proventriculus, gizzard, duodenum, jejunum, ileum, caeca, large intestine, and cloaca. Maternal factors include horizontal transmission, vertical transmission, and maternal antibodies. *Reprinted from Kers et al. Copyrights 2018 by the authors. coming directly from the oviduct of the mother or from the egg management and incubation environment, through the pores in the eggshell (Cason et al., 1994; Gantois et al., 2009; Roto et al., 2016). After hatch, colonization of the GIT evolves rapidly in a process of ecological succession. Newly hatched chicks are exposed to microbes from the hatchery environment, human handlers, transport boxes, and transport vehicles before they are exposed to farm and feed microbes (Stanley et al., 2013). In the ileum, the number of bacteria increases from 10^8 CFU per g of digesta on day one posthatch to 10^9 CFU and 10^{8-9} CFU per g of digesta 3 and 42 days after hatch, respectively (Chambers and Gong, 2011). In the ceca, the number of bacteria increases from 10^{10} to 10^{11} and 10^{10-11} CFU per g of digesta 1, 3, and 42 days after hatch, respectively (Chambers and Gong, 2011). The first 14–21 days posthatch are considered as the developmental stages of microbiota and are characterized by transient changes in bacterial composition in the GIT. The intestinal microbial richness defined as the number of different microbial taxa, increases during the first week posthatch and the individual variation in microbiota composition decreases with chicken age (Ballou et al., 2016; Crhanova et al., 2011; Danzeisen et al., 2011). Chicken intestinal microbiota colonization and maturation is influenced by diverse microbial communities carried by poultry feed (Haberecht et al., 2020). The presence of microbiota in the GIT influences the development, morphology, and the weight of the small intestine and ceca in chickens (Forder et al., 2007; Furuse and Okumura, 1994; Gabriel et al., 2006).

The GIT of chickens is composed of the crop, proventriculus, gizzard, duodenum, jejunum, ileum, ceca, large intestine, and cloaca. Each of these sections plays different metabolic function affecting their microbial community (Shang et al., 2018). The diversity of microbiota in chickens is relatively low in comparison to other animals due to the anatomical and physiological differences between birds and mammals, mentioned earlier. Bacterial communities of the small intestine and ceca differ in alpha diversity indexes such as richness, evenness, numbers of operational taxonomic units or Shannon index (Figure 21.23A). Principal coordinate analysis based on the Unweighted UniFrac (beta diversity) clearly shows separations of bacterial communities between duodenum, jejunum, ileum, and cecum and between mucosal and luminal population of bacteria in each of the gut section (Figure 21.23B author's unpublished data).

The taxonomic composition of chicken microbiota depends on the location in GIT (Table 21.14). The proximal part of the digestive tract (crop, proventriculus, and gizzard) is mainly colonized by Lactobacilli that are responsible for starch decomposition and fermentation (Rychlik, 2020; Shang et al., 2018; Wei et al., 2013). The total number of bacteria decreases from 10^{8-9} in crop to 10^{7-8} CFU per g of digesta in proventriculus and gizzard due to presence of low pH of gastric juices (Yeoman et al., 2012). The composition and complexity of the microbiota increases in distal parts of the GIT. The small intestine, with the ileum being the most studied, harbors bacterial population dominated by three main phyla, Firmicutes, Bacteroides, and Proteobacteria with smaller abundance of Actinobacteria (Shang et al., 2018). In comparison to the ileum, the cecum is populated by the most diverse, rich and stable microbial population with, Firmicutes and Bacteroidetes being the most abundant phyla followed by Proteobacteria and Actinobacteria (Shang et al., 2018; Wei et al., 2013). Cecal microbiota is responsible for digestion of feed particles rich in cellulose, starch, and polysaccharides (Clench and Mathias, 1995; Goldstein, 1989). Based on metagenomic data, cecal bacteria are characterized by high proportion of sequences encoding glycosyl hydroxylases with more than 200 genes of nonstarch polysaccharide degrading enzymes (Sergeant et al., 2014; Waite and Taylor, 2014). Excreta samples are not properly representative of the GIT microbiota due to differential mixing effects and less frequent voiding of the ceca in comparison to the rest of the GIT (Oakley et al., 2014).

Similar taxonomic composition was observed in turkey microbiota, but with different distribution of genera in comparison to chicken microbiota in the GIT (Wei et al., 2013).

The numbers of studies concerning microbiota in wild birds are limited (Grond et al., 2018; Hird, 2017). The microbiota of birds, especially wild birds, can be influenced by migratory behavior, flight capacity, diet, mating system, longevity, and birds physiology (Grond et al., 2018). It is well established that captivity alters the microbiota in mammals, fish, amphibians, as well as in birds due to the dietary, social, and environmental conditions in captivity (Hird, 2017). Excreta samples are most commonly analyzed for wild birds as this is one of the few nondestructive methods to determine avian microbiota (Borrelli et al., 2020). In general, core microbiota of wild birds is very similar to the domesticated chicken with Firmicutes, Bacteroidetes, Actinobacteria, and Proteobacteria been the predominant phyla (Grond et al., 2018). Among arctic migratory birds, Firmicutes and Bacteroidetes are dominant in snow buntings and sanderlings while pink-footed geese excreta are dominated by Proteobacteria. Moreover, bacterial diversity is much higher in buntings and sanderlings in comparison to pink-footed geese (Cho and Lee, 2020). Environmental factors such as urbanization and landscape affect the alpha and beta diversity of gut microbiota in the white-crowned sparrow. Among these birds, "urban" and "rural" microbiota differed with urban communities being driven by host morphology while rural communities were influenced more by environmental factors (Berlow et al., 2020).

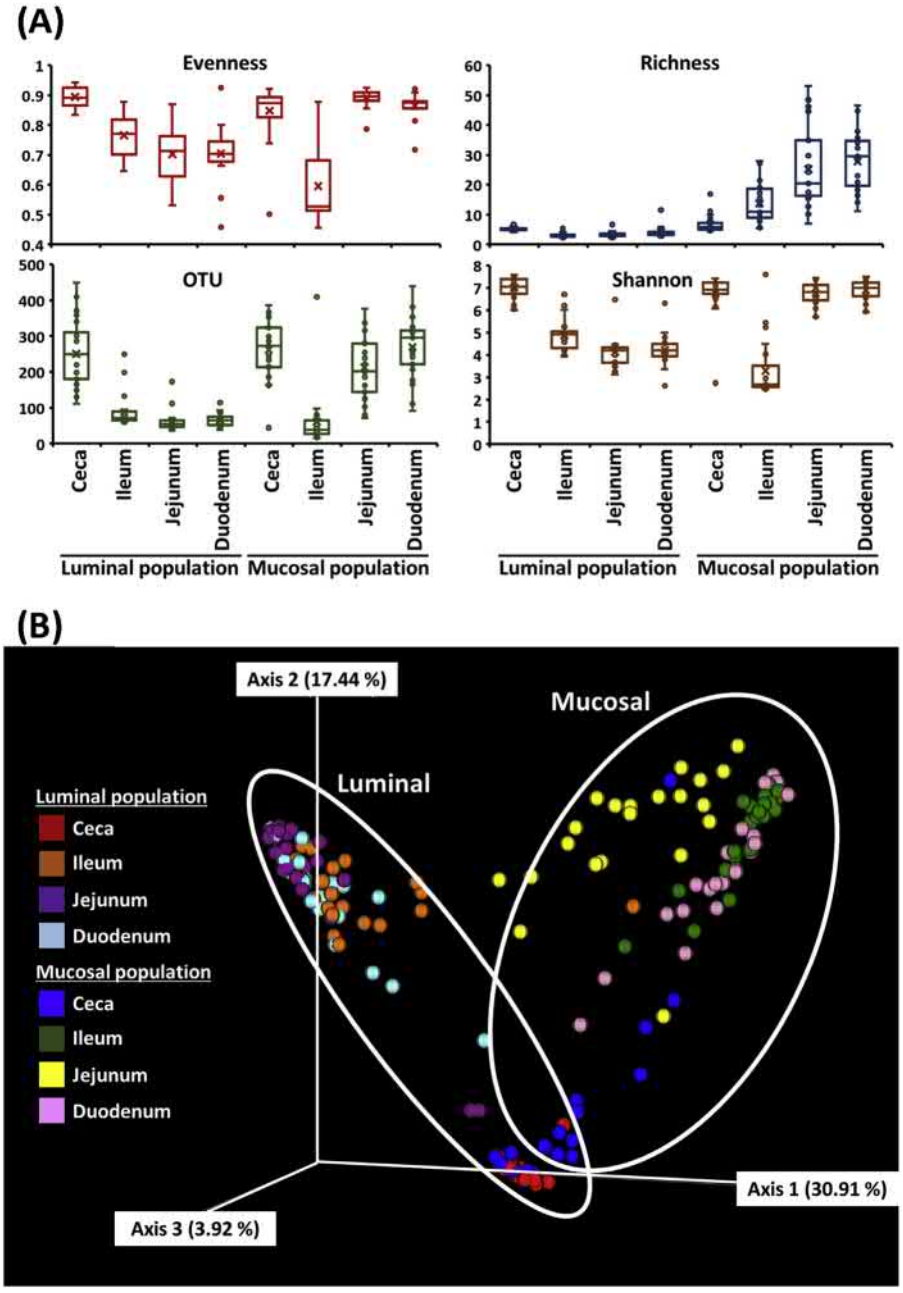

FIGURE 21.23 Alpha and beta diversities of luminal and mucosal population of bacteria in four different parts of chicken gastrointestinal tract. (A) Comparison of evenness, richness, numbers of operational taxonomic units and Shannon index between mucosal and luminal bacterial populations in ceca, ileum, jejunum, and duodenum in broiler chickens. (B) Beta diversity based on Unweighted UniFrac in luminal and mucosal population of ceca, ileum, jejunum, and duodenum in broiler chickens.

Among other wild birds, hoatzins have very well-developed foregut fermenting crop system that contains microbial population functionally analogous to the bovine rumen (Godoy-Vitorino et al., 2008, 2012). In birds, such as carnivores, piscivores, nectarivores, or frugivores, that do not have ceca, the specific function of cecal bacteria is fulfilled by other areas of GIT (Grond et al., 2018).

21.9 Intestinal barrier

In addition to their role in digestion, secretion, and absorption, intestinal cells also form a physical barrier separating the external environment from the internal environment of the host. The intestinal barrier prevents loss of water and electrolytes and entry of antigens and

TABLE 21.14 Spatial distribution of most common and abundant bacteria taxa at phylum and genus level in the gastrointestinal tract of chickens irrespectively of age, diet, or technique used to determine the taxonomy.

GIT location	CFU per g of digesta	Taxonomy level

microorganisms into the body, and allows exchange of molecules between the host and its environment (Brandtzaeg, 2011).

The intestinal barrier is formed by mechanical (mucus layer, glycocalyx, epithelial cells, and tight junction in the paracellular spaces), humoral [defensins and immunoglobulin A (IgA)], immunological (lymphocytes, innate immune cells), muscular, and neurological elements (Bischoff et al., 2014; Okumura and Takeda, 2017). The mucus layer is divided into an outer layer associated with bacteria and loosely attached to the epithelium while the inner layer is characterized by high concentrations of IgA and mucin, and is adherent to the epithelium. In chickens, three transmembrane mucins (MUC4, 13, and 16) and four gel-forming mucins (MUC2, 5ac, 5b, and 6) have been identified (Lang et al., 2006). In comparison to mammals, chickens lack gel-forming MUC19 and transmembrane MUC3, 12, 15, and 17 (Lang et al., 2006). Chicken mucin genes show differential expression in among the regions of the GIT suggesting that they have specific roles in maintaining mucosal integrity (Forder et al., 2012). MUC2 gene codes for the main secreted mucin in the intestine (Van Klinken et al., 1995a,b) and is exclusively expressed in the small intestine, ceca, and large intestine in birds (Woodfint et al., 2017). MUC2 mRNA expression increases during late embryonic development and early posthatch in chickens and ducks (Zhang et al., 2015) while lack of feed during first 48 h posthatch decreases MUC2 expression in chickens (Proszkowiec-Weglarz et al., 2020). Decrease in MUC2 gene expression is associated with deterioration of intestinal mucosa (Forder et al., 2012) and can lead to spontaneous inflammation of the small intestine (Van der Sluis et al., 2006). Mucus secretion from GCs is regulated by the host sensing the presence of gut microbes or their metabolites (Kim and Ho, 2010).

Mucin can be classified into neutral mucin, sialic acid containing mucin, and ester sulfate containing mucin (Deplancke and Gaskins, 2001). Before hatch, an acidic type of mucin is predominantly produced, while after hatch, neutral mucin is coproduced in GCs (Cheled-Shoval et al., 2014). The physiological relevance of the distinct mucin types is not well understood, but it has been suggested that it can influence their protective properties (Deplancke and Gaskins, 2001). Acidic mucin protects against bacterial translocation because it appears to be less degradable by bacterial enzymes and proteases than other mucin types (Deplancke and Gaskins, 2001).

Mucins provide adhesive sites for IgA, the most abundant immunoglobulin isotype at mucosal sites (Brandtzaeg, 2010) and an important factor in preventing infection and regulating the composition of microbiota (Den Hartog et al., 2016). In birds, IgA is poorly expressed during the first week of life and increases during the second week posthatch (Proszkowiec-Weglarz et al., 2020; Zhang et al., 2015). The function of IgA depends on its transport from lamina propria, where it is secreted, via IgA receptor (pIgR) located on the basolateral side of mucosal epithelial cells (Johansen et al., 1999; Kaetzel, 2005). Similarly to IgA, pIgR expression was upregulated later during posthatch development in birds (Proszkowiec-Weglarz et al., 2020; Zhang et al., 2015).

One of the major components of the intestinal barrier are tight junctions that occur between epithelial cells (Anderson and Van Itallie, 1995; Mitic et al., 2000). Tight junctions are multiprotein complexes that seal the paracellular space between adjacent epithelial cells and regulate the permeability of the intestinal barrier (Awad et al., 2017; Chen et al., 2015). They open and close when exposed to a range of stimuli including, nutrients, absorption processes, hormonal or neuronal signals, various cellular pathways, and inflammatory mediators (Barekatain et al., 2019). A tight junction consists of zona occludens-1, occludins, claudins, and actin-myosin cytoskeletal proteins (Gil-Cardoso et al., 2016). Occludins and claudins are the main transmembrane proteins that contribute to the paracellular seal while zona occludens-1 serves as cytoplasmic plaque proteins that interact with both transmembrane, and cytoskeletal proteins (Fanning et al., 1998; Yu and Turner, 2008). Expression of genes that encode tight junctions is modulated among others, by heat stress, access to feed, feed additives, stocking density, bacterial stimuli, pathogen bacteria, and LPS challenge, and can also differ between slow, moderate, and fast-growing broiler chickens (Chen et al., 2018; Goo et al., 2019; Huang et al., 2019; Li et al., 2015; Liu et al., 2018a, 2018b; Saeed et al., 2019; Shao et al., 2013; Song et al., 2014; Tabler et al., 2020; Uerlings et al., 2018; Yang et al., 2015).

Failure of the intestinal barrier in birds can be caused by oxidative stress, glucocorticoids, poorly digestible protein in the diet, or coccidiosis (Barekatain et al., 2020; Latorre et al., 2014; Tellez et al., 2014; Williams, 2005), and leads to increased intestinal permeability (Bischoff et al., 2014). Intestinal permeability can be altered by several factors including diet, intestinal microflora, stress, diseases, infections, toxins, antibiotics, and short- or long-term fasting, epithelial damage, disruption of tight junctions, and alteration of the mucosa layer (Barekatain et al., 2020; Bischoff et al., 2014; Gilani et al., 2017, 2018a, 2018b; Kansagra et al., 2003; Kuttappan et al., 2015; Schumann et al., 2005). Increased intestinal permeability in chickens is often associated with compromised health and performance, bacterial translocation, coccidiosis, immune activation, and lameness (Chapman, 2014; Chen et al., 2015; Gilani et al., 2016; Wideman et al., 2012). Modern broiler chickens are characterized by higher intestinal permeability in comparison to their ancestors, the red junglefowl (Baxter et al., 2019).

TD Tibial dyschondroplasia
TGF-β Transforming growth factor beta
TRAP Tartrate resistant acid phosphatase
VEGF Vascular endothelial growth factor
VVD Valgus-varus deformity
WNT Wingless-ints.
ZPA Zone of polarizing activity

22.1 Introduction

In vertebrates, the skeleton serves as the main structural framework of the body which supports the attachment of muscles and tendons and protects the internal organs. As the main reservoir of calcium (Ca) and phosphorus (P), the skeleton also maintains mineral homeostasis and acts as repository for different growth factors bound to its extracellular matrices (Clarke, 2008; Moreira et al., 2019). It also acts as an endocrine organ that releases fibroblast growth factor (FGF-23), a hormone that regulates P and vitamin D metabolism acting through kidney (Erben, 2018; Gonciulea and de Beur, 2015; Robling and Bonewald, 2020; Schwetz et al., 2012; Zofkova, 2018) and harbors bone marrow, the body's main site of hematopoiesis and immunity (Okamoto and Takayanagi, 2019). Thus, the skeleton contributes to a variety of physiological functions of the body. In birds, the skeleton has undergone several structural modifications and functional adaptations to support its aerial life and egg laying behavior (Canoville et al., 2019; Novitskaya et al., 2017; Sullivan et al., 2017). Rigid, yet light-weight skeleton with fused cranial, vertebral, and collar bone (wish bone), and the keel sternum attaching pectoral muscles, provide support for flying. The hollow limb bone of flying birds act as extensions of lungs providing additional oxygen and energy during flight (Costain, 2018; Dumont, 2010). On the other hand, some of those skeletal adaptations do not exist in flightless birds such as penguins where the bone are generally dense and heavier to support their diving habits and in some flightless birds the keel sternum is reduced or absent (Zheng et al., 2012).

Skeleton consists of both cartilage and bone with the later constituting the major bulk of adult skeletal tissue while cartilage persist only at some special sites such as joints and intervertebral spaces to protect against friction between adjacent bone. Nonetheless, the cartilage occur transiently in most parts of the skeleton preceding the development of bone. "Stable" or "permanent" cartilage make articular cartilage (AC) of joints and fibrocartilage of intervertebral spaces, whereas the "transient" cartilage

Sturkie's Avian Physiology. https://doi.org/10.1016/B978-0-12-819770-7.00037-2

develop temporarily during long bone formation and fracture healing (Bahney et al., 2019; Chijimatsu and Saito, 2019; Sophia Fox et al., 2009; Staines et al., 2013). Bone morphogenesis occurs in two ways: one, through "intramembranous ossification (IMO)", where the embryonic mesenchymal cells undergo direct ossification to form bone and the other, through "endochondral ossification (ECO)" where a cartilage template develops prior to bone formation (Hall and Miyake, 2000; Yang, 2009). Most flat bone such as skull, mandible, and keel sternum develop through intramembranous processes whereas, the long bone such as axial and appendicular bone develop through endochondral route (Clarke, 2008; Moreira et al., 2019).

22.2 Embryonic skeletal differentiation

Skeletal ontogenesis begins during gastrulation. Different instructive signals emanating locally from the neighboring cells, in the form of gene expression and the production of different growth and transcription factors, act in a highly orchestrated manner to guide embryonic cell migration, their survival, proliferation, and differentiation into prospective skeletal elements (Creuzet et al., 2005; Davey et al., 2018; Le Douarin, 2004; Ros et al., 2000). Both intramembranous and endochondral ossification pathways share many similar growth and signaling factors which facilitate their development and differentiation. However, the ultimate structural differentiation of presumptive skeletal elements and their three-dimensional patterning depend upon the origin and the locations of the responding cell population, the time of action of different growth factors, and the expressions of relevant genes (Kozhemyakina et al., 2015; Schneider, 2018). Some of the major signaling proteins and genes known to play critical roles in the early development of skeleton are: sonic hedgehog (SHH), fibroblast growth factors (FGF), bone morphogenetic proteins (BMP), and wingless-related (WNT) families of proteins, their respective receptors, and several transcription factors such as homeotic (HOX), Runt-related (RUNX), and Sry-related (SOX) genes and proteins (Creuzet et al., 2005; Eames and Helms, 2004; Schneider, 2018; Tickle, 2015). These growth and differentiation factors work through complex interactions involving synergistic, cooperative, and feedback loops. Besides the above-mentioned growth and transcription factors, there can be other secondary signaling factors that are produced locally or downstream; therefore, the commitment to either cartilage or bone lineage depend upon reciprocal and timely interactions between the precursor cells and different signaling proteins and genes (Schneider, 2018; Tickle, 2015).

Craniofacial skeletons develop from cephalic mesoderm that differentiate from neural crest cells (NCC) of the gastrulating embryo. The NCC migrate rostrally in the embryo to pharyngeal arches where they undergo epithelial to mesenchymal transition, a process that involves changes in their cytoskeletal organization and leads to the expression of specific adhesion molecules and glycoproteins, consequential to their subsequent developments (Abramyan and Richman, 2018; Creuzet et al., 2005; Minoux and Rijli, 2010; Olsen et al., 2000; Schneider, 2018). Cell migration and their transitions are regulated by SHH, one of the first signaling proteins of cranial skeletogenesis produced by ectodermal and neuroectodermal cells. The rostral domain of cephalic mesoderm is HOX gene negative that differentiates into parts of cranial skeleton (skull and mandible) through IMO, whereas the HOX gene positive posterior domain develops into parts of craniofacial skeleton (parietal, skull base) through endochondral route. The HOX genes specify the anteroposterior axis of the body structures and axial patterns acting as road maps and are expressed during development of different parts of the embryonic body (Iimura and Pourquié, 2007; Nolte et al., 2019). SHH along with FGF and BMP, produced by neuroectoderm, ectoderm, and pharyngeal endoderm, interact with cranial mesoderm cells and promote their survival, proliferation, condensation, and differentiation into different skeletal primordia (Eames and Helms, 2004; Minoux and Rijli, 2010; Schneider, 2018). The transcription factor RUNX-2 is the master regulator of osteoblast differentiation which helps in making the craniofacial dermal bone (Abramyan and Richman, 2018; Abzhanov et al., 2007; Komori, 2017; Schneider, 2018). WNT is another signaling factor that along with SHH helps in the differentiation of mesodermal cells to osteoblasts and specifies the axial patterning of skeletal rudiments (Day et al., 2005; Kozhemyakina et al., 2015; Rutkovskiy et al., 2016; Wu et al., 2016). Osteogenic differentiation is marked by the production of type I collagen (Col1α) and osteopontin (OP) by the osteoblasts (Abzhanov et al., 2007).

Paraxial and lateral mesoderm cells give rise to axial (vertebral) and appendicular (limb) skeletons respectively, through ECO. Paraxial mesoderm, flanking on either side of the neural tube, undergo somitogenesis and become the precursors of different organs including the axial skeletons (Gilbert and Barresi, 2016). Based on their locations, specific somites give rise to specific vertebral structures. Somites give rise to sclerotome under the influence of SHH produced by the notochord and floor plate neural tube, and differentiate into precartilage through the expression of a transcription factor PAX1 (Gilbert and Barresi, 2016). This differentiation process is supported by a combined action of SHH and the members of BMP, WNT, and FGF families of proteins produced by surface ectoderm and other neighboring cells (Pourquié, 2018; Pourquié et al., 1993). The lateral plate mesoderm, located ventral to intermediate and paraxial mesoderm, give rise to wing and limb skeletons (Creuzet et al., 2005; Eames and Helms, 2004; Gilbert and Barresi, 2016; Tickle, 2015). In chick embryo, the wing and

leg buds develop from lateral plate mesoderm in the levels of somites 15–20 and 26–31, respectively (Davey et al., 2018; Tickle, 2015). During limb bud chondrogenesis, the ectoderm covering the distal part of the limb bud, thicken to form apical ectodermal ridge (AER) and the proximal posterior part of the zone of polarizing activity (ZPA). AER produces FGF8 which instructs the production of other signaling proteins including different other members of FGF family-, BMP, and WNT proteins by the mesodermal cells. These proteins induce mesodermal cells to proliferate, condense, and differentiate into chondrocytes (Berendsen and Olsen, 2015; Davey et al., 2018; Kozhemyakina et al., 2015; Mariani and Martin, 2003; Tickle, 2015). Expression of a Sry-related transcription factor, SOX-9, by the condensing mesoderm is pivotal to chondrocyte differentiation and the establishment of cartilage anlagen. However, at later stages of development, the transcription factor RUNX-2, expressed by the hypertrophic chondrocytes, drives the mineralization of cartilage matrix and its replacement by the bone (Davey et al., 2018; Eames et al., 2003; Hallett et al., 2019; Long and Ornitz, 2013). Meanwhile, ZPA produces SHH that along with HOX gene and WNT helps axial morphing of the limb bud skeletons and determines their anteroposterior, dorsoventral, and proximodistal polarities. Interference of these crucial signaling processes can result in skeletal defects (Abramyan and Richman, 2018; Davey et al., 2018; Maas et al., 2011). Although the avian skeletal differentiation completes by the time of hatch, the post hatch bone growth continues through sexual maturity.

22.3 Cartilage

22.3.1 Cartilage of endochondral bone

During embryonic as well as post hatch development, the longitudinal growth of bone take place through endochondral ossification. In the embryo, the primary ossification begins at the center of the cartilage anlagen, formed by the differentiation of condensed mesoderm of embryonic limb bud, that attracts blood vessels along with osteoblasts to form bone and replace the cartilage. In post hatch avian growth plate (GP), a "reserve" or "resting zone" mesenchymal cells beneath AC, undergo successive transitions to proliferative, prehypertrophic (PH), hypertrophic chondrocytes, and form the cartilage that goes through mineralization and vascular invasion. The chondrocytes in the cartilage undergo chondrolysis and apoptosis while vascular invasion brings in the osteoblasts which lay down bone replacing the cartilage (Figure 22.1). Osteoclasts remodel the newly forming bone. This complex series of development is regulated by many different growth and signaling factors, similar to those involved in embryonic limb development; however, there may be other growth factors which are also participate in post hatch GP development (Eames et al., 2003; Haraguchi et al., 2019; Kozhemyakina et al., 2015; Kronenberg, 2003; Mackie et al., 2008; Samsa et al., 2017; Vortkamp et al., 1996, Table 22.1). BMP, FGF, and Indian hedgehog (IHH) interactively regulate proliferation of chondrocyte precursors and their differentiation to prehypertrophic (PH) chondrocytes through the expression of a transcription factor SOX-9. IHH is produced by PH and early hypertrophic chondrocytes and belongs to the same family of proteins as SHH (Kronenberg, 2003; Provot and Schipani, 2005). BMP helps in proliferation and condensation of prechondrocytic mesenchymal cells, while FGF signaling not only promotes chondrocyte proliferation but also induces their hypertrophy. Chondrocyte proliferation is regulated by parathyroid hormone-related protein (PTHrP) produced by the perichondrium that also helps in long bone growth (Zhao et al., 2002). IHH regulates the expression of PTHrP through a negative feedback loop and promotes chondrocyte hypertrophy (Vortkamp et al., 1996; Wu et al., 2016). Cartilage differentiation is marked by discrete morphological transition of mesenchymal cells to chondrocytes that produce type II collagen and aggrecan. The expression of RUNX-2 by the

TABLE 22.1 Skeletal cell differentiation associated signaling factors and their effects.

Target cells	Signaling factors	Skeletal outcome and cells differentiated	Biomarkers	Morphogenetic processes
Neural crest cell (NCC)-derived mesodermal cells	SHH, FGF, BMP, WNT, RUNX-2↑, HOX (-ve)	Osteoblasts	Collagen I, ALP, OP, Osteocalcin	IMO: Osteogenesis
Mesenchymal stem cells	FGF, BMP, IHH, PTHrP↑, TGF-β, SOX-9 ↑	Articular chondrocytes	Collagen I, Collagen II, Aggrecan	Chondrogenesis (stable cartilage)
Mesenchymal stem cells	FGF, SHH, BMP, WNT, PTHrP ↑, SOX9 ↑	Chondrocytes	Collagen II, Aggrecan	ECO: Chondrogenesis, mesenchymal proliferation ↑, condensation, and chondrocyte differentiation
PH chondrocytes	WNT, IGF-1, FGF, IHH ↑, PTHrP ↓, SOX9 ↓, RUNX-2 ↑	Chondrocyte hypertrophy	Collagen II, MMP, OP, VEGF	ECO: Chondrocyte transition, proliferation ↓, chondrocyte hypertrophy
Hypertrophic chondrocytes	IHH, BMP, RUNX-2↑, VEGF↑	Chondrolysis/chondrocyte apoptosis	Collagen II ↓, Collagen X ↑, MMP	ECO: Matrix mineralization,
Osteoblast and angiogenic precursors	VEGF ↑, RUNX-2 WNT, IHH	Vascularization, Matrix degradation, Osteoblasts	Collagen I, ALP, OP, Osteocalcin	ECO: Matrix degradation, angiogenesis, osteogenesis
Monocytes	M-CSF, RANK/RANKL, PTH, Vitamin D, IHH	Osteoclasts	CA, cathepsin K, MMP, Na^+ K^+ ATPase, TRAP	Osteoclastogenesis, bone resorption and remodeling

ALP, Alkaline phosphatase; *BMP*, Bone morphogenetic protein; *CA*, Carbonic anhydrase II, *ECO*, Endochondral ossification; *FGF*, Fibroblast growth factor; *HOX*, Homeotic gene; *IGF-1*, Insulin-like growth factor-1; *IHH*, Indian hedgehog; *IMO*, Intramembranous ossification; *M-CSF*, Macrophage colony stimulating factor; *MMP*, Matrix metalloproteinases; *MSC*, Mesenchymal stem cells; *Na^+ K^+ ATPase*, Sodium potassium ATPase; *OP*, Osteopontin; *PH*, Prehypertrophic; *PTHrP*, Parathyroid hormone-related protein; *RANK/RANKL*, Receptor activator of NF-kB/RANK-ligand; *RUNX-2*, Runt-related transcription factor 2; *SHH*, Sonic hedgehog; *SOX-9*, Sry-related transcription factor; *TGF-β*, Transforming growth factor beta; *TRAP*, Tartrate resistant acid phosphatase; *VEGF*, Vascular endothelial growth factor; *WNT*, Wingless-ints. Upregulated ↑ and downregulated ↓.

hypertrophic chondrocytes brings about the downregulation of their type II collagen production and the onset of type X collagen production helping in the mineralization of cartilage matrix. RUNX-2 also promotes the expression of matrix-degrading enzymes that include matrix metalloproteinases (MMP) and vascular endothelial growth factors (VEGF) that help vascularization, and the infiltration of osteoblasts and osteoclasts (Kozhemyakina et al., 2015). Several other local and systemic factors including transforming growth factor β (TGF-β), growth hormone, insulin-like growth factor-1 (IGF-1), and thyroid hormones also participate in cartilage growth and development (Mackie et al., 2011; Nilsson et al., 2005; Van der Eerden et al., 2003). Although the cellular succession and their overall regulation are comparatively similar between mammalian and avian GP, the later is a relatively better vascularized organ compared with the avascular mammalian GP. The avian GP contains capillary vessels and cartilage canals penetrating deep into the chondrocyte transition zone (Figure 22.2) and the cartilage columns of avian GP are loosely organized compared with the parallel columns of mammalian GP (Blumer et al., 2004; Pines and Hurwitz, 1991). The cartilage canals serve as conduits for blood vessels and express VEGF and their corresponding receptors. Some of those structural differences likely make poultry GP vulnerable to certain bone problems such as tibial dyschondroplasia (TD), femoral head separation (FHS), and bacterial chondronecrosis with osteomyelitis (BCO), where vascular impediments can factor in their pathogenesis (Huang et al., 2018; Rath et al., 2005; Wideman, 2016). Microvascular clefts and vascular channels also account for hematogenous spread of opportunistic bacteria leading to the pathogenesis of BCO and osteomyelitis (Emslie et al., 1983; Wideman and Prisby, 2011).

22.3.2 Articular cartilage

AC belongs to "stable" cartilage group that protect bone in the joints against friction. AC remains as hyaline cartilage

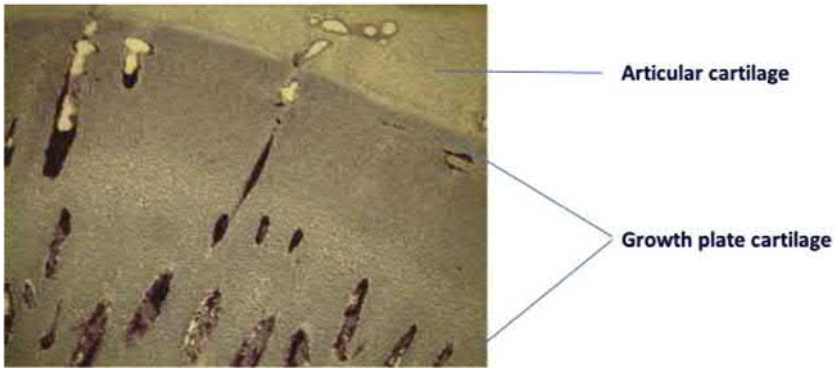

FIGURE 22.2 Growth plate of a two-week-old chicken showing the occurrence of capillary vessels and vascular clefts.

and occurs as a white translucent cap at the end of epiphysis between synovium and the GP. It is a sparsely cellular and avascular tissue rich in type II collagen and aggrecan, and contains up to 80% water. However, the avian cartilage also contains type I collagen, the proportions of which increases with the chicken's age (Eyre et al., 1978). Articular chondrocytes produce some special proteoglycans which provide lubricity to the AC. The articular chondrocytes, likely originate from a different lineage of mesenchymal cells than GP chondrocytes, following the development of joint cavity (Chijimatsu and Saito, 2019; Staines et al., 2013). The articular chondrocytes are terminally differentiated and do not undergo hypertrophy or mineralization unlike the transient cartilage of GP. Damage to AC can result in the development of degenerative joint disease such as arthritis, since this type of cartilage is difficult to heal (Li et al., 2015). There are very limited studies on the biology of avian AC.

22.4 Bone

22.4.1 Cellular components

Bone is the largest component of skeleton; it is a complex tissue consisting of cells and matrices. Osteoblasts, osteocytes, and osteoclasts are three major cell types of bone which contribute to its formation, resorption, and remodeling, therefore, responsible for maintaining the bone mass. Under normal physiology, the bone resorption and formation are coupled, and regulated by the interactions of osteoblasts and osteoclasts (Florencio-Silva et al., 2015; Moreira et al., 2019). Osteoblasts differentiate under the regulation of a transcription factor RUNX-2 and produce type I collagen, osteopontin (OP), alkaline phosphatase, and several other proteins that regulate bone mineralization (Clarke, 2008; Moreira et al., 2019; Murshed, 2018). Osteoblasts work on bone surfaces and are subject to regulation by local factors such as BMP, TGF-β, platelet-derived growth factor, FGF, and many systemic factors including growth hormone, IGF-1, thyroid hormone, calcitonin, parathyroid hormone (PTH), vitamin D3, and the sex steroids many of which support their proliferation and stimulate matrix production (Florencio-Silva et al., 2015; Rath et al., 2000; Rutkovskiy et al., 2016). Calcitonin promotes bone formation by osteoblasts and inhibits bone resorption, whereas PTH, acting through osteoblast, stimulates osteoclastic bone resorption (Goltzman, 2018; Silva and Bilezikian, 2015). Vitamin D affects bone mineralization through stimulation of osteoblast activities and its proliferation (van Driel and van Leeuwen, 2017; Zofkova, 2018).

Osteocytes are mature osteoblasts which reside in the lacunae of the Haversian system entrapped in mineralized bone matrix and communicate with other osteocytes and osteoblasts through dendritic processes extending through canaliculi (Dallas et al., 2013; Semeins et al., 2012). The actions of various growth factors, WNT, BMP, and TGF-β, are responsible for the transition of osteoblasts to osteocytes (Bonewald, 2011; Florencio-Silva et al., 2015). Osteocytes do not make bone but control the bone remodeling process through their interaction with both osteoblasts and osteoclasts, and regulate bone mass through their mechanosensory function (Bonewald and Johnson, 2008; Turner et al., 2009). Mechanical stimulation enables osteocytes to produce secondary messengers such as prostaglandin E2, nitric oxide, and several kinases which promote bone formation and improve bone strength (Turner et al., 2009; Zofkova, 2018). Osteocytes produce FGF-23 and osteocalcin (OC), the former acts through kidney to maintain phosphorus homeostasis and the latter regulates energy metabolism (Moser and van der Eerden, 2018; Robling and Bonewald, 2020; Turner et al., 2009).

Osteoclasts are multinucleate bone resorbing cells which are responsible for bone remodeling throughout life (Feng and Teitelbaum, 2013; Gay and Weber, 2000; Okamoto and Takayanagi, 2019). Osteoclasts differentiate from myeloid lineage mononuclear cells by fusion under the influence of M-colony stimulating factor (M-CSF) and through the activation of receptor activator of NF-κB (RANK) by RANK ligand (RANKL), a transmembrane

protein belonging to tumor necrosis factor (TNF) super family and produced by the osteoblasts. (Feng and Teitelbaum, 2013; Hiyama et al., 2019; Ono and Nakashima, 2018). However, there are many other factors such as interleukin-6, TGF-β, and reactive oxygen species, which also promote osteoclast activities. Osteoclasts have ruffled border through which they interact with bone surface and produce H^+, Cl^- ions, catalytic enzymes such as cathepsin K, MMP, carbonic anhydrase, and tartrate resistant acid phosphatase that hydrolyze and resorb bone matrices (Clarke, 2008). PTH, 1, 25 dihydroxy vitamin D3, calcitonin, glucocorticoid, estrogen, prostaglandins, cytokines, interleukins 1 and 6, and TNF-α are some of many factors that regulate osteoclast activities (Okamoto and Takayanagi, 2019; Ono and Nakashima, 2018). Calcitonin decreases osteoclast activity whereas PTH enhances it. Calcitonin and PTH work in a feedback loop to regulate serum calcium levels and osteoclast activity. Osteoclasts are responsible to resorb "medullary bone" which is a special bone that forms in the bone marrow cavities of hens under the regulation of estrogen and provides Ca for egg shell formation (Whitehead, 2004). Imbalance between osteoclast and osteoblast activities lead to changes in bone volume due to increased bone resorption by osteoclasts causing osteoporosis in laying hens (Jendral et al., 2008; Whitehead, 2004). Conversely, dense bone may result from low osteoclast activities leading to "osteopetrosis". Bone resorption ends with the death of osteoclasts, stimulated by calcitonin and other factors such as estrogen (Chen et al., 2018b; Ono and Nakashima, 2018).

22.4.2 Bone tissue

Bone is a dynamic tissue subject to regulation by intrinsic physiological factors and extrinsic elements such as physical activity, mechanical stress, and gravity (Setiawati and Rahardjo, 2019). Externally, bone is covered by a fibrous sheath of connective tissue called "periosteum" which contains the precursor cells of osteoblasts and blood vessels. Periosteum helps in the radial growth of bone and fracture repair. The majority mass of bone is its mineral matrix called hydroxyapatite [Ca_{10} $(PO_4)_6(OH)_2$] that makes up to 65−67% of mature bone in chickens (Rath et al., 2000). The organic matrix, called osteoid, is predominantly type I collagen that constitutes up to 85−90% of its mass and the rest consisting of several proteins that include minor collagens, proteoglycans, OP, matrix-Gla protein (MGP), and osteocalcin (OC) some of which, regulate bone mineralization (Clarke, 2008; Murshed, 2018). Collagen forms the primary scaffold of bone tissue and provides oriented support for the mineral matrix. Based on collagen orientations, the bone are termed as "woven" or "lamellar." The woven bone are immature bone with loosely organized collagen fibers and hence have lower mechanical strength and form during early stages of bone development, for instance, during intramembranous ossification and fracture healing. The "lamellar bone", on the other hand, are mature bone with collagen fibrils organized and oriented as parallel sheets or lamella. With respect to their structures, the bone are termed as "cortical" or "cancellous" bone. Cortical or "compact" bone are thick and dense bone compared to their counterpart, "cancellous" or "trabecular" bone which arrange in lattice or spongy structures. Both cortical and cancellous bone are made up of lamellar bone. The diaphyseal shafts of both tibia and femur, and the outer surface of many bone are cortical bone, whereas the metaphyseal parts of many long bone contain cancellous bone. Flat bones (skull, keel sternum) contain large amounts of cancellous bone. Compared with cortical, the cancellous bone are less calcified and contain many osteoblasts therefore, play a larger role in metabolic functions of the bone (Clarke, 2008; Florencio-Silva et al., 2015). Haversian systems are made by concentric rings of lamellar bone that run lengthwise down the axis of cortical bone and supply blood to the bone and the osteocytes residing in the Haversian system. As mentioned earlier, the birds have a type of specialized bone called "medullary bone" which exclusively form in the marrow cavities of egg laying birds (Bar, 2009; Canoville et al., 2019; Squire et al., 2017). Medullary bone are woven bone that supply calcium for egg shell formation through osteoclastic resorption (Canoville et al., 2019; Hadley et al., 2016; Whitehead, 2004). Calcification of bone takes place at discrete sites of collagen matrix initiated by the deposition of Ca^{+2} and phosphate ions on the osteoid leading to hydroxyapatite formation (Moreira et al., 2019). Membrane bound matrix vesicles, produced by osteoblasts and hypertrophic chondrocytes containing calcium mineral particles and alkaline phosphatase, facilitate the mineralization process (Kerschnitzki et al., 2016). Several other proteins in the organic matrix including MGP, OC, and OP regulate mineralization process (Murshed, 2018). Mineralization of bone is also controlled by PTH, calcitonin, and vitamin D through their effect on plasma Ca levels. PTH increases plasma Ca levels through bone resorption, whereas calcitonin decreases bone resorption and vitamin D increases intestinal absorption of Ca (Fleisch, 1997). Mineral matrix provides compressive strength and mechanical rigidity, whereas the collagen matrix provides tensile strength (Viguet-Carrin et al., 2006). The overall bone strength, however, does not depend solely upon their matrix content but also on the shapes and sizes of the bone, the distribution and the microarchitecture of their materials (Cole and van der Meulen, 2011; Fleming et al., 1998; Rath et al., 2000). Bone with similar material content but with different shapes and material structures (cortical or cancellous), and molecular properties of their constituents, for example, collagen crosslinks can differ in their strengths (Knott and Bailey, 1999). Compromised bone strength can be a

welfare issue that leads to bone deformities and breakage in both meat-type and egg layer poultry. In young broiler chickens, the leg bone deformity and lameness are thought to be related to the lack of maturity of bone making them weak to support the rapidly growing body weight, whereas in older laying hens the fractures can be due to osteoporosis (Sanchez-Rodriguez et al., 2019; Thorp, 1994; Webster, 2004). The bone of younger birds are stiff and less ductile likely, due to low content of collagen crosslinks (Rath et al., 2000). In osteoporotic hens, excessive loss of matrix increases the porosity of cortical bone and increases their vulnerability to breakage. Flying birds usually have pneumatized and high-density bone (Dumont, 2010). The hollow bone of the wing, containing struts and ridges in the medullary cavity, not only provide better buoyancy but also torsional strength for flight (Dumont, 2010; Novitskaya et al., 2017; Sullivan et al., 2017). Besides, the hollow bone are connected to air sacs which allow birds to oxygenate their blood while inhaling and exhaling and thus, provide extra energy during flight (Costain, 2018).

22.5 Poultry bone disorders

Genetics, nutrition, metabolism, infection, and housing conditions are some of the factors that underlie several poultry skeletal problems. Whereas the genetic mutations can cause structural and metabolic defects, there are several bone problems in commercial poultry that arise because of nutritional deficiencies, infection, malabsorption, physical inactivity, and poor housing and hygienic conditions (Julian, 1998; Knowles et al., 2008; Rodriguez-Navarro et al., 2018; Thorp, 1994, Figure 22.3).

In young, meat-type poultry, lameness-related leg bone problems predominate, whereas in prolific egg layers, osteoporosis and cage layer fatigue occur in older birds as a result of structural loss of bone leading to bone fragility that decreases their locomotion and increases morbidity and mortality rates. Hypoactivity increases the chances of bone weakness since mechanical loading of bone is essential for its optimal function including bone mass preservation, mineralization, and growth. Chicken embryos subjected to experimental immobilization show bone abnormalities including abnormal expressions of genes associated with bone development (Nowlan et al., 2010), whereas moderate weight loading increases mineralization and enhances vascularization of GP of young chickens (Reich et al., 2005). In young fast-growing chickens and turkeys, several leg problems appear to be associated with the proximal aspects of their leg bone which are the weight bearing ends. Cage confinement enhances bone loss in egg laying hens (Aguado et al., 2015) while increased physical activities of hens raised in aviary improve bone strength and biomechanical properties (Regmi et al., 2015; Rodriguez-Navarro et al., 2018). Thus, it posits that imposed physical inactivity due to overcrowding and cage confinement can be a major risk factors for some of the poultry leg problems.

Genetic selection of poultry for better performance with respect to growth, feed conversion, and egg production are presumed to factor in their negative impact on bone health, leading to some leg problems such as lameness in meat-type poultry and osteoporosis in laying hens (Havenstein et al., 2003; Julian, 1998; Knowles et al., 2008; Paxton et al., 2013; Weeks et al., 2002). However, genetic correlation of poultry leg problems in young chickens with better growth characteristics has not been conclusive (González-Cerón et al., 2015a,b; Sanchez-Rodriguez et al., 2019; Shim et al., 2012). The following sections describe specific poultry bone disorders/ diseases encountered in commercial, backyard, and free-range flocks.

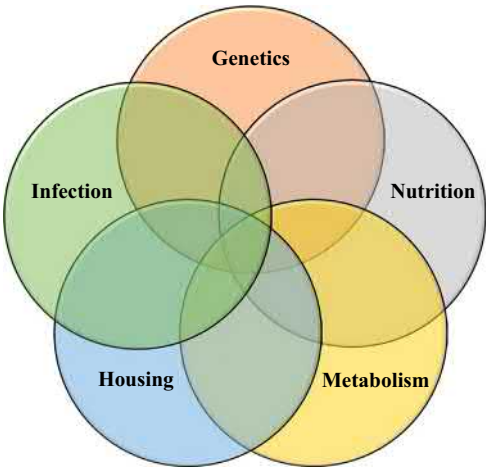

FIGURE 22.3 Poultry bone deformities and diseases are of multifactorial etiology.

22.5.1 Cage layer fatigue/osteoporosis

Cage layer fatigue/osteoporosis is a metabolic bone problem which occurs in high egg-producing layers, as a result of the loss of structural bone due to excessive osteoclast activities (Fleming, 2008; Thorp, 1994). However, osteoporosis in poultry can be related to several etiological factors. Housing system, genetics, and nutrition play major roles in the development of osteoporosis. The affected birds lose the ability to stand and resume a recumbent position. Osteoporosis manifests towards the end of laying cycle and is provoked by nutritional deficiency of Ca and P in older layers causing depletion of medullary bones. Genetics play some roles in avian osteoporosis (Fleming et al., 2006; Johnsson et al., 2015). There are several studies correlating the role of different genetic loci with bone strength of laying hens that include genes regulating bone mass, bone resorption, and metabolism (Bishop et al., 2000; Fleming et al., 2006; Johnsson et al., 2015; Raymond et al., 2018). Genetic

correlation of bone quality in older hens and the resistance to breakage with their collagen crosslink content, was reported in one study (Sparke et al., 2002). Estrogen deficiency is also implicated in avian osteoporosis, since estrogen regulates Ca absorption and its mobilization both in the uterus and the intestine (Bar, 2009; Beck and Hansen, 2004).

22.5.2 Keel bone deformity and fracture

Keel bone deformity (Figure 22.4) and fractures are prevalent in hens when they reach peak egg production which can be influenced by different management systems (Wilkins et al., 2011). Anatomical position of keel bone along with smaller breast muscle in laying hens, compounded with bone weakness due to osteoporosis, trauma, unfavorable housing conditions, and Ca deficiency contribute to keel bone problems (Fleming et al., 2004; Jung et al., 2019; Riber et al., 2018).

22.5.3 Cervical scoliosis

Poultry cervical scoliosis, characterized by an abnormal posture of neck, is a relatively new and emerging bone disease associated with excessive osteoclast activities that leads to the failure of embryo hatching (Olkowski et al., 2019). However, the inheritance of this problem or its genetic basis remains unknown.

22.5.4 Chondrodystrophy, slipped tendon/perosis, and rickets

Deficiencies of certain essential nutrients such as lysine, choline, biotin, pyridoxine, vitamin D, and trace elements including zinc and manganese contribute to chondrodystrophy, angular deformities, rickets, and osteomalacia (Fleming, 2008). Slipped tendon/perosis, indicated by enlarged tibiometatarsal joints with twisting of tibia and metatarsal bone, are common in chickens, turkeys, and ducks (Thorp, 1994). Uneven growth of long bone are also indicated in the cause of chondrodystrophy, possibly related to some metabolic disturbances that negatively impact the production of certain proteoglycans (Pines and Reshef, 2015). Failure of mineralization due to the deficiencies of vitamin D, Ca, or P and their imbalance cause rickets characterized by the thickening of GP with the accumulation of proliferative and mature chondrocytes in young and osteomalacia in older birds (Lacey and Huffer, 1982; Takechi and Itakura, 1995). Hypocalcemic chickens exhibit more proliferative and immature chondrocytes in the GP compared with hypophosphatemic birds that exhibit more hypertrophic chondrocytes.

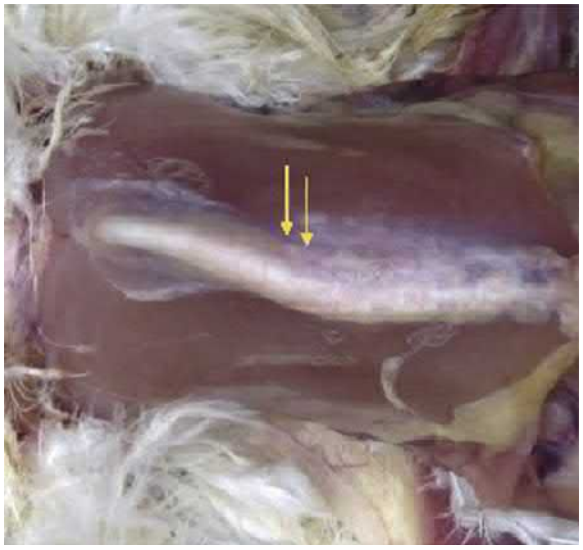

FIGURE 22.4 Keel bone deformity in chicken (*arrows* show deformed regions of keel bone).

22.5.5 Valgus-varus deformity

Valgus-varus deformity/twisted legs are caused by distortion of the long bones of legs characterized by deformed intertarsal joints. The outward angling of the leg is called valgus deformation whereas the inward bending called varus deformation (Riddell et al., 1983, Figure 22.5). Traumatic injuries to the joints are likely involved in the cause of these deformities. A recent study showed differential and abnormal expression of several bone-regulatory genes in the cartilage of chickens with VVD compared with their normal counterparts (Guo et al., 2020). It is however, not known whether the differential expression of those genes associated with bone development are the causes of VVD or they are differentially expressed as a result of to the injury induced angulation.

22.5.6 Tibial dyschondroplasia

TD is another frequently encountered poultry bone disorder that affects the proximal GP of tibia and tibiotarsal bone of fast-growing broiler chickens, turkeys, and ducks, identified

FIGURE 22.5 Valgus deformation of legs in turkeys.

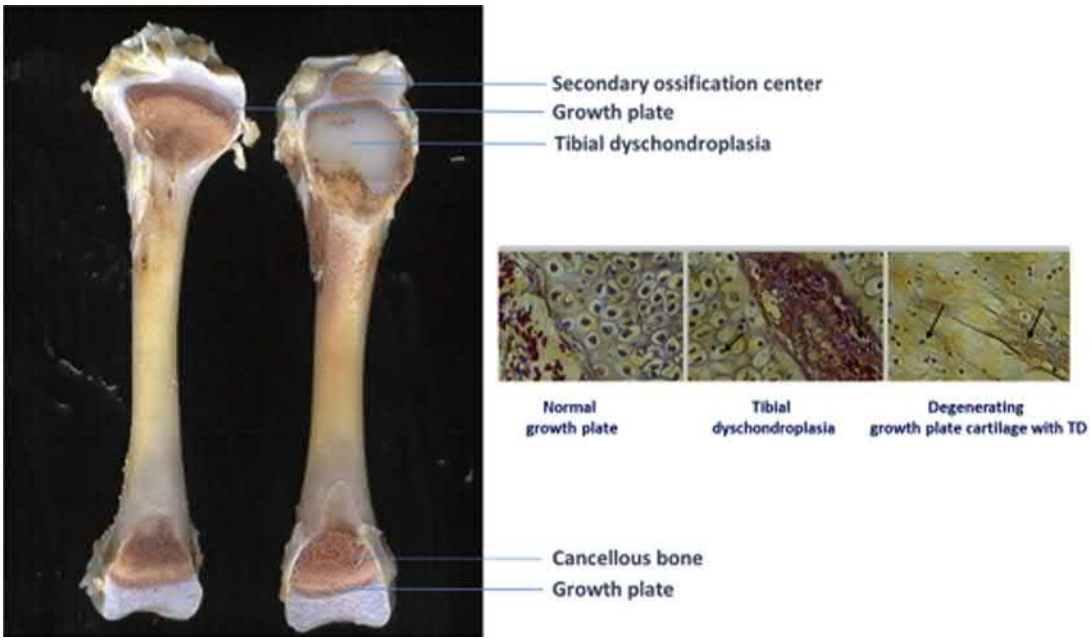

FIGURE 22.6 Tibial epiphyseal growth plates of a normal (left) and a dyschondroplasia-affected chicken bone (right) showing the histology of the hypertrophic zone of a normal and the affected growth plates with degenerating chondrocytes and blood vessels.

as a plug of opaque, nonvascularized cartilage in the GP that fails to ossify (Farquharson, 2002; Leach and Monsonego-Ornan, 2007; Lilburn and Leach, 1980; Orth and Cook, 1994; Pines et al., 2005, Figure 22.6). The presence of nonossified cartilage in the GP produces lameness and vulnerability to bone deformity and breakage. A variety of mechanisms concerning the failure of GP cartilage to form bone and the pathogenesis of TD have been proposed. These include but not limited to the deficiency of one or more critical growth factors of bone development such as, BMP, FGF, and vitamin D3 to some mineral nutrition imbalance, hypoxia, endoplasmic stress, and the factors that interfere with the GP development (Genin et al., 2008; Huang et al., 2017; Leach and Monsonego-Ornan, 2007; Pines et al., 2005; Praul et al., 2000; Rath et al., 2005; Thorp, 1994). Impaired angiogenesis and vascularization of GP has been suggested as a mechanism for the pathogenesis of TD (Huang et al., 2018). Exposure to certain dithiocarbamate pesticides, mycotoxins, copper chelators, and the vitamin D deficiency during early growth also induces TD in broiler chickens (Orth and Cook, 1994; Rath et al., 2007a; Vargas et al., 1983; Whitehead et al., 2004). Both in naturally occurring and experimentally induced TD, aberrant chondrocyte death and their accumulation in the transition zone of GP prevent ossification leading to its pathogenesis (Praul et al., 1997; Rath et al., 1998, 2005). The interesting feature of TD is that, it is primarily a proximal GP problem of tibia and tibiotarsal bone while the distal GP remain unaffected suggesting that the disease may be related to the weight bearing functions of these bone (Figure 22.6). Inclusion of vitamin D3 in the diet was shown to decrease the incidences and severity of TD induced by Ca/P deficiency (Whitehead et al., 2004). However, vitamin D3 did not have any ameliorating effect on thiram induced TD (Rath et al., 2007b).

22.5.7 Femoral head separation

FHS, also referred to as "epiphysiolysis" or "proximal femoral head degeneration," is frequently seen in heavier poultry. Loss of adhesion between AC and GP is the primary feature of FHS (Julian, 2005; Packialakshmi et al., 2015) which may be enhanced by mechanical stress on the leg bone. FHS has been linked to metabolic dyslipidemia, vascular problems of femoral epiphysis, and sporadic chondrocyte death that likely progresses to cartilage necrosis and infection (Duff and Randall, 1987; Durairaj et al., 2009; Knowles et al., 2008; Packialakshmi et al., 2015, Figure 22.7). "Proximal femoral degeneration" is another chicken femoral head problem similar to FHS that has been associated with excessive bone resorption, high MMP and altered osteoclast activities, that lead to the loss of cortical and trabecular bones (Olkowski et al., 2011). Vascular interruption is implicated as a cause of avascular necrosis of femoral head which is often the case with the mammalian disease.

22.5.8 Femoral head necrosis, osteomyelitis, bacterial chondronecrosis

Osteomyelitis, synovitis (Emslie et al., 1983; Huff et al., 2000; McNamee and Smyth, 2000; Nairn, 1973), mycoplasma chondrodystrophy (Ley et al., 2010), spondylitis

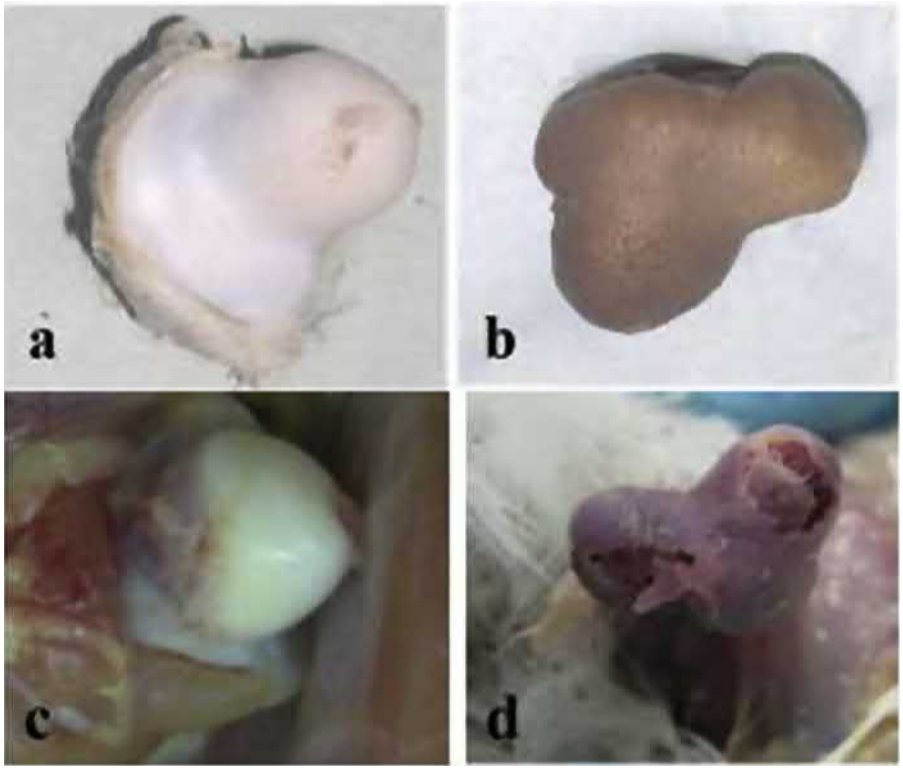

FIGURE 22.7 Healthy femoral head epiphyses with intact articular cartilage (A and C), a femoral head separated from articular cartilage without necrosis (B), and a separated femoral head with necrotic lesions (D).

(vertebral osteomyelitis) (Braga et al., 2016), and enterococcus spondylitis (Borst et al., 2017), osteochondrosis (Chen et al., 2018a), infectious synovitis, viral arthritis (Lockaby et al., 1998; Van Der Heide, 1977), and bacterial chondronecrosis with osteomyelitis (BCO) are some of the avian skeletal diseases associated with infectious agents. Infection with opportunistic pathogens induce tibial head and femoral head necrosis (THN, FHN) in chickens (Dinev, 2009; Dinev et al., 2019; Huff et al., 2000; Jiang et al., 2015; McNamee and Smyth, 2000; Mutalib et al., 1996; Nairn, 1973; Paxton et al., 2014; Wideman, 2016; Wijesurendra et al., 2017). Bacterial pathogens such as *Salmonella, Escherichia coli, Staphylococcus, Streptococcus, Ornithobacterium rhinotracheale, Mycoplasma synoviae* cause synovitis and arthritis (Clark et al., 1991; Köhler et al., 1980; Lockaby et al., 1998; Padron, 1990; Travers et al., 1996). Recently, *Staphylococcus aureus,* a bacteria involved in the pathogenesis of human osteomyelitis, was found to cause BCO in chickens and osteoblast death in culture (Greene et al., 2019). Vascular insufficiency due to inadequate blood flow into the GP because of microvasculature limitation and embolism, is implicated in the pathogenesis of BCO and GP fractures (Dinev et al., 2019; Jiang et al., 2015; Wideman, 2016; Wideman and Prisby, 2011). Mycoplasma infections cause swollen joints and vertebral chondrodystrophy (Ley et al., 2010; Morrow et al., 1997). Some bone problems in chickens have also been observed with reovirus and avian leukosis virus infections which cause FHN and brittle bone disease (van der Heide and Horzinek, 1981).

22.5.9 Amyloid arthropathy

Amyloid arthropathy in chickens is caused by the extracellular deposition of amyloid fibers in the joints that largely affect AC and synovial membranes (Landman, 1999; Peperkamp et al., 1997). The hip and tibiotarsal joints are affected more than other smaller joints. Infection-induced release of an acute phase protein serum amyloid A (SAA) from the liver and its aggregation in the joints cause inflammation and the infiltration of inflammatory cells (Zekarias, 2000). SAA has been reported in birds infected with *Enterococcus faecalis* and *Staphylococcus aureus* and show amyloid arthropathy (Blanco et al., 2016; Sevimli et al., 2013; Steentjes et al., 2002).

22.6 Conclusion

The developmental paths of both avian and mammalian skeletal elements are comparatively similar; however, the avian skeleton has evolved to support the aerial life of birds with some exceptions that occur in flightless birds, where

the skeletons show different adaptations. The lightweight bone along with fused vertebrae not only impart buoyancy and rigidity to the skeleton for flight, but also their hollow wing bone with struts and ridges support and impart high torsional strength and connection to the respiratory system, providing extra supply of oxygen to blood during flight. The keel sternum provides leverage for pectoral and wing muscles in flying birds, while it is either reduced in size or absent in flightless birds. The commercial poultry species that descended from their wild flying ancestors, have undergone rigorous genetic selections for better feed conversion, growth, and egg production, are often raised under constrained husbandry conditions forcing their adaptation to a relatively sedentary life. In the absence of adequate mechanical stimulation, the epiphyseal circulatory physiology is likely affected negatively leading to some of the degenerative joint problems. Nutritional deficiencies, poor housing, and hygienic conditions also contribute to certain skeletal problems in commercial poultry. In older laying hens, osteoporosis is a major cause of bone fracture which can be eased by proper nutrition and enhanced housing conditions that increase their physical activities. Understanding the mechanobiological basis of poultry bone diseases can improve poultry welfare.

23.1 Introduction

Skeletal muscle is the largest tissue in the body, constituting about 40% of its mass. This chapter covers the development and growth of avian skeletal muscle, beginning with a discussion of its structural diversity in different bird species, muscle fiber types, and the mechanism of skeletal muscle contraction. An overview of embryonic and posthatch development is then provided, with a focus on satellite cells, the adult myoblast stem cells that are responsible for all posthatch muscle growth. This is followed by a description of the roles of myogenic transcriptional regulatory factors and growth factors in muscle myogenesis. New emerging areas in avian skeletal muscle biology are addressed, including satellite cell heterogeneity, myopathies in meat-type poultry, and the association of these diseases with extracellular matrix organization and regulation. New strategies to combat the myopathies are discussed.

23.2 Diversity of avian skeletal muscle

The ability to fly has allowed avian species the widespread utilization of many diverse environments and habitats. Perhaps due to this mobility, they may be the most successful terrestrial vertebrate in terms of numbers of species and body forms (Welty, 1982). There are approximately 8900 living species of birds compared to 3000 amphibians, 6000 reptiles, and 4100 mammals. The structure of the musculoskeletal system of birds varies tremendously among species depending on their flight characteristics or whether they are flightless. Most prominent on the sternum of flying birds is a large keel structure to which the powerful flight muscles are attached. Although the penguin is unable to fly, the keel serves as an anchor for muscles controlling the vestigial wings called flippers used for swimming. Flightless birds either lack a keel (ostrich) or the structure is minimal. Other skeletal structures peculiar to birds include a greatly lengthened pelvis fused with the synsacrum, covering approximately half the length of the body. Consequently, there is relatively little dorsal musculature in birds. The majority of the muscle tissue in birds is on the ventral side of the torso, but great differences exist among species. For instance, birds such as hummingbirds and swallows are highly accomplished fliers, but they are limited on the ground; approximately 25−35% of their body weight is devoted to flight musculature and only about 2% to the leg muscles. On the other hand, shore birds that rely more on running than flying have larger leg muscles than wing muscles. Additionally, raptors, which rely on strong grasping of prey, have very strong leg muscles.

The principal flight muscles are the large pectoralis and the supracoracoideus. In some birds, these two muscles may account for 25% of the total mass of the animal. In commercial poultry, genetic selection has largely focused on the size of these muscles because they are the most economically important part of the carcass. Both of these muscles arise from the keel with the supracoracoideus lying dorsal to and under the pectoralis muscle. The pectoralis attaches to the humerus and is responsible for depressing the wings. The supracoracoideus attaches to a tendon that passes dorsally through a foramen and attaches to the dorsal surface of the humerus. This “rope-and-pulley” arrangement allows for the upward movement of the wings. Additionally, there are many other smaller muscles that cause changes in the angle of the wings.

Throughout the skeletal muscular systems of birds, there are many variations in structure that allow this diverse class of vertebrates to adapt to environmental niches and feed sources. For instance, the jaw closing muscles of birds that feed on coarse seeds are stronger than those that feed on smaller grains or noncoarse materials. As will be discussed below, movement requirements of each muscle must be properly matched with the appropriate type of contractile fibers, metabolic characteristics, and neural signal.

Sturkie’s Avian Physiology. https://doi.org/10.1016/B978-0-12-819770-7.00024-4

Members of the class *Aves* are classified as either precocial or altricial in their developmental patterns. Precocial birds hatch with open eyes and a coat of down feathers; they leave the nest within 2 days. Altricial birds hatch with closed eyes, with little or no down feathers, and must be fed by parents. Included in the latter group are passerine birds, the largest order of birds. Additionally, there are birds that fall between these two classifications, which are referred to as semiprecocial or semialtricial. Among the precocial birds include aquatic species such as gulls, terns, ducks, geese, and rails. These species are able to run and swim in the first day following hatching. However, they cannot fly until fully grown (Dial and Carrier, 2012). The early maturation of the leg skeletal muscle system versus the wings allows these species to escape predators without relying on the ability to fly. Although not capable of walking following hatching, altricial birds are capable of performing alternating stepping movements following hatch, indicating that locomotor program is in place early in development (Muir, 2000). Some of the differences between precocial and altricial species are explained by the immaturity of the neurological system in the latter species (Oppenhiem, 1972). However, the sequence of movements leading to pipping and emergence from the egg remains the same in all avian species examined except for members of the family Megapodiidae (Oppenhiem, 1972).

23.3 Muscle structure and contraction

The skeletal muscles are connected to the skeleton through tendons near the joints. The entire muscle is surrounded by a connective layer, the epimysium, which consists mostly of collagen [Fig. 23.1A (old Figure 16.1)]. Within the muscle, the muscle fibers (myofibers) form bundles or fasciculi. The bundles are separated from each other by a connective tissue layer called the perimysium. Muscle bundles can vary in size from 50 to 300 myofibers per bundle, with each myofiber surrounded by the endomysial connective tissue layer. The connective tissue layers are all joined together at the myotendinous junction (the interface of the muscle–tendon connection), and thus are not independent from each other. The interconnection of the three connective tissue layers provides a strong structural framework for the muscle, with capillary beds and water-holding molecules (Koeppen and Stanton, 2018).

Mature myofibers can vary in length and diameter. They are multinucleated muscle cells with myonuclei located at their periphery, just underneath the sarcolemma. The sarcolemma is the plasma membrane of the muscle cell and contains invaginations into the myofiber called the transverse tubule (T-tubule) system. This system allows for the rapid release of calcium from the inner sarcoplasmic reticulum to the cytoplasm upon sufficient membrane depolarization (Koeppen and Stanton, 2018). Invaginations of the T-tubule system into the myofiber occur at regular intervals along the myofiber, close to the myofibrils—contractile filaments that are aligned longitudinally to the myofiber. The myofibrils have a rod-like shape and are organized as repeating units of sarcomeres (the smallest contractile unit of the muscle); each individual sarcomere is bordered by Z bands and consists of thin and thick filaments. The thin filaments are composed primarily of actin, tropomyosin, troponin complex, tropomodulin, and nebulin. The filaments are anchored to the Z band through α-actinin and CapZ. The end of the thin filament closest to the M-line is capped with tropomodulin which, in part, regulates actin filament length (Fowler et al., 1993). The troponin complex is attached to tropomyosin and contains troponin I, troponin T, and troponin C, which are involved in regulating the myosin head–actin filament interaction (Fig. 23.1C). Nebulin is an actin-binding protein. Nebulin-knockout mice have reduced actin filament length and impaired contractile properties (Bang et al., 2006). In the I zone, the actin filaments do not overlap with the myosin filaments.

The thick filaments, the myosin, in the sarcomere do not overlap with the actin filaments in the H zone, whereas the two do overlap in the A zone (Fig. 23.1B and C). Myosin is a protein dimer composed of two heavy chains and two copies of two different light chains. The N-terminus globular domain is the region that binds to actin and is attached to an α-helical myosin tail region. Located near the globular myosin head is one copy of each of the two light chains.

In a state of muscle relaxation, the troponin I–T complex causes tropomyosin to move from its natural position in the grooves of the actin helix to a position that prevents the myosin heads from binding to the actin. Muscle contraction is initiated by myosin head attachment to the actin thin filaments in the sarcomere. For a review on the muscle-contraction process, see Alberts et al. (2008). Upon motor neuron stimulation at the neuromuscular junction and generation of an action potential along the sarcolemma, calcium is released from the sarcoplasmic reticulum and binds to troponin C, causing release of the troponin I–T complex from actin. This allows tropomyosin to return to the actin groove and facilitate the binding of the myosin heads to the actin filament, leading to the latter being pushed toward the center of the sarcomere (Fig. 23.1B and C). The myosin heads need to be released from the actin filaments to prevent a constant state of contraction, and this release requires the recruitment of an adenosine triphosphate (ATP) molecule and its binding to the myosin head. The ATP is then hydrolyzed to adenosine diphosphate (ADP) by ATPase located on the myosin head, facilitating another round of myosin–actin binding (cross-bridge cycle) and further pushing of actin filaments into the

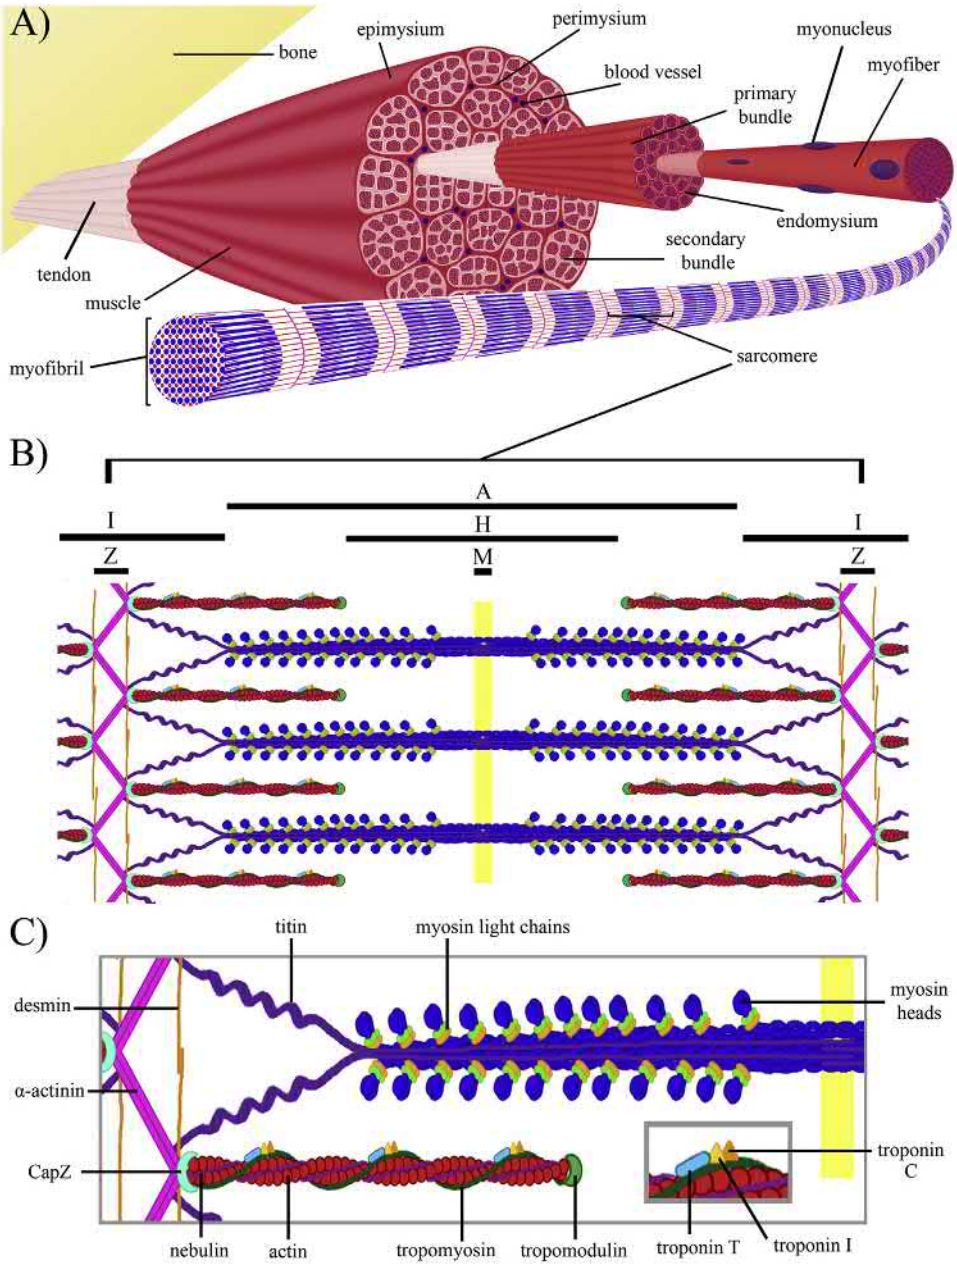

FIGURE 23.1 Schematic of muscle structure. (A) Overview of a cross-sectional area of muscle highlighting muscle fiber structure. (B) Sarcomere structure. (C) The myosin-actin overlap with the associated molecules.

sarcomere. The contraction of an entire muscle is facilitated by synchronized contractions of motor units, each unit consisting of a neural cell body residing in the dorsal root of the spinal cord and its axon, which extends to the muscle being innervated. The single axon splits into numerous branches (from a few to hundreds), each branch innervating an individual myofiber (motor unit). Motor units are interspersed throughout the muscle group regions, so individual motor units influence the contractility of a wide area (Lieber, 1992).

23.4 Skeletal muscle fiber types

Muscle fibers differ greatly in terms of contraction rate, metabolism, and function. There is generally accepted to be three muscle fiber types: (1) slow-twitch, oxidative, type I or red fiber; (2) fast-twitch glycolytic, type IIB or white myofiber; and (3) fast-twitch, oxidative/glycolytic, type IIA or intermediate fiber (Koeppen and Stanton, 2018). The myofiber types housed within muscle groups vary depending on the particular requirements for motion.

Additionally, the same anatomical muscle may differ greatly in fiber composition between species. For instance, when comparing the pectoralis major muscle of a duck and a chicken or a pheasant, it is obvious that the duck pectoralis major muscle is primarily an oxidative muscle due to its high proportion of myoglobin, giving it a red color. This powerful flight muscle ideally suits the duck for long, sustained flights of several hundred miles as required for migration. In migratory wild birds, the muscles will have a higher proportion of type I fibers compared to type IIB (Ashmore et al., 1972). The type I fibers have a higher aerobic capacity and higher blood supply necessary for sustained activity. In contrast, the pectoralis major muscle of the domestic chicken is composed of type IIB fibers and has a lower blood supply because prolonged flight activity is not necessary and the muscle will fatigue more quickly.

Aerobic muscles oxidize glycogen and glucose through glycolysis and the tricarboxylic acid cycle and oxidize fatty acids via β-oxidation. Consequently, these muscles contain greater numbers of mitochondria, smaller fiber diameter to facilitate oxygen diffusion, greater triglyceride levels, and greater capillary density. The chicken or pheasant pectoralis major muscle is primarily composed of glycolytic fast twitch muscles and myoglobin levels are much lower, giving the muscle a white color. Glycolytic muscles oxidize glycogen and glucose to lactate, and the lactate is returned to the liver for gluconeogenesis (Cori cycle). Therefore, much less energy is derived from oxidizing glucose in these muscles, so energy is expended quickly and serves to provide a rapid (but short) burst of activity. In addition to differences in energy metabolism between fiber types, contraction properties are determined by the protein isoforms contained in the contractile apparatus of the fibers. Fast-twitch fibers contain myosin isoforms with fast ATPase activity (generating energy quickly for rapid movements) and slow-twitch fibers contain myosin isoforms with slow ATPase activity (generating energy more slowly for sustained movements). Patterns of action potentials generated from nerves innervating slow muscle fibers differ from those that innervate fast muscles. The slow-switch fibers contain smaller motor units than the fast-twitch fibers. Motor units are generally recruited in order of smallest to largest, hence slow fibers will be activated before fast fibers as contraction increases. Nerve transplantation studies have revealed that the patterns of neural stimulation influence myosin isoform expression (Cerny and Bandman, 1987). When fast muscles were innervated by nerves normally innervating slow muscles, fast myosin isoforms were replaced by slow myosin isoforms. However, neural stimulation is not the only factor affecting the contractile fate of muscles. Fiber type is also influenced by the myoblast lineage that makes up the muscle fiber (Dimario and Stockdale, 1997).

Cross-sectional area of myofibers is influenced by muscle fiber type. Type I muscles have a smaller cross-sectional area than type IIB myofibers (Ashmore et al., 1972). The cross-sectional area of myofibers is not a static situation and will change based upon usage. The flight muscles of migratory birds change in myofiber diameter in anticipation of migration and during the migratory flight (Price et al., 2011). For example, during a long-migratory flight, the muscle fibers may decrease in diameter to coincide with a lighter bird weight as fat is oxidized (Lindström et al., 2000). During a stopover or rest period, the muscles may rebuild for the next flight and increase in diameter (Landys-Cianneli et al., 2003).

23.5 Embryonic development of skeletal muscle

Following gastrulation—the transformation of the spherical blastula into an elongated tubular structure, three primary germ layers are defined. The outer structure comprises the ectoderm, and the inner surface comprises the endoderm. Between these layers is the mesoderm, which is the source of cells that lead to the formation of the skeletal muscle and other internal structures. As the embryo elongates due to lengthening of a structure termed notochord, the mesoderm grows as "slabs" on both sides of the notochord, with the ectoderm above and the endoderm below (for detailed review, see Gilbert, 2019). Part of the mesoderm, called the paraxial mesoderm, will give rise to segments consisting of epithelial cells termed somites. This dynamic process, beginning at the anterior end and terminating at the posterior end of the embryo, is regulated in a well-coordinated temporal manner—"the segmentation clock" (Pourquié, 2011). The somites gradually mature and compartmentalize into different structures, depending on their location. The region of cells that flanks the notochord in the ventral half of the somite will undergo epithelial-to-mesenchymal transition and form the sclerotome, giving rise to the axial skeleton and tendons. The dorsal half of the somites will form the dermomyotome, which will further split into two layers; the dorsal layer—the dermatome—will give rise to the dermis, as well as some skeletal muscle and brown fat; the other layer—the myotome—will be created by mesenchymal cells migrating from the extreme ends of the dermomyotome to beneath the dermatome. The myotome will give rise to intrinsic back muscles and abdominal muscles. Other myogenic precursors migrate out of the dermomyotome lips to populate the body wall and limb buds, and form the limb muscles. Muscles of the head and neck do not originate from the somites but from other regions in the mesoderm.

The first myogenic precursors, the myocytes (embryonic myoblasts) are formed in the myotome. During the

first wave of myogenesis, these cells elongate along the anterior-posterior axis of the myotome and form the primary (embryonic) myofibers by fusing with cells that migrate from the dermomyotome. The primary myofibers will serve as a scaffold for the second wave of myogenesis in which the secondary (fetal) myofibers are formed. During this wave, muscle growth continues by cell fusion and the addition of myonuclei from proliferating myoblasts. In chicken, the first (embryonic) wave of myogenesis occurs between embryonic day (E) 3 and embryonic day 7 (E7) and the second (fetal) wave of myogenesis occurs from E8 until hatch.

Myofiber formation is essentially complete at the time of birth or hatch. However, a third wave of myogenesis that starts in the embryo and continues until adulthood contributes to postnatal or posthatch muscle growth. This wave consists of a specific subset of muscle precursor cells, the satellite cells, also termed "adult myoblasts" (Hartley et al., 1992). For many years, the origin of satellite cells in the embryo was unknown; however, the elegant studies of Gros et al. (2005) and Relaix et al. (2005) revealed that these cells originate from the central part of the dermomyotome in the somites. Satellite cells can be distinguished in their niche underneath the basal lamina of myofibers at later stages of embryogenesis. Whereas in the embryo they only proliferate, after birth or hatch, these muscle precursor cells undergo proliferation, terminal differentiation, and fusion into the growing myofibers.

23.6 Postnatal or posthatch skeletal muscle development

After birth or hatch, skeletal muscle growth is due to enlargement of the existing myofibers (i.e., hypertrophy). The detailed mechanism of this hypertrophy remained a mystery until the 1960s; much of what is now known about posthatch or postnatal muscle growth today was gained from studies with chickens. Smith (1963) demonstrated increases in myofiber number in chickens prior to hatch, and subsequent growth due to hypertrophy. The importance of initial myofiber number following hatch was further demonstrated by studies with different chicken lines. A growth-selected heavy strain of chickens had a greater number of myofibers that were slightly smaller in diameter at hatch than a layer strain of chickens. After 10 weeks of growth, myofiber diameters in the growth-selected line were much greater than those in the layer strain (Smith, 1963).

One of the major puzzles of muscle growth in those years was the source of the nuclei in growing and regenerating skeletal muscle. Early experiments with isolated chick embryonic myoblasts revealed that the myonuclei in the myotubes were incapable of mitotic division and that another cell was responsible for DNA accretion (Stockdale and Holtzer, 1961). While it seemed clear that embryonic myoblasts were likely responsible for the development of myofibers prenatally, the source of the cells leading to postnatal growth was unknown. The historic discovery of satellite cells by Mauro (1961), based on electron microscopic examination, paved the way to clear this enigma. Those cells, unique to skeletal muscle in all vertebrates, were termed "satellite cells" due to their peripheral location on myofibers, residing in a niche between the sarcolemma and basal lamina of the myofibers. The cell mass consisted mostly of nuclei, and there was little cytoplasm and only a few organelles, such as mitochondria or Golgi apparatus.

Early evidence of a role for satellite cells in postnatal growth was reported by Moss and Leblond (1971), where tritiated thymidine label injected into young growing rats was followed in the muscle tissue. The label was localized to the satellite cells, indicating their division in the myofibers; later, the label began to appear within myonuclei, indicating that the satellite cells had fused with the adjacent fibers. These observations established a key role for satellite cells in myofiber DNA accretion, especially in young growing animals. Moss (1968) established the idea that DNA accretion occurs only via satellite cell incorporation into the growing myofiber, and that it is based on a constant ratio of myofiber diameter to DNA content. However, recent genetic studies have challenged this idea: in mice lacking the paired box 7 (Pax7) gene (which marks only satellite cells), myofibers still retained their capacity for hypertrophy under conditions of overload (McCarthy et al., 2011). Nevertheless, it is largely accepted that satellite cells are an essential source for new myonuclei in the growing muscle and long-term hypertrophy (Wang and Rudnicki, 2011). At birth or hatch, the satellite cell population makes up about 30% of the total myonuclei; however, their proliferative capacity and numbers diminish rapidly to 1−5% toward the end of the growing period (Hawke and Garry, 2001; Halevy et al., 2004), when they become quiescent (Schultz et al., 1978) and reside in their niche. In heavy-strain chickens, satellite cell myogenic activity persists for the first 8 days posthatch and peaks on day three posthatch (Halevy et al., 2004, 2006a).

In birds, during early growth, satellite cell myogenic activity is largely influenced by nutritional and/or environmental conditions such as light or temperature, all of which affect the pool of these cells for future hypertrophy. In chicken and turkey poults, changes in nutrition (Halevy et al., 2000, 2003; Mozdziak et al., 2002; Bigot et al., 2003; Powell et al., 2014; Velleman et al., 2019) or in environmental conditions (Halevy et al., 2006b; Piestun et al., 2009a; Liu et al., 2010; Hadad et al., 2014; Patael et al., 2019) during the early posthatch period impaired or enhanced the proliferation and differentiation activity of satellite cells, resulting in changes in the cell reservoir and

long-term effects on muscle hypertrophy and growth. Recent studies have shown long-term promotive effects on satellite cells in late-term chick embryos that experienced nutritional (Kornasio et al., 2011) or environmental manipulations during the third wave of myogenesis (Halevy et al., 2006b; Piestun et al., 2009a; Zhang et al., 2012), The proportion of myofiber nuclei residing in satellite cells out of the total number myonuclei is diminished upon malnutrition in humans (Hansen-Smith et al., 1979).

Despite the inactive state of satellite cells and their diminished numbers in mature animal muscle, upon injury, excessive exercise, overload, or various types of stress, quiescent satellite cells residing in their niche do have the capacity to become active and undergo myogenesis and fusion into existing or newly formed myofibers to regenerate damaged skeletal muscle (Bischoff, 1975; Hawke and Garry, 2001). As such, satellite cells serve as a reservoir for muscle precursor cells, and are therefore considered "adult skeletal muscle stem cells" (Collins et al., 2005). They fulfill the definition of a stem cell in that they undergo asymmetric division in which one daughter cell will continue the myogenic program, and the other will replenish the muscle precursor cell reservoir. In addition, under specific external signals, satellite cells can transform from the myogenic lineage to adipogenic, chondrogenic, or fibrogenic lineages. Moreover, the small population of satellite cells can regenerate an entire muscle (reviewed in Sambasivan and Tajbakhsh, 2015).

23.7 Muscle development: function of myogenic regulatory factors

The commitment and later differentiation of muscle precursor cells during both embryonic and posthatch periods require the precise expression of myogenic regulatory factors (MRFs). The MRFs are a family of basic helix-loop-helix transcription factors that are expressed in a specific temporal order. They activate muscle-specific gene expression by heterodimerizing with E proteins and binding as heterodimers to the conserved sequence, the E-box, located on the promoters of muscle-specific genes (Olson, 1990). Myogenic determination factor 1 (MyoD) was the first identified MRF; its importance was immediately recognized because it could convert nonmyogenic cells to a skeletal muscle lineage (Davis et al., 1987). Myogenic factor 5 (Myf5) has functions that overlap with MyoD. Genetic studies on knockout mice have demonstrated that MyoD and Myf5 are functionally redundant in that disruption of either gene will allow embryonic muscle development with only minor defects (Rudnicki et al., 1992, 1993). However, the absence of both MyoD and Myf5 will result in the absence of skeletal muscle formation, suggesting their role in myogenic commitment (Rudnicki et al., 1993). Both genes are involved in early myotome formation, are expressed in two subsets of cells (Kablar et al., 1998), and are important for myoblast proliferation. Myogenin acts downstream of MyoD and Myf5 and is necessary to activate the expression of muscle-specific proteins needed for terminal differentiation with the fusion of myoblasts to form myotubes. Absence of myogenin in knockout mice results in disruption of myocyte or myoblast differentiation, with little or no muscle myofiber formation (Hasty et al., 1993). Myogenic regulatory factor 4 (MRF4, Myf6 in humans) is expressed and functions in a species-dependent manner. In mice, it is expressed in a biphasic manner: first, in the dermomyotome where it overlaps with MyoD and Myf5 in directing myogenic specification; then, in fetal myoblasts where it regulates myogenic differentiation. However, in birds, MRF4 is only expressed at later embryonic stages, in parallel to myogenin, and regulates myogenic differentiation (Mok et al., 2015). In the postnatal animal, Myf5 expression is maintained in quiescent satellite cells, while MyoD and myogenin are sequentially expressed only in activated satellite cells (Cornelison and Wold, 1997; Yablonka-Reuveni and Paterson, 2001). MRF 4 is upregulated during muscle regeneration in forming myotubes (Pavlath et al., 2003). However, in birds, it may also play a role during cell proliferation: Shin et al. (2012a) showed high MRF4 expression during turkey satellite cell proliferation. The myocyte enhancer factors (MEFs) are positive upregulators of muscle differentiation (Naya and Olson, 1999). No skeletal muscle phenotype has been attributed directly to MEFs, but they appear to function in a positive feedback manner, especially with myogenin (Ridgeway et al., 2000).

The MRFs act in concert with the paired domain and homeobox-containing transcription factors paired box 3 (Pax3) and Pax7 at different stages of myogenesis in the embryo and adult. Pax3 acts upstream of MyoD and is necessary for the delamination and migration of the muscle progenitor cells from the somites to the limb bud (Bober et al., 1994; Tajbakhsh et al., 1997). Satellite cells are formed from Pax3- and/or Pax7-expressing muscle precursor cells in the somites (Relaix et al., 2005; Schienda et al., 2006). In the postnatal or posthatch animals, Pax7 is exclusively expressed in quiescent and activated satellite cells and is required for their proliferation during muscle growth (Halevy et al., 2004), and their maintenance and self-renewal (Seale et al., 2000; Zammit et al., 2004). Pax3 expression is mostly downregulated before birth, although a subset of satellite cells expresses this gene in adult animals (Relaix et al., 2006). It has recently been shown that this subset of cells remains resistant to environmental stress, and thus may protect the muscle stem cell reservoir (Der Vartanian et al., 2019).

23.8 Growth factors affecting skeletal muscle myogenesis

Much of what has been learned about the factors regulating the proliferation and differentiation of satellite cells has been derived from cell-culture studies and the development of serum-free medium formulations for various species. Satellite cells were first isolated and cultured by Bischoff (1974) from the skeletal muscle of adult rats. The cells were capable of proliferating and differentiating into multinucleated myotubes. Since then, satellite cells have been isolated and cultured from nonmammalian and mammalian species using various approaches, among them mechanical, enzymatic, and cell sorting and fractionation by density gradient. In addition, methods to isolate and culture whole myofibers, mainly from rodent muscles, have been developed, to study the behavior of satellite cells while they are still connected to the myofiber, thus reflecting their native environment (reviewed in Yablonka-Reuveni, 2011). Notably, to date, attempts to isolate chicken myofibers have failed. Similarities have emerged between findings with avian species and with mammals. Here, we discuss the most studied growth factors—the fibroblast growth factors (FGFs), platelet-derived growth factors (PDGFs), insulin-like growth factors (IGFs), hepatocyte growth factor (HGF), transforming growth factor-beta (TGF-β), and myostatin.

The FGFs are a large group of polypeptide growth factors with diverse actions on cells and tissues. Of this group, only FGF1, FGF2, FGF4, and FGF6 are produced by, and secreted from satellite cells, and FGF1 and FGF4 are expressed in developing muscles. Satellite cells express various types of FGF receptors, mainly 1 and 4, and to a lesser extent FGF receptors 3 and 2. FGF signaling in satellite cells is regulated by a complex of cell-surface (e.g., syndecan 4) and extracellular matrix (e.g., fibronectin) molecules. The FGFs are important for self-renewal of satellite cells and proliferation of embryonic and adult myoblasts (reviewed in Pawlikowski et al., 2017). In birds, omission of FGF from serum-free media resulted in no proliferation of turkey satellite cells or embryonic myoblasts, even if other mitogens were present (McFarland et al., 1993). Some types of FGFs have more potent mitogenic activity than others: in satellite cells derived from turkey (McFarland et al., 1993) and chicken (Wilkie et al., 1995), FGF2 induced proliferation better than FGF1. While FGFs play a role as mitogens, they inhibit muscle cell differentiation in both rodents and birds. Loss of FGF receptor activity by adding an inhibitor to the receptor or expressing a dominant-negative mutant induces terminal differentiation of cultured mouse satellite cells. It is believed than by inhibiting differentiation, FGF allows the self-renewal of satellite cells (Pawlikowski et al., 2017). Addition of FGF to cultures inhibits differentiation of chicken (McFarland et al., 1997; Hodik et al., 1997) and rodent (McFarland et al., 2000) satellite cells.

The PDGF family consists of four isomers (A, B, C, and D) that can be found as homo- or heterodimers, but mainly in their BB form, in many cell types. In skeletal muscle, they are expressed in fibro—adipogenic progenitor cells/fibroblasts and pericytes that work in a paracrine manner on adjacent cells (e.g., satellite cells). The two PDGF receptors (PDGFR-α and β) transmit the PDGF signal as either homo- or heterodimers, and both are expressed in embryonic myoblasts and satellite cells. Among the four types of PDGFs, the PDGF-BB isomer is the most potent mitogen for satellite cells, and induces their migration and proliferation, as well as muscle regeneration (Yablonka-Reuveni et al., 1990; Sugg et al., 2017). Recent studies have suggested that PDGF-BB is involved in the plasticity of satellite cells, changing their fate from myogenic cells to pericytes (Gerli et al., 2019). The expression of both PDGF-AA and PDGF-BB was found to be induced in dystrophic myofibers and was assumed to contribute to their fibrotic state (Zhao et al., 2003; Piñol-Jurado et al., 2017). In birds, PDGF was shown to be a potent mitogen for embryonic chick myoblasts (Yablonka-Reuveni and Seifert, 1993). Similar findings were reported for embryonic turkey myoblasts and satellite cells (Ye et al., 1996).

IGF is a small peptide found in multiple isoforms emerging from multiple IGF mRNA transcripts that are formed by alternative splicing. These transcripts encode various precursor polypeptides that undergo post-translational modifications. The main source of circulating IGFs is the liver, but they are expressed in other tissues as well, including skeletal muscle. The two families of IGFs, IGF-I and IGF-II, share similarities with proinsulin and may elicit similar biological effects. Different forms of pro-IFG-I are expressed in resting versus exercising or regenerating muscles, pro-IGF-Ia in the former and pro-IGF-Ib/c (also termed mechano-growth factor; Yang et al., 1996) in the latter. The locally produced muscle IGF-I is crucial for myogenesis (Shavlakadze et al., 2005; Barton et al., 2012) and is involved in myoblast proliferation, terminal differentiation, and muscle hypertrophy in mammals and birds (Coleman et al., 1995; Halevy et al., 2001; Yu et al., 2015). While most of the muscle IGF-I is produced by myofibers, satellite cells also produce and secrete the peptide (Jennische et al., 1987), as do other cells residing in the muscle, all of which affect the muscle in an autocrine/paracrine manner. IGFs transduce their signal via the IGF-I tyrosine kinase receptor which shares high homology with the insulin receptor, and can therefore heterodimerize with it; both receptors are expressed in skeletal muscle, including satellite cells, and can bind either IGF-I or IGF-II. The mature IGF forms have a short half-life and are thus stabilized by either binding directly to the extracellular matrix

or forming a complex with IGF-binding proteins, which in turn may induce, or, in most cases, inhibit IGF's ability to bind to its receptor (reviewed in Vassilakos and Barton, 2018).

Both, IGF-I and IGF-II enhance proliferation, differentiation, and fusion of embryonic as well as adult myoblasts in poultry (Schmid et al., 1983; McFarland et al., 1993; Hodik et al., 1997). In addition, IGFs have insulin-like activities in both mammals and birds. For instance, IGF stimulates glucose uptake in turkey (McFarland et al., 1994) and chicken (Duclos et al., 1993a) satellite cells. In addition, IGF stimulates protein synthesis and inhibits protein degradation in myotubes derived from chick embryonic myoblasts (Janeczko and Etlinger, 1984), chick satellite cells (Duclos et al., 1993b), and turkey embryonic myoblasts and satellite cells (McFarland et al., 1994). There is recent evidence (Shinichi et al., 2012) points of an association between polymorphism of the IGF-I gene and pectoralis major muscle yield in chickens. A comparative transcriptomic analysis of breast muscle derived from three poultry strains with different growth rates revealed the expression of IGF-II transcript in all strains (Zhang et al., 2019).

Early research described mitogenic activity of a crushed muscle extract that was capable of activating quiescent satellite cells residing on isolated muscle fibers (Bischoff, 1986). One of the substances in this extract was later defined as HGF (Tatsumi et al., 1998). Using cultured quiescent satellite cells, Tatsumi et al. (2001) demonstrated that stretched cells enter the cell cycle earlier than quiescent cells cultured under static conditions. Release of HGF from the stretched satellite cells in culture was dependent on the presence of nitric oxide (Tatsumi et al., 2002). The administration of anti-HGF antibodies abolished the stretch activation of satellite cells and demonstrated that the crushed muscle mitogen was, indeed, HGF. Therefore, HGF is considered an essential factor for the activation of quiescent satellite cells during muscle regeneration postinjury.

HGF (also termed scatter factor) is a heparin-binding molecule found in the extracellular matrix; it exerts its activity via the tyrosine kinase receptor c-met. During development, HGF plays an essential role in the migration of myogenic precursor cells from the somites into the limb bud (Brand-Saberi et al., 1996). During the early growth period in mammals (Sheehan et al., 2002) and birds (Gal-Levi et al., 1998; Zeng et al., 2002), HGF induces myoblast proliferation and decreases differentiation by inhibiting the activity of MRFs and affecting cell-cycle proteins, leading to inhibition of muscle-specific protein expression (Gal-Levi et al., 1998; Leshem et al., 2000). Addition of anti-HGF antibodies to turkey satellite cells in serum-free medium decreased proliferation, supporting the role of HGF as an autocrine or paracrine factor in muscles (Zeng et al., 2002).

The transforming growth factor-β belongs to a large family of pluripotent cytokines with diverse effects during development and adulthood. It was first described as "a very potent inhibitor of myoblast differentiation" by Florini et al. (1986). To date, TGF-β is known to inhibit both muscle growth and regeneration by inhibiting the proliferative and differentiative activity of satellite cells in mammals and birds. It also promotes the pathology of muscular diseases by inducing collagen synthesis in myofibroblasts and increasing muscle fibrosis (Abrigo et al., 2018).

Myostatin is a member of the TGF-β family, believed to be an important regulator of muscle size. Defects in the myostatin gene result in dramatic increases in muscle mass seen in Belgian Blue and Piedmontese cattle breeds (McPherron and Lee, 1997). Similarly, myostatin-null mice have enhanced musculature (McPherron et al., 1997). Srinivasan et al. (2004) demonstrated elevated levels of myostatin during muscle atrophy. It is believed that elevated myostatin during muscle breakdown serves to prevent premature satellite cell activation while the degeneration is occurring. When muscle regeneration commences, myostatin levels decrease (Kirk et al., 2000). Administration of myostatin to muscle explants inhibited satellite cell activation and progression into the cell cycle (McCroskery et al., 2003). Proliferation of both turkey embryonic myoblasts and satellite cells was inhibited in serum-free medium containing myostatin (McFarland et al., 2006). Satellite cells isolated from the pectoralis major muscle of chickens were more responsive to the proliferation- and differentiation-depressing effects of myostatin compared to cells from the biceps femoris (McFarland et al., 2007).

23.9 Satellite cells and myoblast heterogeneity

There is considerable heterogeneity in myofiber structure, metabolism, and response to stimuli, depending on the specific function of the muscle. Muscles for quick short burst movement differ from muscles for sustained movement. Postural muscles also have different properties than muscles not involved in posture. Heterogeneity of satellite cells is noticed during embryogenesis; cells that reside in different muscles originate from different embryonic tissues and can be traced back to their lineage. For example, muscles in the trunk and limbs develop from the somites, whereas, most of the head muscles (apart of the tongue and some muscles of larynx and neck that originate from the paraxial mesoderm and the lateral splanchnic mesoderm). These cells maintain their signature up to adulthood as was reported in studies in which satellite cells derived from

different muscles expressed different genes and maintained the expression pattern during their proliferation and differentiation in culture (Day et al., 2007; Harel et al., 2009; reviewed in Biressi and Rando, 2010).

The heterogeneity of satellite cells was evident in clonal analyses of cultures derived from different muscles. The various clonal subpopulations expressed different myosin isoforms (Stockdale, 1990; Feldman and Stockdale, 1991; Hoh and Hughes, 1988). Based on the ability to proliferate, Schultz and Heckman-Jones (1990) demonstrated the presence of two populations of satellite cells in vivo, where one population did not appear to divide during 7 days of extensive muscle growth. Clonal analysis of chicken satellite cells by Yablonka-Reuveni et al. (1987) identified differences in colony sizes. More than 90% of the clones gave rise to large colonies, whereas 8−9% gave rise to small colonies, suggesting that satellite cells in these colonies differ in their ability to form myonuclei. The ability of these subpopulations to maintain their phenotype in culture out of their in vivo environment, suggests an intrinsic diversity of "slow" and "fast" satellite cells (Biressi and Rando, 2010). The variations in the ability satellite cells to proliferate could be explained at least in part by their different responses to growth factors, such as IGF-I, FGF-II, and PDGF (McFarland et al. 1995, 2003; Yun et al., 1997). Fast-growing clones were all more responsive to FGF2 and expressed greater levels of FGF2 and the FGF receptor-1 at the onset of proliferation than did the slow-growing clones (McFarland et al., 2003). These differences were reflected in the levels of activated intracellular signaling proteins, which were higher in the fast-growing clones (McFarland and Pesall, 2008). Satellite cells also differ in their ability to fuse. In vitro and in vivo studies on turkey satellite cells revealed that cells with high-proliferation rate fused mainly with differentiated myotubes or myofibers, cells that with slow proliferation rate mainly fused together (Rouger et al., 2004).

The heterogeneity of satellite cells in adult animals is also evident with respect to their self-renewal capacity and muscle regeneration. Genetic studies with mice have shown that of the Pax7-expressing satellite cells, the small subset that never express Myf5 contribute to the satellite cell reservoir, whereas the rest of the cells contribute to myofiber regeneration (Kuang et al., 2007). Pax3-expressing satellite cells were reported to be resistant to muscle damage followed by environmental pollutants (Der Vartanian et al., 2019). Satellite cells express a variety of cell-surface proteins (e.g., M-cadherin, CD34, syndecan 4, integrin α7), and show different engraftment and regeneration potential based on the nature of the expressed proteins (Tanaka et al., 2009; Biressi and Rando, 2010). Yet, the actual relationship between the nature of the cell-surface molecules and the ability of the satellite cells to contribute to the muscle regeneration is still unclear. Moreover, exogenous cues from the extracellular environment (e.g., acute injury) can affect satellite cells' behavior upon injury regardless their hereditary history (reviewed in Cornelison, 2018). There is considerable heterogeneity in myofiber structure, metabolism, and responses to stimuli, depending on the specific function of the muscle. Muscles for quick short burst movements differ from muscles for sustained movement. Postural muscles also have different properties than muscles that are not involved in posture. Satellite cell heterogeneity is observed during embryogenesis; cells that reside in different muscles originate from different embryonic tissues and can be traced back to their respective lineages. For example, muscles in the trunk and limbs develop from the somites, whereas most of the head muscles (apart from the tongue and some muscles of the larynx and neck that originate from the paraxial mesoderm and the lateral splanchnic mesoderm), develop from the anterior paraxial mesoderm. These cells maintain their signature into adulthood, as reported in studies in which satellite cells derived from different muscles expressed different genes, and maintained their expression patterns during their proliferation and differentiation in culture (Day et al., 2007; Harel et al., 2009; reviewed in Biressi and Rando, 2010).

The heterogeneity of satellite cells was evident in clonal analyses of cultures derived from different muscles. The various clonal subpopulations expressed different myosin isoforms (Stockdale, 1990; Feldman and Stockdale, 1991; Hoh and Hughes, 1988). Based on the ability to proliferate, Schultz and Heckman-Jones (1990) demonstrated the presence of two populations of satellite cells in vivo; one of these populations did not appear to divide during seven days of extensive muscle growth. Clonal analysis of chicken satellite cells by Yablonka-Reuveni et al. (1987) identified differences in colony sizes. More than 90% of the clones gave rise to large colonies, whereas 8−9% of them gave rise to small colonies, suggesting that satellite cells in these colonies differ in their ability to form myonuclei. The ability of these subpopulations to maintain their phenotype in culture, outside of their in-vivo environment, suggests an intrinsic diversity of "slow" and "fast" satellite cells (Biressi and Rando, 2010). The variations in the satellite cells' ability to proliferate could be explained at least in part by their different responses to growth factors, such as IGF-I, FGF2, and PDGF (McFarland et al. 1995, 2003; Yun et al., 1997). Fast-growing clones were all more responsive to FGF2, and expressed higher levels of FGF2 and FGF receptor 1 at the onset of proliferation compared to the slow-growing clones (McFarland et al., 2003). These differences were reflected in the levels of activated intracellular signaling proteins, which were higher in the fast-growing clones (McFarland and Pesall, 2008). Satellite cells also differ in their ability to fuse. In-vitro and in-vivo studies of turkey satellite cells revealed that cells with a high-proliferation rate fuse mainly with differentiated

myotubes or myofibers, and cells with a slow proliferation rate mainly fuse together (Rouger et al., 2004).

The heterogeneity of satellite cells in adult animals is also evident with respect to their self-renewal capacity and muscle regeneration. Genetic studies with mice have shown that of the Pax7-expressing satellite cells, the small subset that never expresses Myf5 contributes to the satellite cell reservoir, whereas the rest of the cells contribute to myofiber regeneration (Kuang et al., 2007). Pax3-expressing satellite cells were reported to be resistant to muscle damage from environmental pollutants (Der Vartanian et al., 2019). Satellite cells express a variety of cell-surface proteins (e.g., M-cadherin, CD34, syndecan 4, and integrin α7), and show different engraftment and regeneration potentials based on the nature of the expressed proteins (Tanaka et al., 2009; Biressi and Rando, 2010). Nevertheless, the actual relationship between the nature of the cell-surface molecules and the ability of the satellite cells to contribute to muscle regeneration is still unclear. Moreover, exogenous cues from the extracellular environment (e.g., acute injury) can affect the satellite cells' behavior upon injury, regardless of their hereditary history (Cornelison, 2018).

23.10 Novel genes involved in avian myogenesis

Avian muscle growth may involve genes that have not yet been characterized to play a role in myogenesis. A complete transcriptome analysis was performed in turkeys using a turkey skeletal muscle long oligonucleotide array constructed from the pectoralis major muscle at three developmental stages (Reed et al., 2008; Sporer et al., 2011a): E18, 1 day of age and 16 weeks of age. Of the differentially expressed genes (Sporer et al., 2011b), three were further studied for their effects on the proliferation and differentiation of satellite cells. These genes encoded versican, matrix Gla protein, and death-associated protein (DAP).

Versican is a large chondroitin sulfate proteoglycan initially reported in cultured fibroblasts (Zimmerman and Ruoslahti, 1989). By knocking down versican expression in turkey satellite cells, their proliferation increased, supporting a potential role for versican in this proliferation (Velleman et al., 2012). In addition, versican is expressed during early embryonic muscle formation and muscle regeneration; it was shown to be located in the surrounding matrix of the developing myotubes (Carrino et al., 1999). High expression of versican was found in developing synovial joint interzones, suggesting its involvement in facilitating the patterning of muscle and nerves in the developing limb (Snow et al., 2005).

Matrix Gla protein is highly expressed by vascular smooth muscle cells (Proudfoot and Shanahan, 2006), but prior to the report of Sporer et al. (2011b), it had not been identified in skeletal muscle. Knocking down only matrix Gla protein decreased proliferation in satellite cells isolated from growth-selected turkeys (Velleman et al., 2012). A later report demonstrated that matrix Gla protein binds myostatin and prevents its signaling pathway, thereby could inhibit the latter's inhibitory effect on proliferation and differentiation of satellite cells (Ahmad et al., 2017). The highly conserved proline-rich phosphoprotein DAP is a substrate of mTOR (Koren et al., 2010), which is a primary intracellular pathway controlling muscle hypertrophy (Bodine et al., 2001). In both turkey (Velleman et al., 2012) and chicken (Shin et al., 2013b) breast muscle satellite cells, knocking down DAP expression severely inhibits the formation of myotubes, suggesting DAP as a key gene in the regulation of avian myogenesis.

Other genetic factors affecting avian muscle myogenesis have been recently described, among them the microRNAs (miRNAs). These are noncoding small RNAs (i.e., 20−23 nucleotides) that regulate post-transcriptional gene expression by targeting specific sites in the 3′-untranslated region of mRNAs. The miRNAs are widely involved in biological and metabolic processes, including muscle development and growth (Hitachi and Tsuchida, 2013). Harding and Velleman (2016) found specific miRNAs that play a role in the proliferation and differentiation of turkey satellite cells; inhibition of these miRNAs led to impaired myogenesis. In addition, specific miRNAs have been reported to affect chicken growth traits, such as cell proliferation and regulation, calcium signaling, axonal guidance signaling, and oxidative stress response mediated by the nuclear factor NRF2 (Ouyang et al., 2015; Khatri et al., 2018). These miRNAs may therefore serve in future genetic strategies to manage muscle growth.

Circular RNAs (circRNAs) are noncoding closed RNA molecules derived from canonical splice sites; they are abundant in all eukaryotes, and some of them are highly conserved. Although described decades ago, their biological functions have only recently begun to be deciphered. The circRNAs may act as protein or miRNA inhibitors ("sponges or decoys"), or by regulating protein functions in biological processes in various cell systems, including epidermal, neuronal, muscular, and cancer cells (reviewed in Kristensen et al., 2019). They have been suggested to play a role in the regulation of avian myogenesis. For example, temporal expression of circRNAs was found during early and late embryonic stages of chick muscle development; of these, the circRBFOX2s were validated as promoters of myoblast proliferation by binding to and inhibiting the activity of miRNA-206 (miR-206) (Ouyang et al., 2018). In addition, circFGFR2, generated from the FGF2 receptor gene, and circHIPK3 have been reported to improve myoblast proliferation and differentiation by sponging miR-133 and miR-29 (Chen et al., 2018), and miR-30 (Chen et al., 2019), respectively. A recent study has

shown differential expression of circRNAs in breast muscle during the ontogeny of broilers versus layers (Shen et al., 2019). These studies and others suggest an additional layer of regulation which could serve as a basis for selecting specific traits in muscle growth and meat quality.

23.11 Recent emerging breast muscle necrotic and fibrotic myopathies

The poultry breeding industry has placed major emphasis in selection for increased growth rate and breast muscling. Increased growth rates in poultry have helped the poultry industry keep up with consumer demand for economical chicken and turkey products, but these increases must be accompanied by consideration of the cellular mechanisms affecting muscle growth as both the morphological structure and biochemical properties are affected. These changes in muscle, especially the breast muscle, have resulted in meat quality issues which are the end consequence of myofiber defects. Typical myofiber defects found in poultry selected for increased growth rate have included deep pectoral myopathy (Wilson et al., 1990; Sosnicki and Wilson, 1991), focal myopathy (Sosnicki, 1993), and pale, soft, and exudative (PSE) meat (Sosnicki, 1993; Pietrzak et al., 1997). Breast muscle is a fast twitch anaerobic muscle composed mainly by glycolytic myofibers. The fast growth of this muscle causes increase in the size of these myofibers leading to an increase in anaerobic capacity (Dransfield and Sosnicki, 1999; Yost et al., 2002). Being an anaerobic muscle, the breast muscle has a reduced vasculature system compared to a slow twitch aerobic muscle. Reduced capillaries have been found surrounding muscle in necrotic regions of turkey breast muscle fibers (Sosnicki and Wilson, 1991). Lactic acid is produced by anaerobic respiration, which leads to higher acid concentrations in the muscle and decreased pH. Pale soft exudative meat is characterized by low-postmortem pH. The decreased ability to remove lactic acid from breast muscles with limited circulatory supply likely contributes to the reduced pH observed in PSE meat. However, in the last decade especially in fast-growing meat-type broilers, breast muscle myopathies resulting in muscle fiber necrosis and the fibrosis or replacement of muscle fiber with connective tissue have emerged.

At the present time, white striping, wooden breast, and spaghetti breast have been phenotypically identified in the broiler breast muscle (Fig. 23.2). These myopathies have been observed globally where heavy weight fast-growing broiler lines are used. The white striping defect results in white stripes or striations following the muscle fiber orientation. It does not appear to affect the quality of the cooked breast muscle but does affect the appearance. The visual observation of white striations in the boneless skinless broiler breast muscle fillets may reduce consumer acceptance of the product and purchase intent. Almost all heavy commercial broilers marketed in the United States exhibit some degree of white striping in the breast muscle (Kuttappan et al., 2016). Since muscle fibers are surrounded by connective tissue, the white striping may arise from altered connective tissue deposition or structure. Kuttappan et al. (2013) reported that there is an increase in pathological changes in the breast muscle with white striping. White striping can vary in severity and affect the morphology of the muscle. In breast muscle samples with severe or moderate levels of white striping, there is a loss of cross striations, variable muscle fiber size, floccular or vacuolar degeneration and lysis of fibers, mild mineralization, occasional regeneration, mononuclear cell infiltration, lipidosis, and interstitial inflammation and fibrosis. In addition, the fat level is increased, and protein is decreased in white striped muscle.

Sihvo et al. (2014) first reported the wooden breast myopathy in the breast muscle of broilers. Wooden breast results in the phenotypic appearance of muscle discolorations, turbid viscous coating of the outer surface, and a palpably hard consistency (Sihvo et al., 2014; Bailey et al., 2015; Tasoniero et al., 2016). It has been estimated that 48% to 73% of commercial broilers are at least mildly affected by wooden breast (Sihvo et al., 2017). Wooden breast muscle is characterized by varying levels of myofiber necrosis, fibrosis with extensive fibrillar collagen deposition, small regenerating myofibers, hypercontracted fibers, and immune cell infiltration (Sihvo et al., 2014; Velleman and Clark, 2015). Breast muscle in wooden breast affected broilers is in oxidative stress (Abasht et al., 2016), which may result from a reduction in circulatory supply and lower mitochondrial content. Meat product downgrades or condemnation results from severe forms of wooden breast.

Spaghetti breast is a newer named breast muscle myopathy in commercial broilers. As reported by Baldi et al. (2018), spaghetti breast is characterized by the separation of muscle fiber bundles in the pectoralis major muscle. The name spaghetti breast was chosen as the muscle fiber cylindrical rods are visible and resemble pasta noodles. Similar to white striping and wooden breast, spaghetti breast muscle fibers feature large to small diameter muscle fibers along with hypercontracted fibers (Baldi et al., 2018). In contrast to wooden breast and white stripping, following processing the pectoralis major muscle can be pulled apart by hand. As described by Baldi et al. (2018), the endomysial and perimysial connective tissue layer in spaghetti breast progressively degrades. Meat quality is negatively impacted by this myopathy.

23.12 The effect of fibrillar collagen on the phnotype of necrotic breast muscle myopathies resulting in fibrosis

The skeletal muscle is surrounded by three distinct connective tissue layers: the epimysium, perimysium, and endomysium (Fig. 23.1A). The epimysium surrounds the entire muscle and is continuous with the joining of various muscle group or the tendon attaching muscle to bone. Although the epimysium is very thick, it is not a factor in meat quality as it can easily be removed. The perimysium surrounds muscle fiber bundles, and the endomysium surrounds individual muscle fibers. The connective tissue layers are responsible for many of the functional properties associated with muscle and factors affecting meat quality. Tissue structure, the elasticity of the tissue, vascular supply to the muscle tissue, and water-holding capacity are all properties linked to connective tissue primarily the perimysium which can compose up to 90% of the intramuscular connective tissue. Connective tissue is made up of cells and the extracellular matrix.

The extracellular matrix is defined to include all secreted molecules that are immobilized outside cells. Thus, the cell makes its own extracellular environment. The major macromolecular components of the extracellular matrix include collagens, proteoglycans, and noncollagenous glycoproteins. The structure of the extracellular matrix is not random as it is tissue-type and age-specific. The matrix is dynamically expressed and directly impacts muscle proliferation, adhesion, migration, and overall tissue structure including elasticity. The composition and organization are of significant with regard to the fibrotic breast muscle myopathies. The predominant extracellular matrix protein in the avian breast muscle are the fibrillar collagens especially Types I and III. Fibrosis is characterized by the excessive deposition of collagen in response to chronic cellular damage.

The fibrillar collagens are characterized by a single triple-helical domain containing three peptide chains forming a right-handed alpha helix. All collagens have the amino acid repeat in the helical domain of Gly-X-Y where X and Y can be any amino acid but are frequently proline or lysine. After the triple-helical structure is formed, collagen is secreted into the extracellular matrix space where it is aligned into a quarter stagger array leading to the formation of collagen fibrils that are stabilized by crosslinking between the collagens. Crosslinking of the fibrillar collagens is necessary for both its structural stability and functional properties and is a major determinant of meat textural properties. The covalent hydroxyl pyridinoline (HP) crosslink is a mature, nonreducible, trivalent crosslink that forms from the condensation of divalent ketoimine crosslinks (Reiser et al., 1992). The formation of HP crosslinks is progressive with age, and the toughening of meat is directly attributable to crosslink concentration. With tissue injury, the repair process results in collagen fibrils that have higher levels of HP crosslinking (Zimmerman et al., 2001). Since collagen HP crosslinking is progressive with age and increases with tissue injury, fibrotic myopathies will result in increased collagen deposition and crosslinking leading to a stiff breast muscle like what is observed in the wooden breast myopathy. The muscle necrotic and fibrotic process is characterized by both changes in tissue structure and composition of the extracellular matrix. In fibrotic tissue, there is an excessive

deposition of fibrillar collagen (Alexakis et al., 2007; Serrano et al., 2010; Velleman et al., 2017). Thus, necrotic and fibrotic conditions in skeletal muscle will result in an altered structural architecture of the extracellular matrix and function with reduced elasticity.

23.13 Relationship of fibrillar collagen organization to the phnotype of breast muscle necrotic/fibrotic myopathies

The process of fibrosis is a self-perpetuating response to muscle necrosis resulting in the progressive overproduction of fibrillar collagens Types I and III in the perimysial and endomysial connective tissue spaces. The phenotype of necrotic/fibrotic myopathies is not a direct relationship to the concentration of collagen but to the organization of collagen. Factors determining the fibrotic phenotype include, but are not limited to fibril diameter, degree of crosslinking, proteoglycan localization and type, fibril alignment, and morphometric organization of the collagen fibrils.

The three collagen polypeptide chains will wrap around each other intracellularly to form a right-handed triple helix. At this point, the collagen molecule is exocytosed into the extracellular space where fibril and fiber formation take place. The collagen fiber is the functional form impacting tissue structure, elasticity, and ultimately meat quality. After secretion, the collagen molecules will align in parallel to form a quarter staggered array which is a necessary step leading to assembly of collagen fibrils. The collagen fibrils are stabilized by the formation of reversible divalent crosslinks. The alignment of the collagen molecules is not a random process and after alignment there are gap and overlap areas within the quarter staggered array. The length of one overlap zone is 67 nm and termed a D banding-period. If the alignment of the collagen molecules is altered, the length of the D-period will be modified affecting collagen fibril function. After collagen fibril formation, the collagen fibrils will come together forming collagen fibers. With maturation, divalent ketoimine crosslinks are replaced with trivalent nonreversible HP crosslinks. The HP crosslink is a critical factor in tissue stiffening. After three collagen triple helices are linked together, additional helices are linked together increasing collagen fibril diameter and crosslinking. The formation of HP crosslinks is a progressive process with age and is likely a major factor in the phenotypic detection of wooden breast by palpation and the reduction in meat quality.

Since the wooden breast myopathy is characterized by excessive fibrotic deposition of collagen fibrils, it is of importance to understand the ultrastructural intramuscular organization of the fibrillar collagens in fast-growing meat-type broilers of differing parental lineage. A series of studies was conducting examining collagen fibril structure in three fast-growing commercial broiler lines with distinctly different levels of phenotypically detectable wooden breast (Velleman and Clark, 2015; Velleman et al., 2017; Tonniges et al., 2019). The commercial lines used in this study were referred to as A, B, and C. Line C infrequently exhibits any phenotypically detectable wooden breast whereas Line A has a high degree of affected birds, and Line B has intermediate phenotypic detection of wooden breast affected birds. Velleman and Clark (2015) and Velleman et al. (2017) using light microscopy observed that Line A with a high degree of phenotypically wooden breast affected birds, had perimysial collagen fibers characterized by parallel packing (Fig. 23.3). In contrast, Line B by palpation had a low percentage of birds categorized as wooden breast affected. Light microscopic examination revealed that the perimysial collagen was not packed but diffuse in structure. Microscopic histological examination of the muscle showed that 70% of Line B birds observable necrosis and fibrosis.

Transmission electron microscopy (TEM) analysis was used to further investigate histological differences, measure collagen D-periodicity, and collagen fiber diameter in Lines A, B, and C affected and unaffected wooden breast birds (Velleman et al., 2017). As discussed in Velleman et al. (2017), "wooden breast affected Line A muscle had overall smaller average collagen fibril diameter and longer average collagen D-period compared with unaffected Line A muscle, whereas Line B showed no such differences. Fibrotic collagen of WB-affected muscle of Line A exhibited D-period length and fibril diameter more similar to endomysial collagen of unaffected muscle of Line A. The fibrillar structure of fibrotic collagen in Line B affected with WB was more similar to perimysial collagen of Line B-unaffected muscle. The endomysial collagen of Line A was altered with WB myopathy while the endomysial collagen of Line B was not. Endomysial collagen of Line A exhibited decreased fibril diameter and increased D-period length with WB myopathy. Changes in D-period length and collagen fibril diameter are a direct consequence of the ordered arrangement of the collagen molecule within the collagen fibril. These modifications in the collagen fibril are indicative of alterations in the molecular packing of collagen monomers, which can impact collagen function by altering protein binding sites or the flexibility of the collagen fibril."

These TEM studies showed that there is different fibrotic collagen organization in the breast muscle of fast-growing meat-type broilers. These difference in fibrosis most likely represents unique uncharacterized breast muscle myopathies. Myopathies like wooden breast have increased stiffness or hardness of the breast muscle which is likely the result of high levels of collagen crosslinking.

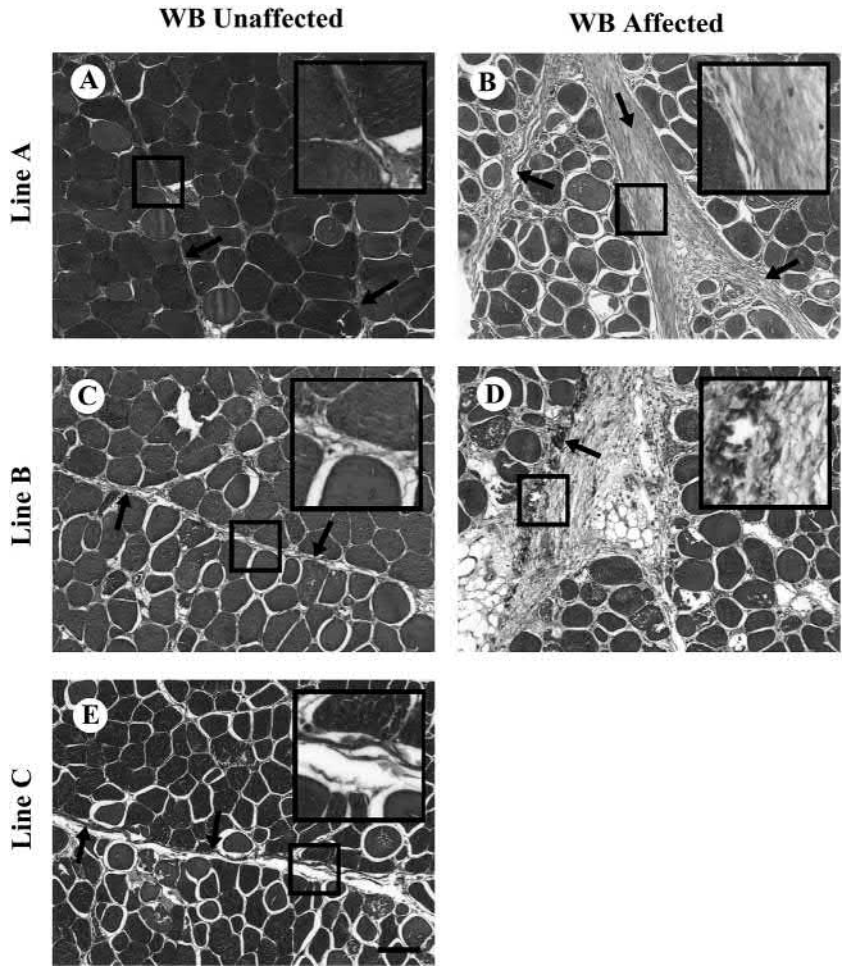

FIGURE 23.3 Masson trichrome staining of collagen organization in wooden breast (WB)-unaffected and affected pectoralis major muscle. (A), (C), and (E) are representative images of WB-unaffected pectoralis major muscle from Lines A, B, and C, respectively. (B) and (D) are representative images of WB-affected pectoralis major muscle from Lines A and B, respectively. The arrows highlight fibrillar collagen and the boxes contain enlargements of the fibrillar collagen. Scale bar = 100 μm. *Figure reproduced with permission from Velleman et al. (2017).*

Greater amounts of the HP crosslink will lead to tightly packed collagen fibrils. Fibrotic myopathies not detected by palpation is due to the collagen fibrils being diffuse with lower levels of crosslinking, and the breast will not be hard. Despite not being phenotypically detectable, the presence of necrosis and fibrosis will still alter the protein content of the breast muscle and impact meat quality.

In addition to the fibril organization differing in fast-growing broiler lines, the fibrillar collagen composition of the fibrils may also be affected by fibrosis. Skeletal muscle contains fibrillar collagens Types I and III. The expression of collagen is age-dependent. During early development, Type III collagen is the predominant collagen but with age there is a shift toward Type I collagen (Bornstein and Sage, 1980; Light and Champion, 1984; Kovanen and Suominen, 1989). With injury and inflammation as occurs in myopathies like wooden breast, the expression of collagen will shift back to an embryonic-like tissue with increased amounts of Type III collagen. With tissue repair, Type I collagen expression will increase, and Type III collagen will decrease (Bailey et al., 1975; Barnes et al., 1976; Weber et al., 1978; Merkel et al., 1988). Collagen fibrils can be homotypic composed of only a single collagen type or heterotypic containing a mixture of collagen types. Although the functional impact of collagen fibril composition is not well understood, it has been postulated that collagen fibril composition can influence muscle stiffness and meat tenderness (McCormick, 1994). Differential collagen fibril composition and its impact on broiler skeletal muscle has not been reported to date. However, in other tissue systems, heterotypic collagen fibrils containing both Types I and III collagen have reduced stiffness and collagen fibril diameter (Romanic et al., 1991; Notbohm et al., 1993; Asgari et al., 2017). When collagen Type III expression increases as observed with skeletal muscle injury (Hurme et al., 1991; Gibertini et al., 2014), Type III

collagen is localized in highly aligned and tightly packed collagen fibrils (Brisson et al., 2015; McConnell et al., 2016) as observed in wooden breast. Thus, collagen Type III expression may be associated with the fibrotic organization of collagen fibrils. Future studies will need to address the relationship of collagen fibril composition and the expression of the different fibrillar collagen types with broiler breast muscle fibrotic myopathies.

23.14 Regulation of muscle growth properties by cell-membrane associated extracellular matrix macromolecules

In addition, to the extracellular matrix having an integral function in the functional attributes and meat quality of the breast, the extracellular matrix proteoglycan component has been shown to regulate muscle growth. The cell-membrane associated proteoglycans can have extracellular, transmembrane, and cytoplasmic domains. Thus, these proteoglycans can play roles in organizing extracellular matrix structure, cytoskeletal organization, cell to cell adhesions, and cell signal transduction. The syndecans and glypicans are two families of heparan sulfate proteoglycans that are integral components in growth factor signal transduction. FGF 2 is a potent stimulator of muscle cell proliferation and a strong inhibitor of differentiation (Dollenmeier et al., 1981). In particular, the growth factor FGF2 binds with a high affinity to its tyrosine kinase receptor by binding to the heparan sulfate chains of the syndecans and glypicans (Steinfield et al., 1996).

The syndecans have four family members, syndecan-1 through -4, and all four types are found in skeletal muscle (Larraín et al., 1997, 1998; Brandan and Larraín, 1998; Fuentealba et al., 1999; Liu et al., 2006). All the syndecans are type I membrane glycoproteins (Deepa et al., 2004) and usually contain at least three heparan sulfate chains as well as N-glycosylated chains. However, the core protein can also have covalently attached dermatan and chondroitin sulfate chains. All the syndecans have extracellular, transmembrane, and cytoplasmic domains. The cytoplasmic domain for syndecan-1 through -4 have two conserved regions (C1 and C2) separated by a variable region (V). The C terminus of the cytoplasmic domain has a conserved amino acid sequence, EFYA, which allows the syndecans to function as a diverse set of cell-surface receptors (Choi et al., 2011). The following describes the known functions of each of the syndecans in skeletal muscle.

Syndecan-1 is a regulator of FGF2 signal transduction and syndecan-1 is expressed at higher levels during muscle cell proliferation than differentiation (Larraín et al., 1997; Liu et al., 2004). In growth-selected turkeys, syndecan-1 expression is higher than in turkeys without selection for growth (Liu et al., 2004). The higher expression of syndecan-1 may lead to a prolonged period of proliferation leading to a larger pool of muscle cells available to differentiate into muscle fibers.

Syndecan-2, in a manner similar to syndecan-1, is expressed at higher levels during the proliferation of avian muscle cells and expression decreases with differentiation (Liu et al., 2006). Less is known about the function of syndecan-2 in muscle than the other syndecans, but there is evidence that the cytoplasmic domain may be involved in regulating cellular responsiveness to TGF-β (Chen et al., 2004).

Recent research on syndecan-3 suggests that it may play a role in the maintenance, proliferation, and differentiation of myogenic satellite cells (Fuentealba et al., 1999; Cornelison et al., 2004; Pisconti et al., 2010). The absence of syndecan-3 leads to muscular dystrophy types of conditions characterized by impaired locomotion, fibrosis, decreased myonuclear number (Cornelison et al., 2004), and satellite cells with reduced proliferation (Pisconti et al., 2010).

Syndecan-4 is the most well studied of the syndecans in poultry muscle development. Syndecan-4 has been shown to play important roles in muscle maintenance and regeneration (Cornelison et al., 2001, 2004). In turkey satellite cells, syndecan-4 is expressed at high levels during proliferation (Velleman et al., 2007), affects satellite cell function in an age-dependent manner (Velleman et al., 2018). The primary role for syndecan-4 in muscle is in its regulation of cytoskeletal organization and muscle cell migration (Shin et al., 2012, 2013a; Song et al., 2012a,b). In the presence of phosphatidylinositol 4,5-bisphosphate (PIP_2) bound to the V region of the syndecan-4 cytoplasmic domain, syndecan-4 functions in the translocation of inactive protein kinase C α (PKCα) to the muscle cell membrane resulting in its activation (Song et al., 2012c; Shin et al., 2012). Once activated, PKCα mediates the activation of downstream RhoA signal transduction which is involved in mediating cell migration (Dovas et al., 2006; Shin et al., 2013a). Deletion of the syndecan-4 cytoplasmic domain or a knockdown of RhoA inhibits cell migration in turkey satellite cells (Shin et al., 2013a). The binding of PIP_2 also functions in the stabilization of syndecan-4 leading to the formation of syndecan-4 oligomers in turkey satellite cells (Shin et al., 2012). The oligomerization of syndecan-4 is required for the activation of syndecan-4 as syndecan-4 in the monomer form is not able to activate PKCα (Horowitz and Simons, 1998a,b).

Syndecan-4 may have varying functions with regard to FGF2 based on cell type. For example in endothelial cells, both the syndecan-4 heparan sulfate chains and the cytoplasmic domain have been shown to be necessary for syndecan-4 mediated FGF2 cell signaling (Volk et al., 1999). However, in turkey satellite cells, the heparan

sulfate chains are not required for syndecan-4 FGF2 signal transduction, but the cytoplasmic domain and cytoplasmic domain Ser^{178} in the conserved C1 region is required for modulating satellite cell responsiveness to FGF2 (Zhang et al., 2008; Song et al., 2012c,d). Horowitz and Simons (1998a,b) found that the Ser residue in the C1 domain can be phosphorylated by growth inhibitors and dephosphorylated by the addition of FGF2. The phosphorylation of the Ser in the C1 region will decrease PKCα activation. In turkey satellite cells, the Ser^{178} amino acid stimulates both PKCα activation and FGF2-induced proliferation (Song et al., 2012d).

23.15 Strategies to reduce myopathies

It has become clear that myopathies in poultry develop mainly in fast-growing meat-type chickens, with the pectoralis major muscle being more affected than the leg muscles (Powell et al., 2014; Harding et al., 2016). The genetic selection for body and breast muscle growth results in a high-metabolic rate and extensive protein accretion (Havenstein et al., 2003a,b), both of which worsen the chickens' ability to cope with stresses, such as oxidative or heat stress. This could be because the pectoralis major muscle, which is a fast glycolytic muscle with low-blood supply, has outgrown its support system (i.e., the vasculature) (Velleman and Clark, 2015; Sihvo et al., 2014, 2017), resulting in more incidences of hypoxia (Boerboom et al., 2018) and an increase in reactive oxygen species (Abasht et al., 2016). In these chickens, such stresses may lead to repetitive muscle degeneration–regeneration cycles accompanied by inflammation, fat deposition, an increase in fibrotic tissue, and depletion in the number of satellite cells (Kuttappan et al., 2016; Daughtry et al., 2017), resembling the situation in human muscular diseases. A very recent paper raised the hypothesis that deregulation of fat and glucose metabolism and chronic overload of these nutrients in the pectoralis major muscle lead to wooden breast phenotype, similar to what is observed in complications of type 2 diabetes in mammals (Lake and Abasht, 2020).

The high-metabolic rate of fast-growing meat-type chickens also leads to overproduction of body heat. Since birds are homeotherms and maintain their body temperature within a narrow range, high metabolic heat production in these chickens makes it more difficult for them to cope with environmental heat stress, even at an early age (for a comprehensive review, see Yahav, 2015). Studies on broilers have demonstrated that chronic heat exposure results in lower weight gain, coupled with a lower absolute growth of pectoralis muscle (Baziz et al., 1996) and decreased vascular support (Hadad et al., 2014; Joiner et al., 2014). Moreover, increased fat and collagen deposition was observed interstitially in pectoralis muscle; fat droplets were observed in the myofibers of chicks exposed to heat stress in the first 2 weeks posthatch (Piestun et al., 2017; Patael et al., 2019), implying a white striping myopathy in these chickens. Accumulation of fat was also observed in satellite cells derived from the heat-exposed chickens. Accumulation of fat and increased adipogenic gene expression were observed in studies using clonal satellite cells exposed to a variety of temperatures (Harding et al., 2015, 2016), suggesting transdifferentiation of satellite cells to adipogenic ones.

The full etiology of the pectoral major muscle myopathies is not fully understood, and it is not known whether onset of the diseases has a single or multiple cause. However, several strategies are being employed to ameliorate the severity of the myopathies and thereby reduce the damage to meat quality. Attempts to slow down the growth rate of fast-growing chickens, which tend to develop myopathies (Baldi et al., 2018; Petracci et al., 2019), could be made by breeding chickens that grow at a slower rate. However, even though it should still be considered, the genetic factor seems to contribute only a relatively small part to myopathy development, while the greater impact is attributed to mostly nongenetic factors (Bailey et al., 2015, 2020). Growth rate could also be reduced through feed restriction during early or later stages of growth. Factors such as the timing or duration of the feed restriction should be considered, as the first week posthatch is crucial for satellite cell myogenic activity (see Section 23.6) and for maturation of the intestinal system (Geyra et al., 2001). Feed deprivation during the first days posthatch leads to irreversible adverse effects on muscle development and growth (Halevy et al., 2001, 2003; Mozdziak et al., 2002), while feed restriction in the second week posthatch leads to compensatory growth (Plavnik and Hurwitz, 1998). Nevertheless, with regard to reducing myopathies and improving meat quality, the feed-restriction approach is still under debate. More recent studies have shown that while energy restriction negatively affects overall performance (e.g., feed conversion), the effects on breast muscle myopathies and meat quality are contradictory (Velleman al., 2014a,b; Trocino et al., 2015; Meloche et al., 2018a). However, altering the balance of dietary amino acids (e.g., D-Lysine) reduced the levels and severity of white striping and wooden breast (Meloche et al., 2018b).

Other approaches to alleviating the muscle degeneration are aimed at improving management and environmental conditions. For example, lighting with green and/or blue monochromatic light during embryonic development and early posthatch initially proved to enhance satellite cell proliferation and muscle growth (Halevy et al., 1998, 2006b; Rozenboim et al., 2004), and improve meat quality (i.e., paleness, pH, drip loss) (Karakaya et al., 2009; Zhang et al., 2012). In addition, the white striping myopathy, which has been suggested to emerge due to chronic heat

stress during the early posthatch period, may be reduced by keeping the hatching chicks under mildly colder temperatures (Patael et al., 2019). Rearing hatching chicks at a gradient of 4 to 2°C below the recommended commercial temperature for the first 2 weeks did not have any adverse effects on body growth or muscle yield, while it reduced the fat and collagen deposition in the muscle (Patael et al., 2019).

Another strategy is acclimating meat-type chickens to high temperature, enabling them to cope with heat stress. Early studies showed that thermal conditioning for 3 or 6 h on day three of age, when satellite cells are at their peak myogenic activity, promotes body weight and pectoralis muscle growth and improves thermal tolerance to heat stress (Halevy et al., 2001). Thermal manipulations in which the incubator temperature was intermittently raised during embryonic periods that are critical for the development of thermoregulation and stress systems, as well as skeletal muscle, had long-term promotive effects on muscle growth and thermotolerance (Piestun et al., 2009a, b, 2011, 2013). Loyau et al. (2013) found that intermittent thermal manipulation from E7 to E16 improves the thermotolerance of broilers exposed to heat stress on day 34 of age, without affecting meat quality of the breast muscle. A different pattern of expression of genes related to, for example, energy metabolism, vascularization, and muscle growth, was observed in a gene-array assay on pectoralis muscle derived from heat-treated embryos compared to nontreated ones (Loyau et al., 2016). These and other studies suggest that thermal manipulations during embryonic or early posthatch periods that are crucial for myogenic and thermoregulation development affect epigenetic processes, resulting in changes in the expression of specific genes and leading to long-lasting effects on thermotolerance and muscle growth (Halevy, 2020).

23.16 Summary

Muscle development involves a wide range of cellular events that have distinct embryonic and posthatch phases. Therefore, many factors can influence the development and growth of avian skeletal muscle. This chapter provides a broad overview of avian muscle structure and function, prehatch and posthatch muscle development, and the genes and factors regulating these processes. In addition, this chapter details the newly evolved muscle myopathies in meat-type chicks, the influence of the extracellular matrix on their development, and strategies to ameliorate these myopathies which have a large impact on meat quality and consequently, the poultry industry.

Chapter 24

Immunophysiology of the avian immune system

Michael H. Kogut
Southern Plains Agricultural Research Center, USDA-ARS, College Station, TX, United States

24.1 Introduction

Like the previous edition of this book, the chicken remains the primary focus of this chapter because of its worldwide economic importance. However, since the last edition of this book, there has been a dramatic, and almost instantaneous, shift in how chickens are grown. The advent and development of ongoing social and political changes in the 21st century has resulted in consumer demands for drug-free poultry products. Consequently, avian immunology research has resulted in more applied exploration into avian immune modulation as an alternative to antibiotics, functional studies on immune mechanisms of action, regulation of host responses by the innate immune system, the impact of the intestinal microbiota on immunity, and the introduction of the area of immunometabolism. Instead of trying to summarize all components aspects of the avian immune system, repeating the anatomy of the avian immune system and describing the differences of the immune response between avians and mammals that was thoroughly covered by our late colleague, Professor Pete Kaiser, this chapter will concentrate on the physiological functions of the avian immune system.

24.2 Innate immune system recognition, sensing, and function

Innate immunity is the first line of defense against pathogens, which, consequently, has critical roles in shaping further specific adaptive immune responses. To induce host resistance against a given pathogen, the immune system must activate mechanisms that aim to overcome potential escape mechanisms induced by the pathogen. Evolution has enabled cells of the innate immune system to develop multiple pattern recognition receptors (PRRs) that sense microbial-associated molecular patterns (MAMPs). MAMPs are molecular structures shared by large groups of pathogens that are conserved products of microbial metabolism not subject to antigenic variability (Fearon and Locksley, 1996). They are required for either the survival or pathogenicity of the microbe and are distinct from any host antigens. The innate immune system can not only discriminate self from nonself via recognition of MAMPs (Janeway, 1989; Palm and Medzhitov, 2009), but it can also discriminate between live and dead microorganisms through a distinct set of MAMPs called vita-MAMPs associated uniquely with live microorganisms (Sander et al., 2011; Blander and Sander, 2012). Vita- MAMPs are detected in combination with classic MAMPs such as lipopolysaccharide (LPS) and DNA, which are shared between live and dead microorganisms (Sander et al., 2011; Blander and Sander, 2012). Detection of MAMPs in the absence of vita-PAMPs signifies a dead microbe, whereas detection of a vita-MAMP alongside a MAMP signifies live microbes and mediates a heightened immune response not warranted to dead microorganisms (Blander and Sander, 2012). The activity of virulence factors associated with live pathogens elicits a vigorous immune response, but continued expression of virulence factors becomes unnecessary once a pathogen has gained access to sterile tissues. Targeting microbial viability per se independently of virulence factors is a far better strategy for the immune system to eliminate the infectious threat and protect tissue integrity. Two vita-MAMPs, bacterial messenger RNA (mRNA) in the context of a response to live gram-negative bacteria (Sander et al., 2011; Barbet et al., 2018; Ugolini et al., 2018), and cyclic-di-adenosine monophosphate (c-di-AMP) in the context of a response to live gram-positive bacteria (Moretti et al., 2017) have been identified so far. The incorporation of a vita-MAMP into a killed or subunit vaccine could recapitulate the efficacy of a live vaccine.

24.2.1 Innate cell receptors: pattern recognition receptors

The host receptors that recognize MAMPs are evolutionarily conserved proteins that are expressed on cells that first encounter infectious agents including all effector cells of innate immunity, antigen-presenting cells, and surface epithelium of the respiratory, genital, and intestinal tracts (Medzhitov and Janeway, 1997a). Functionally, PRRs induce innate effector function and alert the host to the presence of infectious agents. Furthermore, it is readily apparent that an essential function of the innate immune system appears to be to instruct the lymphocytes to develop a particular effector response to a specific pathogen (Janeway, 1989; Fearon and Locksley, 1996). Since MAMPs are produced exclusively by microbes and not by the host, recognition by host PRRs signals the presence of pathogens. MAMP recognition activates effector mechanisms of innate host defenses, including phagocytosis, the synthesis of antimicrobial peptides, and the induction of the respiratory burst and nitric oxide synthase. These endogenous signals orchestrate the recruitment of leukocytes to the site of infection and regulate the activation of the suitable effector mechanisms by controlling differentiation of T lymphocytes into effector cells of a particular type. Lastly, and most importantly, recognition of MAMPs by PRRs induces the expression of co-stimulatory molecules by antigen-presenting cells, i.e., natural adjuvant activity, and leads to the development of highly antigen-specific memory cells (Medzhitov and Janeway, 1997a, b, 2002; Kopp and Medzhitov, 1999). The ability of the lymphocytes to differentiate into effector cells is dependent upon and controlled by signals produced by the cells of the innate system (Medzhitov and Janeway, 1997a). Thus, it can be seen that adjuvants are primarily MAMPs that induce the innate immune response to produce the required co-stimulatory molecules that result in protection.

Innate immune cell activation through distinct PRRs leads to the induction of responses that are adapted to the features of the invading pathogen. The type of innate immune response executed downstream of PRRs has important implications for not only initial host resistance but also for the induction of long-lasting adaptive immunity. Recognition or sensing platforms of the innate immune system are critical for orchestrating the communication between the host and its microbial environment. Further, the genomic sequences and function of PRRs are more extensively conserved than B and T cell receptors (Temperly et al., 2008) signifying that the capability to identify MAMPs may be more essential for species survival than the acquired immune response.

Multiple recognition systems have coevolved to preserve normal interactions with the commensal flora and to initiate immune responses to invading pathogens and perturbations in tissue homeostasis. Endosomal and extracellular toll-like receptors (TLRs) recognize mainly MAMPs found in and on microbes including proteins, lipids, and nucleic acids. Meanwhile, a multitude of cytosolic receptors [nod-like receptors (NLRs)] recognize not only intracellular MAMPS but also the host-derived signals known as "damage-associated molecular patterns" (DAMPs). The cooperation between these compartmentalized surveillance systems allows organisms to sense and respond to a number of infectious and sterile insults to the host. Innate immune recognition of MAMPs initiates a signal transduction cascade that leads to the transcription of immune response genes through nuclear factor-κB (NF-κB) and the production of various effector molecules.

24.2.1.1 Toll-like receptors

TLRs consist of a leucine-rich repeat domain that specifically binds to individual MAMPs, a transmembrane region, and a cytoplasmic Toll/interleukin-1 receptor domain (Rock et al., 1998). Members of the TLR family are typically located either at the surface of eukaryotic cells or in the endolysosomal compartment. Each of the TLRs has a distinct ligand specificity; most often of microbial origin. TLR ligands are structurally conserved, absent in the host, and important, not necessarily for virulence of microbe, but for the survival of the microbe. This ensures detection by the host of a wide range of bacteria, viruses, or fungi with a minimum of TLR.

According to Keestra et al. (2013), the chicken homologs of the human TLRs are TLR1 type 1, TLR1 type 2, TLR2 type 1 and TLR2 type 2, TLR3, TLR4, TLR5, TLR7, as well two that are unique for chickens, TLR15 and TLR21 (Boyd et al., 2001; Dil and Qureshi, 2002; Yilmaz et al., 2005; Higgs et al., 2006; Keestra et al., 2007; Temperley et al., 2008). These receptors can act alone or in concert with other TLRs and adaptors including CD14 (Kogut et al., 2005a) and MD-2 (Keestra and van Patten, 2008). Chicken TLR1, 2, 3, 4, 5, and 7 are orthologous to their mammalian counterparts but chickens lack TLR8 and 9. Chickens have two TLR1s (TLR1A and B) and two TLR2s (TLR2A and B) as a result of gene duplication. These variants dimerise to form cell surface receptors which recognize the same PAMPs as human TLR2 (Higuchi et al., 2008), which can dimerise with human TLR1, 6, and 10, thus suggesting chickens recognize a similar range of MAMPs as mammals, although using a different TLR repertoire (Kaiser, 2010). Chicken TLR2 type 2 can respond to LPS suggesting that this receptor may also covers the function of TLR4 in chicken (Fukui et al., 2001). Further, chicken TLR2 isoform type 2 in conjunction with chTLR16 (putative chicken TLR with unknown function) reacts to both di- and triacylated peptides similar in function to that of mammalian TLR2/1 and TLR2/6 receptor complexes (Keestra et al., 2007).

Activation of TLRs by specific MAMP binding attracts cytoplasmic mediators that direct signal transduction through NF-κB and the mitogen-activated protein kinase (MAPK) pathways. Activation of the NF-κB transcription factor allows it to translocate from the cytosol to the nucleus where it affects expression of numerous genes involved in the immune response (Camaño and Hunter, 2002). In chickens, TLR activation is followed by increased transcription of cytokines, including IL-1β and IL-6, and chemokines, including CXCLi2, CXCLi1, and CCLi4 (Kogut et al., 2005b, 2006).

The two chicken-specific TLRs, TLR15 and TLR21, have been identified and characterized. TLR15 is activated by fungal and some bacterial proteases (De Zoete et al., 2011; Higgs et al., 2006; Oven et al., 2013; Neerukonda and Katneni, 2020). (TLR21 is the functional homolog of TLR9 in humans that recognizes bacterial CpG DNA (Brownlie et al., 2009)). TLR21 activation by CpG oligodeoxynucleotide induces heterophil degranulation in vitro (He et al., 2005) and in vivo primed heterophils degranulation and oxidative burst (He et al., 2007; MacKinnon et al., 2009). Stimulation of chicken heterophils with TLR agonists flagellin (TLR5) and LPS (TLR4) induced the activation of all three members of the MAPK family, ERK, c-Jun, and p38 that then induced the translocation and activation of the transcription factors NF-κB and AP-1 resulting in the increased expression of IL6 and CXCLi2 (Kogut et al., 2005, Kogut et al., 2006, 2008).

24.2.1.2 Nod-like receptors

The NLR family of intracellular PRRs that sense microbial products or the products of damaged host cells, such as ATP and uric acid, play a pivotal role in the initiation of antimicrobial immune responses. Despite the increased understanding of NLR function and interactions in mammals, most aspects related to mechanisms of sensing, downstream signaling, and in vivo functions in avians remain elusive (Neerukonda and Katneni, 2020). To date, there have only been four NLRs found in the chicken genome: NOD1 (Tao et al., 2015) NLRP3 (Ye et al., 2015), NLRC5 (Lian et al., 2012; Ciraci et al., 2010), and NLRC3 (Neerukonda and Katneni, 2020) with only NLRP3 and NLRP5 having been functionally characterized (Ciraci et al., 2010; Ye et al., 2015; Liu et al., 2015).

24.2.1.3 RIG-like receptors

The RIG-like receptor family are select cytosolic RNA helicases which bind nucleic acids (Loo and Gale, 2011). RLRs sense viral pathogens from non-self RNA (Magor et al., 2013; Campbell and Magor, 2020). In mammals, the RLR family contains the retinoic acid-inducible gene 1 (RIG-1), melanoma differentiation-associated protein 5 (MDA5), and laboratory of genetics and physiology 2 (LGP2) as members. However, chickens lack RIG-1 while ducks possess tissue specific RIG-1 (trachea and intestine) (Campbell and Magor, 2020) which accounts for the susceptibility of chickens to single-stranded RNA viruses such as influenza A and Newcastle disease virus and the relative resistance of ducks to both viruses (Campbell and Magor, 2020; Neerukonda and Katneni, 2020). Interestingly, the MDA5 family, present in chickens and ducks, can detect avian influenza and generates an interferon response (Karpala et al., 2011; Campbell and Magor, 2020; Neerukonda and Katneni, 2020). LGP2 lacks two N-terminal components that are involved in downstream signal transduction integration, but LGPs does appear to be a positive regulator of interferon-beta production following viral recognition by RIG-1 and MDA5 (Satoh et al., 2010).

24.2.1.4 C-type lectin receptors

Nerren and Kogut (2009) were the first to report that the C-type lectin receptor, dectin-1, primary PRR for exogenous β-glucan, a component of fungal and bacterial cell walls, respond to a Dectin-1-specific agonist by significantly increased production of an oxidative burst. Further, we have shown that administration of β-glucan as a feed additive resulted in increased phagocytosis, oxidative burst, and bactericidal capacity of chicken heterophils, resulting in significantly reduced organ invasion by *Salmonella enterica* serovar Enteritidis (Lowry et al., 2005).

Cooperation of TLR signaling with other PRRs in bacterial recognition and signal integration is indicative of the life cycle of the respective pathogen. The example of *Salmonella typhimurium* infection best illustrates this concept. As mentioned above, both TLR5 and NLRC4 recognize bacterial flagellin, but at different subcellular localizations. Both PRRs initiate distinct signaling pathways in response to *Salmonella* infection (NF-kB signaling and inflammasome, respectively), which proceed independently of one another. This strategy accounts for the hierarchy of effector mechanisms and the fitness cost that is associated with it; Extracellular *Salmonell*a is detected by surface-bound TLR5, initiating a MyD88-dependent NF-kB response and the induction of cytokines. Once *Salmonella* has invaded the cell cytoplasmic flagellin triggers the inflammasome, a pathway that causes pyroptotic cell death and the release of IL-1β, one of the most potent proinflammatory mediators and modulators of systemic organism physiology.

24.2.2 Host defense peptides

Host-defense peptides (HDPs), formerly known as antimicrobial peptides, are a diverse group of small peptides found in most species of life (Cuperus et al., 2013; Mansour

et al., 2014; Robinson et al., 2015). HDPs are 10–50 amino acids peptides that are enriched in hydrophobic and cationic amino acid residues. As part of the innate immune system, HDPs possess both antimicrobial and immunomodulatory properties. HDPs antibacterial mode of action is via a physical electrostatic interaction that disrupt the bacterial cell membrane. The majority of the HDPs are synthesized by the host's phagocytic and mucosal epithelial cells lining the urogenital, respiratory, and gastrointestinal (GI) tracts (Zasloff, 2002). Mature HDPs are active *Salmonella* and *Campylobacter* (van Dijk et al., 2012; Garcia et al., 2018, 2020) and have activity against fungi and enveloped viruses (Zhang and Sunkara, 2014; Robinson et al., 2015). There are three classes of HDPs found in chickens including 14 β-defensins (AvBD1-14), four cathelicidins (CATH1-3 and CATH-B1) (Zanetti, 2005), and liver-expressed antimicrobial peptide 2 (LEAP2) (Zhang and Sunkara, 2014). HDPs also recruit and activate immune cells, which are involved in host defense against pathogens (Cuperus et al., 2013).

Avian β-defensins (AvBDs) were the first to be discovered in chickens. Sequencing of all 14 AvBDs revealed that the N-terminal signal peptide regions are highly conserved. AvBDs are synthesized as inactive prepropeptides consisting of a short signal peptide, a propeptide and the mature peptide. Transcriptional analysis of AvBD genes have found that AvBD1, 2, and 4 to 7 are predominately expressed in the bone marrow, while AvBD3, and 8 to 14 are expressed by epithelial cells (Lee et al., 2016). However, AvBDs can be expressed in either the bone marrow or epithelial cells as well as in other tissues.

Presently, four avian cathelicidins (CATHs) have been discovered in chickens (Zanetti, 2005). CATH1 and CATH2 are predominantly expressed in the bone marrow but have been shown to be expressed in other tissues. CATH1 expressed in the gizzard, small intestine, and large intestine while CATH2 expression is highest in liver and in the cecal tonsils. CATH3 is predominately expressed in the lung bone marrow and liver (Goitsuka et al., 2007; Achonta et al., 2012). CATHB1 expression has been predominantly found in the bursa of Fabricius (Lee et al., 2016).

LEAP2 is expressed as part of the epithelial innate defense system (Lynn et al., 2007; Townes et al., 2004) and functions to prevent pathogens from interacting with epithelial surfaces and potentially invading tissues. Townes et al. (2004) found that in 4-day-old 16 chicks, which had been orally inoculated with *Salmonella*, there was a significant upregulation of LEAP2 mRNA in the small intestine and liver. It was later reported that in vitro, LEAP2 is able to affect the permeability of the bacterial outer membrane, leading to cell death (Townes et al., 2009). Host defense peptides are essential since they are the first response to pathogens as part of the innate immune system.

24.2.3 Innate immune memory: trained immunity

Recently, the concept of "trained immunity" or innate immune memory has emerged and challenged conventional paradigms of T and B cell-mediated adaptive memory (Netea et al., 2011). Essentially, trained immunity is induced after either a primary infection or innate modulation and confers protection independently of T or B cells, is mediated by innate immune cells, and increases resistance to infection by the same and other pathogens. In addition, several studies have demonstrated that priming with *Candida albicans* or the fungal cell-wall component β-glucan nonspecifically induces enhanced secondary responses. Recent studies have shown, however, that innate immune cell populations such as myeloid cells and NK cells also undergo functional adaptation after infection or vaccination, a de facto innate immune memory that is also termed trained immunity (Netea et al., 2011, 2016). In addition, several studies have demonstrated that, in mouse and human cells, priming with *Candida albicans* or the fungal cell-wall component β-glucan nonspecifically induces enhanced secondary responses. Trained immunity differs from immune priming since after recovery from infection, innate immune responses do not return to the steady-state level. This is due to the epigenetic reprogramming of innate immune cells rather than the short-lived change of state seen in immune priming. Stimulation of the innate immune response with prominent microbial components that activate PRRs offer therapeutic and adjuvant potential in poultry since they not only directly stimulate arrange of cell types but can give rise to robust adaptive responses through driving maturation of antigen-presenting cells. Recent data have provided compelling evidence that the innate immune system can be "trained" to respond more rapidly and effectively to pathogens following treatment with Dectin-1 agonists (Lowry et al., 2005; Nerren and Kogut, 2009; Kogut et al., 2010·2012, 2013). We have successfully purified multiple natural Dectin-1 ligands from yeast that change the transcriptional program of innate immune cells from poultry. Innate immune memory differs from adaptive memory in many aspects, including the lack of gene rearrangements, the epigenetic reprogramming, the type of cells involved (innate cells vs. T and B lymphocytes), and the receptors engaged in pathogen or antigen recognition (selective PRRs vs. antigen-specific T cell and B cell receptors) (Netea et al., 2011, 2016).

24.3 Acquired immune recognition and function

24.3.1 The major histocompatibility complex

The adaptive immune response is only triggered when pathogen antigens are presented to T cells in the context of molecules called the major histocompatibility complex (MHC). The region of the genome that encodes the MHC is highly polymorphic and in mammals includes approximately 300 genes. The most relevant for antigen presentation are the class I genes, which present antigens from intracellular pathogens, mainly to CD8+ T cells, and the class II genes, which present antigens from extracellular pathogens, mainly to CD4+ T cells. MHC class I proteins are expressed on most cell types, whereas MHC class II proteins are mainly expressed on antigen-presenting cells such as dendritic cells (DCs), macrophages, and B cells. In contrast to the mammalian MHC, the chicken has a minimal essential MHC (Kaufman et al., 1999). In mammals, there are several class I and class II genes; precise numbers vary from species to species and in some cases between individuals of the same species. In contrast, in the chicken, the minimal essential MHC contains only two class I genes and two class IIβ genes, with only one of each dominantly expressed (reviewed in Kaufman, 2000). This has some striking consequences, particularly for the chicken's ability to mount an immune response to a pathogen, especially a virus.

24.3.2 Th1/Th2 paradigm and T helper cell subsets

The polarization of naïve chicken CD4+ T cells into two subsets of activated CD4 T cells, Th1 and Th2 cells, which differ from each other in their pattern of cytokine production and their functions (the Th1/Th2 paradigm) was demonstrated over 15 years ago (Degen et al., 2005). Broadly, Th1 cells mediate a cellular immune response, and Th2 cells potentiate a humoral response. Specifically, Th1 cells are especially effective in protecting against intracellular infections by viruses and bacteria and microorganisms that grow in macrophages. Th2 cells are indispensable for host immunity to extracellular parasites, such as helminths (Kidd, 2003). Functional genes of signature cytokines hallmarking Th1- and Th2-type responses in mammals, particularly interleukin (IL)-4, IL-12, IL-13, IL-18, and interferon-γ (IFN-γ), have been identified in chicken (Avery et al., 2004; Balu and Kaiser, 2003; Degen et al., 2004; Kaiser, 2010). In addition, the existence of a Th1-like system was shown in vitro through IL-18-induced proliferation and IFN-γ secretion of chicken splenic $CD4^+$ T cells (Göbel et al., 2003). Another study also found Th1 and Th2-like responses in vivo, characterized by elevated expression of IFN-γ, IL-4, and IL-13 following infection of birds with a virus (Newcastle disease virus) and a helminth (*Ascaridia galli*), representing intracellular and extracellular pathogens, respectively (Degen et al., 2005; Pleidrup et al., 2019; Dalgaard et al., 2015). However, it should be noted that the avian Th1/Th2 system has some oddities, for example, during a Th2 response in chickens, IL-4 and IL-13 are expressed (Degen et al., 2005; Powell et al., 2009), but IL-5 expression is switched off. In mammals, IgE production is dependent on Il-5 expression by Th2 cells, but in chickens, IgE is not produced and there is an absence of the effector cell of IgE, functional eosinophils, which are involved in the mammalian Th2 response (Kaiser and Stäheli, 2014).

More recently, two more CD4+ subsets have been discovered in chickens. First, T regulatory (Tregs) have been identified (Shanmugasundaram and Selvaraj, 2010, 2011). Treg cells secrete IL-10 and transforming growth factor (TGF)-β that temper CD4+ T-cell activity and suppress some of their functions, inducing tolerance to antigens. More recently, a fourth subset of CD4+ cells, the Th17 cell, has been identified in the chicken (Reid et al., 2016). Th17 effector cells play a fundamental role in both tissue inflammation and activation of granulocytes to combat extracellular bacteria predominantly in the mucosal surfaces of the intestine and respiratory systems. Remarkably, the master regulators of transcription for Tregs and Th17, Forkhead box P3 (FoxP3) and the retinoic-acid-related orphan receptor gamma t, respectively, have not been identified in the chicken although a recent study has shown phylogenetic evidence of FoxP3 in birds (Denyer et al., 2016). However, all of the cytokines crucial to driving mammalian Th lineage development have now been identified in the chicken (Kaiser, 2012) including the recently identified IL-23 (Truong et al., 2017).

24.4 Gastrointestinal tract and immune system of poultry

The GI tract lumen can be considered as being part of the external environment. One of the most important roles of the gut is providing a barrier between the internal and external environment, as the GI tract is the site of colonization and invasion of many pathogenic bacteria. Through this and several other functions, the GI tract has an important role in the immune function of a bird (Patterson and Burkeholder, 2003; Beal et al., 2006). Posthatching is a vital time for the development of the gut immune system of the bird. The immune system must differentiate between food, beneficial bacteria, and harmful pathogens, so there is

a fine balance between tolerance and response to antigens. This is fundamental to gut health as a prolonged immune response can cause problems such as villus atrophy. The sequential development of various phase of intestinal immunity have been characterized in broiler chickens during the first weeks of posthatch: (a) innate development and influx of immune cells; (b) immune differentiation and specialization; and (c) maturation and immune regulation (Bar-Shira et al., 2003; Bar-Shira and Friedman, 2006; Schokker et al., 2009).

24.4.1 Mucosal lymphoid tissues and cells

The combined mucosal surfaces of the gut, respiratory, and reproductive tracts represent by far the largest surface area in contact with the external milieu. They can also be considered the largest organ system in vertebrates, with each tract involved in diverse physiological functions, such as digestion and gas exchange. These functions come along with the continuous movement of external substances—nutrients and air, respectively—and the need to transport or exchange essential molecules across the mucosal surface. Hence, there is a continual challenge from new materials and microorganisms, including pathogenic microorganisms, which pass through the system. To prevent the entry of pathogens through the mucosal tissues, a wide variety of protective mechanisms has evolved. These range from barrier functions (e.g., keratinized skin, ciliated cells in the trachea, mucus secretion) to highly specialized immune cells (e.g., Langerhans cells in the skin) and organized lymphoid structures. In particular, the mucosal immune systems of the respiratory, gut, and reproductive tracts have highly developed lymphoid tissues, such as bronchus-associated lymphoid tissues and gut-associated lymphoid tissue, along with Peyer's patches, cecal tonsils, and lymphoid follicles. In addition, the lamina propria harbors a wide range of immune cells, such as intraepithelial and lamina propria lymphocytes, macrophages, and DCs. In mammalian species, the gut contains more lymphocytes than all secondary lymphoid tissues collectively. It is likely that this is also the case in avian species (reviewed in Schat and Meyers, 1991), particularly because birds lack lymph nodes. Numerous lymphoid follicles are found throughout the gut; typically, these consist of one or more B cell follicles and a surrounding T cell zone. It is not clear if these structures represent secondary or tertiary lymphoid tissues; however, given the increasing number of different classes (Baptista et al., 2013) of similar structures that have been identified in mammals, it is likely that the lymphoid follicles of the chicken gut represent lymphoid tissues of diverse ontogenies and functions. Finally, the epithelial cells of the mucosal surfaces are able to sense pathogens and actively shape the response of the immune cells underneath.

24.4.2 Intestinal barrier system

The intestinal innate defenses are characterized by a "mucosal firewall," a system of barriers that separates the lumenal side of the intestine from the subepithelial tissues (Macpherson et al., 2009; Belkaid and Hand, 2014). The reliability of the mucosal firewall is vital for the interactions between the immune system components and the intestinal contents. The first component of the mucosal firewall is the microbiological barrier where the microbiota live in or at the upper mucus layer. These commensal bacteria function to provide colonization resistance against pathogen colonization, produce metabolites/components that modulate immune signaling, and promote immune homeostasis (Garrett et al., 2010; Belkaid and Hand, 2014; Belkaid and Harrison, 2017). The second firewall is the chemical barrier consisting of the mucus overlaying the gut epithelium. The mucus regulates contact between the commensal bacteria and the epithelial cells. This division between the epithelium and commensals is achieved by the activity of the mucus produced by goblet cells in the epithelium, antimicrobial peptides released by the epithelial cells, and mucosal IgA produced by DCs in the intestine (Vaishnava et al., 2011; Belkaid and Harrison, 2017). The third component of the firewall is the physical barrier provided by the single cell epithelial cell layer. The intestinal epithelium is a single cell layer that assists the absorption of nutrients while providing a physical barrier that prevents both pathogen invasion and extraintestinal translocation of commensal microbes. Besides being the primary barrier preventing a microbial breach of the intestine, the epithelial cells should also be considered part of the cellular component of the innate immune response possessing PRRs for sensing MAMPs, but also capable of producing cytokines and chemokines to drive an inflammatory response against pathogen infection. The final component of the mucosal firewall is the immunological barrier where the professional immune cells (macrophages, DCs, lymphocytes) reside in the lamina propria (Abraham and Medzhitov, 2011). Further innate sensing of microbes is conducted by the macrophages and DCs which can present antigens to T cells resulting in the differentiation and activation of various T cell subsets (Abraham and Medzhitov, 2011). Specialized epithelial cells of the GI tract function together with lymphoid, myeloid, and stromal cells to secrete mucus, antimicrobial peptides, IgA, and chemokines that limit direct contact between the epithelium and infectious agents and activate target cells that mediate innate defenses (Medzhitov, 2001; Akira et al., 2006; Abreu et al., 2005; Kawai and Akira, 2009; Mantis and Forbes, 2010). The importance of these epithelial defense mechanisms is highlighted by the ability of enteric pathogens to target these mechanisms to achieve invasion and

dissemination (Awad et al., 2017; Goto et al., 2017; Alemka et al., 2012).

24.4.3 Intestinal microbiota

Chickens, like all production animals, are metaorganisms that maintain a diverse population of microorganisms on their barrier surfaces, collectively named the microbiota. Since most pathogens either cross or inhabit barrier surfaces, the microbiota plays a critical and often protective role during infections, both by modulating immune system responses and by mediating colonization resistance. However, the microbiota can also act as a reservoir for opportunistic microorganisms that can "bloom," significantly complicating diseases of barrier surfaces by contributing to inflammatory immune responses. With the advent of next-generation sequencing technologies, our understanding of the complex relationship between the host and its resident microbes has been fundamentally changed. The microbes that inhabit the intestinal barrier surface are not the result of random colonization but are shaped by interactions with the host and are therefore unique to each tissue site (reviewed by Bloom and Kogut, 2018). Chickens have evolved in the context of microbial colonization; therefore, there are multiple host functions dependent upon cues derived from the microbiota (Sommer and Backhead, 2013; Bloom and Kogut, 2018). Not least of these is the immune system, which can sense the microbiota directly via its expression of microbe-associated molecular patterns, enzymatically derived metabolites, and foreign antigens (Belkaid and Hand, 2017; Bloom and Kogut, 2018). Thus, the immune system relies upon the microbiota for protection against invading pathogens, but this close relationship comes with a significant risk in that if it becomes perturbed, responses against the microbiota can contribute to disease.

Poultry are naturally adapted to hosting a complex GI microbial community with hundreds of bacterial species and up to 10^{11} CFU per gram of gut contents (Barnes, 1979). Benefits conferred by this microbial community (the GI microbiome) include promoting beneficial development of the intestinal mucus layer, epithelial monolayer, and lamina propria (Shakouri et al., 2009; McCraken and Gaskins, 1999), excluding pathogenic taxa (Nurmi et al., 1992), breaking down polysaccharides (Beckman et al., 2006), providing energy as amino acids and short chain fatty acids (Dunkley et al., 2007; van Der Wielen et al., 2000) and promoting proper development and homeostasis of the immune system (Oakley et al., 2014).

The GI tract, or "gut," regulates homeostasis of the microbiological, physiological, and physical functions that allows the host to endure infectious and noninfectious stressors that it encounters (Crhanova et al., 2011; Sansonetti, 2004; Garriga et al., 2006; Maslowski and Mackay, 2011; Quintero-Fiho et al., 2012). Because the gut has the greatest surface area separating the environmentally exposed lumen and the internal subepithelial tissue, it is constantly exposed to infectious and noninfectious stressors making it an active immune organ containing more resident immune cells than any other organ in the host. The gut mucosal immune system, a highly regulated network of innate and acquired elements, provides a remarkable ability to respond and modify to these extremely diverse encounters (Thaiss et al., 2016; Honda and Littman, 2016). The development of the different divisions of the immune response has corresponded with the acquisition and maintenance of a symbiotic microbiota. The microbiota trains, stimulates, and functionally adjusts the different features of the immune system (Hooper and Macpherson, 2010; Hooper et al., 2012).

24.4.4 Intestinal immune functionality

24.4.4.1 Gut microbiota-immunity communication

The crosstalk that occurs between the host and its gut microbiota affects host metabolism, immunity, and health mediated by dietary nutrients, host and microbiota metabolites, microbial structural components, as well as antimicrobial compounds. Microbiota growth and anatomical location are regulated by the host through production of nonspecific antimicrobial peptides such as defensins (Xiao et al., 2006; Bomnineni et al., 2014), IgA (Lammers et al., 2004; Den Hartog et al., 2016), and miRNAs that regulate bacterial transcripts and bacterial growth (Liu et al., 2016).

The commensal microbes in the intestinal tract sense the local environment to induce biochemical pathways to activate bacterial metabolism that allows them to avoid, alter, and/or survive host innate immune killing. Moreover, some microbial-based molecules can promote specific commensal processes that are beneficial to both host and microbe. Similarly, the host detects the microbes through their production of specific molecules or components with unique molecular patterns that leads to activation of innate and acquired immune responses. Thus, the adaptation of the commensal bacteria (as well as viruses and fungi) living in the intestine of a host has resulted in a mutually beneficial coexistence for both microbiota and host during homeostasis (Kogut, 2013; Kogut et al., 2017; Broom and Kogut, 2018). The interdependent relationship between host and microbiota pointedly influences the host immune response to induce an immune tolerance to commensal microbes while also maintaining responsiveness to invading pathogens (Bene et al., 2017; Guo et al., 2017; Shi et al., 2017). Altering the intestinal microbial communities disturbs this immune balance and leads to immune dysregulation and susceptibility to diseases.

24.4.4.1.1 Components of the microbiota

The microbiota is directly engaged in maintaining the functional innate immunity of the host. The host immune system consistently senses the intestinal microenvironment to determine the metabolic state and colonization status (Levy et al., 2016). In the steady state, the metabolites and/or components of the commensal microbiota are recognized by various PRRs to regulate intestinal epithelial barrier function, cellular lifespan of phagocytes, and induce secretion of antimicrobial peptides and IgA (Levy et al., 2016; Blacher et al., 2017). Further, beneficial bacteria ferment dietary fibers to produce small chain fatty acids (SCFAs) which stimulate the production of anti-inflammatory cytokines (Levy et al., 2016; Blacher et al., 2017) that drives the production of regulatory T cells (Tregs). In addition, the microbiota influences the priming signal of the inflammasome activation that leads to the transcription of IL-6, as well as pro-IL-1β and pro-IL-18.

There is growing evidence that some commensal and symbiotic bacteria have MAMPs that promote a tolerant host phenotype. *Bacteriodes fragilis* polysaccharide A, for example, interacts with TLR2 on regulatory T-cells (T_{regs}) to promote tolerance and inhibit T_{H17} responses (Round and Mazmanian, 2010; Round et al., 2011). Other bacteria, particularly *Clostridia* species, are able to stimulate the development of T_{regs} as well (Round and Mazmanian, 2010; Round et al., 2011; Atarashi et al., 2011), while attachment of segmented filamentous bacteria, notably Candidatus Savagella, in the ileum has been shown to stimulate differentiation of proinflammatory T_{H17} type cells (Ivanov et al., 2009).

24.4.4.1.2 Microbial metabolites

It has also become apparent that the intestinal immune system can also detect the metabolic state of the microbiota by recognition of microbial metabolites via their PRRs (Levy et al., 2017; Blacher et al., 2017). The microbiota, using several biochemical pathways, metabolizes both diet- and host-derived metabolites that then influence various components of the intestinal immune system. For example, the microbiota converts nondigestible fibers to SCFA that have several anti-inflammatory activities (Postler and Ghosh, 2017). Dietary tryptophan can be degraded by the microbiota into indoles which promote epithelial cell barrier function (Postler and Ghosh, 2017). Likewise, the microbiota can metabolize dietary arginine to polyamines that inhibit the production of proinflammatory cytokines by macrophages (Postler and Ghosh, 2017). The microbiota converts primary host-derived hepatic bile acids to secondary bile acids that inhibit proinflammatory cytokine secretion by DCs and macrophages (Thaiss et al., 2014). Besides having a repertoire of metabolite sensing receptors, the host has developed immune signaling pathways (inflammasomes) expressed in various intestinal cell subsets (macrophages, DCs, epithelial cells, T cells) that recognize microbial-mediated metabolic activity that can stimulate antimicrobial activity involved in stable colonization of the intestine (Levy et al., 2015; Wang et al., 2015; Birchenough et al., 2016).

24.4.4.1.3 Microbial epigenetic modifications

Epigenetics involves genomic modifications through post-translational and post-transcriptional modifications induced by environmental factors, but without modifying the nucleotide sequence of the host cell (Shenderov et al., 2012). Epigenetic mechanisms regulate transcriptional control by external environmental including host-microbe crosstalk (Woo and Alenghat, 2007; Grabiec and Potempa, 2018). Since epigenetic events do not alter the DNA, the epigenomic effects are associated with the attachment of different chemical groups to DNA, histones, and chromatin post-translationally and the epigenetic alterations can persist for several generations (Furrow et al., 2011; Shenderov et al., 2012). These epigenetic alterations affect both the chromatin structure and serve as recognition elements for proteins with motifs dedicated to binding particular modifications.

Since the gut microbiota plays such a pivotal role in poultry metabolism, microbiota-induced epigenetic alterations by dietary nutrients could be a significant environmental factor affecting poultry performance and health. Based on studies in mammals, microbiota-generated metabolites of dietary components can be epigenetic activators of gene expression that modify or inhibit enzymes involved in epigenetic pathways (Alenghat et al., 2013; Alenghat and Artis, 2014; Hullar et al., 2014, Woo and Alenghat, 2007). This can best be exemplified by the production of SCFAs (acetate, propionate, butyrate) produced by intestinal microbiota by bacterial fermentation of non-digestible carbohydrates (Guilloteau et al., 2010; Jian et al., 2015). Butyrate is best known for its beneficial effects on intestinal barrier function, anti-inflammatory activity, and as the primary source of energy to intestinal epithelial cells (Hamer et al., 2008; Guilloteau et al., 2010; Leonel and Alvarez-Leite, 2012; Huang et al., 2015). Butyrate regulates these biological activities of host gut health by functioning as a histone deacetylase inhibitor (HDAC) (Canani et al., 2012; Liu et al., 2018). Butyrate anti-inflammatory activity is mediated by HDAC suppression of NF-κB in phagocytic cells and DCs, increased production of anti-inflammatory cytokines, and the increased differentiation of naive T cells into T regulatory cells (Usami et al., 2008; Arpaia et al., 2013). Other microbial metabolites derived from dietary components, such as nicotinamide adenine dinucleotide (NAD)-dependent deacetylases called sirtuins, have been shown to mediate the regulation of epigenetic

modifications, including DNA methylation noncoding RNAs and histone modification, in the host intestinal immune-barrier function of mammals (Kobayashi et al., 2012; Ganal et al., 2012; Singh et al., 2012). Further research is needed to determine whether such gut microbiota metabolite-mediated epigenetic modifications of the immuno-barrier function occur in the poultry intestine.

24.4.5 Gut microbiota: immune homeostasis

Based on new concept brought forward by Andreas Baumler and colleagues, homeostasis of the gut microbiota-immune interactome is a "state of immune competence" (Byndloss et al., 2019; Litvak and Baumler, 2019) that involves two complimentary elements: the traditional protective *anti-infective immunity* and a distinct type of immune response called *microbiota-nourishing immunity* (Byndloss et al., 2019; Litvak and Baumler, 2019). During homeostasis or health, the microbiota can effectively inhibit colonization and overgrowth by invading microbes such as pathogens. This phenomenon is called "colonization resistance" and is associated with a stable and diverse microbiota in tandem with a controlled lack of inflammation, and involves specific interactions between the mucosal immune system and the microbiota (Lawley and Walker, 2013; Buffie and Pamer, 2013). According to Byndloss et al. (2019), the first step in intestinal immune protection against pathogens is microbiota-nourishing immunity which functions in maintaining a balanced intestinal microbiota so that colonization resistance may be initiated. Microbiota-nourishing immunity involves the activation of two components of colonization resistance: direct (microbiota origin) and indirect (host origin) activities which function to protect the "microbial organ" within the host intestinal organ. The second component of the intestinal immune response is the activation of the conventional anti-infective immunity which prevents colonization and growth of pathogens through antimicrobial peptide production, inflammasome activation, and the expression and production of IL-17, IL-10, and IL-22 (Belkaid and Hand, 2014; Sassone-Corsi and Raffatellu, 2015; Lee and Mazmanian, 2010; Round and Mazmanian, 2009; O'Mahony et al., 2008; Ivanov et al., 2009). As described above, in a healthy microbiota, the commensal microbiota provides colonization resistance against potential pathogens in the gut. However, when perturbations (antibiotics, dietary changes) disrupt the commensals, colonization resistance is compromised. Pathogens like *S. typhimurium* and *Clostridium perfringens* can exploit the ecological opportunity by the availability of resources to expand. Thus, the pathogens change the playing field by inducing inflammation and causing other physiological changes (diarrhea) that influences the intestinal environment to promote their own growth (Winter et al., 2013).

24.4.5.1 Gut microbiota: immune dysfunction—dysbiosis

The microbiota in the GI is impacted, and potentially altered, when exposed to antibiotics, infection of the host by pathogens, diet, and several other host- and environmental-dependent influences. As describe previously, during homeostasis, the bacteria work together to produce beneficial metabolites that are used by the host. Dysbiosis (dysbacteriosis) occurs when there is a perturbation in the microbiota composition and/or function that leads to an imbalance between beneficial and harmful bacteria resulting in an unwanted immune response against commensal bacteria. Dysbiosis leads to a decrease in bacterial diversity and essential functions directly affecting metabolic activity, which can then deprive the host of valuable end products leading to poor gut health and bird performance (Ducatelle et al., 2015). Based on the Baumler concept (Byndloss et al., 2019), dysbiosis is a weakening in microbiota-nourishing immunity that disrupts colonization resistance, thus, allowing pathogens a physiological "opening" to exploit for colonization. As described above, in a healthy microbiota, the commensal microbiota provides colonization resistance against potential pathogens in the gut. However, when perturbations (antibiotics, dietary changes) disrupt the commensals, colonization resistance is compromised. Pathogens like *S. typhimurium* and *Clostridium perfringens* can expand by exploiting the ecological opportunity of increased availability of nutritional and physiological resources. Thus, the pathogens change the playing field by inducing inflammation and causing other physiological changes (diarrhea) that influences the intestinal environment to promote their own growth (Strecher et al., 2007; Winter et al., 2013; Hughes et al., 2017).

Intestinal inflammation is involved in dysbiosis in poultry (Ducatelle et al., 2018; Kogut et al., 2018), but it is not clear if the inflammation is the cause or the effect of the disruption in gut homeostasis (Sommer et al., 2017; Zeng et al., 2017). However, both pathogenic (microbial infection or tissue injury) and metabolic (excess dietary nutrients) inflammation cause dysbiosis (Kogut et al., 2018). Targeted use of dietary interventions, direct-fed microbials (DFMs) including pro/prebiotics, and other bioactive compounds may constitute an effective therapeutic strategy to rebalance gut dysbiosis and restore colonization resistance. However, existing microbe-targeted therapies, including prebiotics, probiotics, enzymes, and DFM have been developed for enhancing performance (increase nutritional value of feed, improved feed conversion, breast meat yield, egg production) not for normalizing immune cell function. Nevertheless, there are a few examples of the use of commercial feed additives improving immunity or decreasing gut inflammation including β-mannanase (Arsenault et al., 2017; Scapini et al., 2019), amino acids

(Bortoluzzi et al., 2018, 2020), and butyrate (Zou et al., 2019; Song et al., 2017; Bortoluzzi et al., 2017).

24.4.5.2 Gut microbiota: immune dysfunction—inflammation

Inflammation is basic physiological function of the innate host defense system in reaction to alterations in tissue homeostasis (Medzhitov, 2008). Inflammation is elicited by PRRs that detect not only infectious agents but also host damage and danger signaling molecules (DAMPs) that activate a highly regulated network of immunological and physiological events for the purpose of maintaining homeostasis and restoring functionality (Chovatlya and Medzhitov, 2013). Activation of the innate responses directs the production of a number of cells and proinflammatory molecules crucial to controlling most infectious and noninfectious challenges (Nathan, 2002; Barton, 2008).

24.4.5.2.1 Inflammatory phenotypes

Inflammation is an adaptable physiological response that adjusts to the conditions of a particular environment such as tissue injury or malfunction, excessive nutrients and metabolites, toxins, or infection (Garret et al., 2010; Sansonetti and Medzhitov, 2009; Hotamisligil, 2017) resulting in a large range of inflammatory reactions. The animal production industries are most familiar with gut inflammation as a pathological process associated with a decrease in weight gain, feed intake, feed efficiency, survivability, and uniformity (Iseri and Klasing, 2014; Kogut, 2013; Gaskins, 2008). However, recent research has shown that inflammation, although tightly regulated, displays phenotypic plasticity that is dependent upon the "trigger" that activates the response (Medzhitov, 2008; Ashley et al., 2012). For example, even under homeostatic conditions, the gut is continually exposed to a multitude of exogenous antigenic, dietary and toxic stimuli, as well as, endogenous stimuli such as structural bacterial components [LPSs and peptidoglycans (PGNs)] and bacterial-derived metabolites from bacterial microbiota all of which induce a low-grade stimulation of the innate immune system that is continuously regulated and contained; thus preventing intestinal tissue damage. This controlled inflammatory response has been defined as "hysiological inflammation" (Smith and Nagler-Anderson, 2005; Fiocchi, 2008) and is dependent upon the balance of the innate immune response that mediates host defense and tolerance in the gut. However, the induction of an infection resulting in an increase in pathogenic microbe-specific molecules (MAMPs) and/or virulence factors or cell debris from tissue injury (DAMPs) would transform physiological inflammation to "pathological inflammation" or classical or inflammation (Medzhitov, 2008; Barton, 2008).

24.4.5.3 Induction of inflammatory phenotypes

24.4.5.3.1 Physiological inflammation

Under homeostatic conditions, the immune system in the intestine concurrently performs two different functions: (1) defense against pathogen organisms and prevention of access of the intestinal microflora and (2) maintains a state of tolerance to the commensal microbes in the gut (Medzhitov, 2008; Abraham and Medzhitov, 2011). This continuous monitoring of the microbiota involves the constitutive physical and biochemical barriers of the mucus layer, epithelial cell layer, and secreted antimicrobial peptides, as well as, the immunological barrier of the immune cells dispersed in the intestinal mucosa and secretory IgA released from plasma cells also in the intestinal mucosa (Abraham and Medzhitov, 2011). During physiological inflammation or as described by Abraham and Medzhitov (2011) immune homeostasis, the immune tolerance in the intestine to the resident microbiota and food antigens is preferential to activation of an inflammatory response.

During physiological inflammation, the intestinal microbiome and the intestinal immune system exist in a symbiotic homeostasis sharing a bidirectional relationship, with both elements influencing each other's development, composition, and functionality (Nicolson et al., 2012). The normal host immune defenses that prevent pathogen invasion of the intestine also play a functional role in tolerance. Tolerance still involves the activation of PRRs initiated by the continuous release of commensal gut bacterial-derived products (MAMPs) and bacterial metabolites, such as SCFAs and polysaccharide A which drive down inflammation (Takeuchi and Akira, 2010; Pedra et al., 2009; Abraham and Medzhitov, 2011). However, the PRRs that are activated are found on unique populations of innate immune cells that regulate the PRR-mediated signaling pathways that alter PRR responsiveness, induce the production of high levels of regulatory proteins such as IL-10 and TGF-β, and induce the differentiation of the T-regulatory cells (Abraham and Medzhitov, 2011; Kinnebrew and Pamer, 2012).

24.4.5.3.2 Pathological inflammation

When an acute microbial infection or tissue injury occurs, the host defense: tolerance balance is disturbed and physiological inflammation converts to a true inflammatory response or pathological inflammation (Medzhitov, 2008; Barton, 2008). A number of cell types in the intestinal tissue express PRRs, especially TLRs and NLRs, that recognize the various triggers of inflammation (Nathan, 2002; Medzhitov, 2007; Takeda et al., 2010; Bianchi, 2007). The primary inducers of pathological inflammation are the MAMPs found on microbial pathogens, pathogen

virulence factors, DAMPS, such as ATP and nucleic acids, normally found intracellular, but are released into the extracellular space following tissue injury and cell death, and commensal gut bacterial-derived products and bacterial metabolites (Medzhitov, 2008; Barton, 2008; Rock and Kono, 2008; Bianchi, 2007).

24.4.5.3.3 Sterile inflammation

A low-grade chronic inflammation, in the absence of an infection, in response to a chemical (oxidative stress), physical (microbiota-derived components), and metabolic (nonstarch polysaccharides [NSPs] from dietary components) stimuli is known as sterile inflammation (Rubartelli et al., 2013). With a sterile inflammatory response, the stimulus persists without being eliminated suggesting that collateral damage is the cause of the disease (Rock et al., 2010). In sterile inflammation, PRRs recognize microbiome-derived components like LPS, PGN, and bacterial DNA (CpG) following microbiome bacterial cell wall turnover or bacterial lysis, but also DAMPs released from host cells after oxidative stress induced cell death (Rock et al., 2010).

Further, certain ingredients used in commercial broiler diets contain dietary NSPs that are indigestible by poultry, but represent a potential energy source which can be utilized with the proper addition of exogenous enzymes (Meng et al., 2005). For example, soybean meal (SBM) is a primary source of vegetable protein that contains 3% soluble NSP and 16% insoluble NSP, consisting mainly of mannans and galactomannans (Slominski, 2011). β-mannan is similar in structure to surface components of multiple pathogenic microbes and is recognized by a specific PRR, the mannose receptor, that stimulates the intestinal innate immune system leading to a purposeless energy draining immune response called feed-induced immune response (FIIR) (Hsiao et al., 2006; Martinez-Cummer, 2015).

Each meal leads to postprandial (low-grade) inflammation response in the intestine, the magnitude of which is related to the caloric value, specific components. If not properly regulated, postprandial inflammation could lead to unwanted consequences such as muscle catabolism, inappetite, and predisposition to infections (Niewold, 2014; Margioris, 2009).

However, standard feed ingredients in US commercial broiler diets, such as soybean, sesame, and sunflower meal, contain the immunogenic indigestible NSPs. Dietary NSPs are indigestible by poultry but do represent a potential valuable energy source that can be utilized by the birds with the addition of enzymes to the diet (Meng et al., 2005). Unfortunately, many of these NSP can be recognized by host PRR, for example, the mannose receptor, recognizes the major NSP in SBM, β-galactomannan (Hsaio et al., 2006). Recognition of these NSP by PRRs can lead to a chronic feed-induced inflammation resulting in a nonproductive energy expenditure on immunity. The addition of exogenous enzymes to the diet, such as β-mannases, phytases, and amylases, enhance NSP-containing feed not only by increasing digestion but also by reducing the FIIR because the NSPs are no longer recognized by PRR as demonstrated recently (Ferriera et al., 2016; Arsenault et al., 2017).

Finally, the largest potential source of endogenous triggers of sterile inflammation in the intestine are the 10^7–10^{11} bacteria/g in the microbiota. For example, PGN is the foremost component of gram-positive bacterial cell walls as well as being present in gram-negative bacterial cells walls (McDonald et al., 2005). Likewise, LPS (gram-negative bacterial cell wall) and unmethylated CpG oligodeoxynucleotide of all prokaryotic DNA are all ligands of host TLR and NLRs (Keestra et al., 2013; He et al., 2011). Both PGN and LPS are shed when bacteria in the microbiota divide and all components are released upon bacterial lysis (Myhre et al., 2006). Under homeostatic conditions, these components play a role in physiological inflammation. However, under stress conditions, such as FIIR, oxidative and heat stress, or feeding diets with high levels of NSPs that increase feed passage time and or decrease intestinal motility, as well as the frequency of reverse peristalsis, results prolonging the exposure to these triggers resulting in the induction of a low-grade sterile inflammatory response (Sacranie et al., 2007).

24.4.5.3.4 Metabolic inflammation

A chronic low-grade inflammation generated by excessive nutrient intake and the metabolic surplus fosters metabolic dysfunction by activating the same signaling transduction molecules and pathways as immune responses to infections (Hotamisligil, 2006). Metabolic dysfunction appears to take center stage by integrating signals from both the immune and metabolic systems (Kogut, 2013). Further, Humphrey et al. (2014) believed that "in modern broiler breeds, the drive toward improved productivity and carcass conformity has a negative impact on immune regulation in the gut, microbiota dysbiosis, and a persistent nutrient excess (fatty acids and carbohydrates) that result in chronic systemic inflammation, poorly controlled local and systemic inflammation, and increased metabolic diseases." This metabolic or metainflammation due to modern genetic/management practices for growing broilers and turkeys are virtually identical to those characteristics that lead to metabolic diseases in humans as a result of chronic low-grade inflammation, i.e., increased muscle mass, increased fat deposition, high-metabolic rate, ingesting high-nutrient dense diets, and consume food at a high rate, just to name a few (Hotamisligil, 2006; Hotamisligil and Erbay, 2008; Gregor and Hotsamisligil, 2011).

The innate immune cell recognition system and immune cell metabolism have coevolved and share the same signal transduction pathways (Assamann and Finlay, 2016). Thus, nutrient excess from diets can result in overloads of metabolites that act as DAMPs that can be sensed by PRRs of the innate immune system (Assamann and Finlay, 2016; Land, 2015; Lackey and Olefsky, 2016); thereby, simulating a chronic inflammation. PRRs, such as TLR4 and NLRP3, act as metabolite sensors activated by different metabolite DAMPS including free fatty acids, carbohydrates, and lipids (Gregor and Hotsamisligil, 2011). Continuous activation of these PRRs through excessive nutrient intake leads to the production of proinflammatory cytokines, such as IL-1β and IL-6, which maintain the low-grade inflammatory response.

Lastly, when nutrient excess leads to activation of PRR-mediated inflammation, there is a concurrent increase in metabolic pathways in the mitochondria of activated immune cells (Tannehil et al., 2013; McGettrick and O'Neill, 2013) that results in the overproduction of various metabolites via the Krebs cycle (succinate, citrate, NAD^+) and glycolysis (lactate) (Tannehil et al., 2013; McGettrick and O'Neill, 2013; Tretter et al., 2016). All four metabolites have been shown to be signals for multiple inflammatory mediators that result in a low-grade chronic inflammation (Tannehil et al., 2013; Loftus and Finlay, 2016). Increased succinate production results in an increase in stabilization of the transcription factor hypoxia inducible fact (HIF-1α) (Tannehil et al., 2013; Pucino et al., 2017). The stabilization of HIF-α results in increased glycolysis and the persistent production of the proinflammatory cytokine IL-1β (Tannehil et al., 2013; Loftus and Finlay, 2016). Likewise, citrate is also increased via the Kreb's cycle and is a signal for the increase production of inflammatory mediators such as reactive oxygen species, nitric oxide, and prostaglandins (Infantino et al., 2011). Lactate is a waste production produced in the immune cell cytoplasm at the end of glycolysis that affects local T cell immunity by inhibiting T cell motility, inducing the change of CD4+ cells to Th17 proinflammatory T cell subset that leads to the production of IL-17, which is a hallmark of chronic inflammation (Haas et al., 2016).

24.5 Tissue immunometabolism: tissue homeostasis and tissue resident immune cells

Cellular metabolism is a collective phrase to describe how cells generate the energy and metabolites required for cell growth and maintenance. Immunometabolism refers to the central role that metabolism plays in shaping the development, differentiation, and function of immune cells (O'Neill et al., 2016; Chauhan and Saha, 2018). The foundation of immunometabolism is the assertion that the engagement of specific metabolic pathways, the production or utilization of specific metabolites, or the noncanonical functions of metabolic enzymes can be decisive in the balance between inflammation, immune tolerance, or resolution.

The interface of the immune system and metabolism is an emerging field of study. The initial impetus for researchers to consider an immune-metabolic perspective was the human health concerns related to obesity, diabetes, and metabolic disorders. Excessive fat deposition can lead to an innate immune inflammatory response (O'Neill and Hardie, 2013). This chronic low-grade inflammation was linked to resultant diseases such as type 2 diabetes, fatty liver disease, gout, and cirrhosis. It has become apparent that metabolic shifts within immune cells result in shaping the effector responses (Jha et al., 2015 ; Norata et al., 2015). The resultant shifts in energy supply and demand can lead to transcriptional and translation changes in tissue phenotype (Palsson-McDermott and O'Neill, 2020). Such phenotypic shifts can imprint fundamental changes to tissue metabolism and local inflammatory/immune cell functions. In mammals, cell intrinsic metabolic programs are orchestrated by multiple metabolic sensors, including mTOR, AMPK, PPARγ, HIF-1γ, and sirtuins, that modulate immune cell trafficking and function (Gonzales et al., 2020; Chun et al., 2017; Palsson-McDermott and O'Neill, 2020).

An intricate relationship exists between macrophage and T cell biology and host metabolism (Palsson-McDermott and O'Neill, 2020). A proinflammatory phenotype of monocytes M1 macrophages, activated B cells and Th1 and Th17 T cells is characterized by an increase in aerobic glycolysis (Jha et al., 2015; Norata et al., 2015). Alternatively, the anti-inflammatory phenotype of M2 macrophages and T regulatory cells is characterized by oxidative phosphorylation-mediated metabolism (Jha et al., 2015; Norata et al., 2015).

The metabolic phenotype of immune cells can be modulated by the tissue environment where they are present. The immediate and sustained metabolic alterations that modulate host defensive functions during infection through metabolic regulations regulated by nutrient-sensing machineries. Thus, the availability of nutrients can impact the functional activity of the immune system to control or eliminate tumors and pathogens. However, exploiting the immunometabolic mechanisms in a complex tissue microenvironment in an effort to fine-tune cellular metabolism of resident immune cells either in homeostatic or diseased settings is still being explored and characterized. Nevertheless, the immune cell mitochondria metabolism has been found to be a primary regulator of immune cell phenotype and function (Aguilar-Lopez et al., 2020; Weinberg et al., 2015). Mitochondria can rapidly switch from being catabolic organelles generating ATP to anabolic organelles that

generate both ATP and building blocks for macromolecule synthesis, enabling them to deliver suitable metabolic demands of different immune cells. Mitochondria have multiple mechanisms that allow them to activate intracellular signaling pathways that can alter AMP/ATP ratio, release ROS and TCA cycle metabolites, and localize immune regulatory proteins on the outer mitochondria membrane (Aguilar-Lopez et al., 2020; Weinberg et al., 2015).

Within poultry production, a consideration of the immunometabolic consequences would be invaluable. A focus solely on maximizing animal growth can reduce immune potential, while a strong immune response has negative consequences on growth (Humphrey and Klasing, 2014). A consideration of the integrated whole may allow one to maximize growth and animal production without having a detrimental impact on animal health and immune potential. We have shown the nearly innumerable links between cellular signaling proteins classically characterized as members of either the immune or metabolic functional groups (Arsenault et al., 2014).

A feature of avian salmonellosis is persistent intestinal infection or carrier state. Intestinal carriage may occur for several months following infection. The establishment of persistence is in the face of a substantial immune response that requires either evasion or modulation of the response by the bacteria. The fact that many *Salmonella* serovars persist within the chicken intestinal tract with little sign of GI disease despite eliciting a considerable inflammatory response, and that inflammatory responses to *Salmonella* are relatively short-lived (Withnage et al., 2005), strongly suggests there is a degree of regulation of this response. Some years ago, it was shown that the lowering of intestinal proinflammatory signals following colonization with *S. typhimurium* corresponded to increased expression of TGF-β, suggesting that regulation of inflammation was taking place (Tang et al., 2018, II 86:e00307-18). Upon infection of chickens with paratyphoid serovars of *Salmonella*, the regulation of immune and metabolic pathways are altered. Based on our findings (Kogut and Arsenault, 2017), combining Treg cell isolation and functional studies, cytokine transcriptional analysis and kinome analysis of immune and metabolic signaling pathways in the cecum of chickens during an early (4 to 48 h) and late (4 to 14 days) infection with *Salmonella* Enteritidis, we observed three separate immune-metabolic phases associated with different times postinfection. First, we observed an inflammatory phase 1 to 3 days postinfection, characterized by the up-regulation of proinflammatory cytokine mRNA transcription and the induction of mTOR-mediated anabolic metabolism (protein synthesis, glycogen synthesis, and fatty acid synthesis). The second phase appears around 4 days postinfection characterized by profound changes in cecal immunity and metabolism. In general, the local immune microenvironment changed from proinflammatory to anti-inflammatory exemplified by a decrease in proinflammatory cytokine mRNA transcription to control levels and a dramatic increase in anti-inflammatory cytokine mRNA expression accompanied by a significant increase in the number and function of Tregs in the cecum. In addition, we observed a remarkable metabolic reprogramming in the cecal tissue at this time with a shift from anabolic to catabolic reactions mediated by the significant phosphorylation of AMPK. It is during this phase that we speculate that *Salmonella* takes advantage of the lack of host response to infection to begin to establish a persistent cecal colonization. The third phase appears to begin shortly after day four postinfection with a gradual return to homeostasis. The number of Tregs in the cecum remains elevated over noninfected tissue and IL-10 and TGF-β appear to regulate a more tolerant microenvironment. Lastly, there is a final metabolic reprogramming from catabolic to homeostasis with no difference in metabolism between infected and noninfected birds. We speculate that the *Salmonella* have established itself as part of the normal microbiome of the cecum and is no longer recognized by the host immune system.

UTP uridine triphosphate

25.1 Overview of carbohydrate metabolism in birds

25.1.1 Introduction

Carbohydrate metabolism in birds has close similarities to that in mammals. Glucose is absorbed in the small intestine. Glucose can be used for energy via glycolysis, the citric acid cycle, or the pentose pathway. Some tissues only use glucose, being incapable of using fatty acids. Glucose can be stored as the polysaccharide glycogen in the liver, muscles, and other tissues or used as a substrate to produce fatty acids (lipogenesis). Glucose can be synthesized from lactate, amino acids, and other gluconeogenic precursors in the liver and kidneys. The differences between avian and mammalian carbohydrate metabolism include the following:

- The very high circulating concentrations of glucose in birds (discussed in more detail in Section 25.2)
- The site of lipogenesis being the liver

Several caveats need to be introduced. The energetic needs for extended flight are met using fatty acids, not glucose. Discussion of carbohydrate metabolism in birds is hampered by the preponderance of evidence coming from studies in domesticated birds, particularly from a single species, the chicken. The control of carbohydrate metabolism of (and hence circulating glucose concentrations by), the pancreatic hormones, glucagon, and insulin is addressed elsewhere in this volume.

The respiratory quotient (RQ) (carbon dioxide released divided by the oxygen consumed) informs as to the major substrate being used by an animal for energy. If the RQ is 1.0, carbohydrate (glucose) is the major substrate. If the RQ is 0.7, triglyceride (fatty acids) is the major substrate. If amino acids are being used for energy, the RQ is 0.8−0.9. Table 25.1 summarizes the RQ for a number of avian species. Birds seem to have an RQ of either 0.7 or 1.0, indicating that they are using either triglyceride/fatty acids or glucose. An RQ of 1.1 and greater, as reported in young chickens (Geelissen et al., 2006), reflects glucose utilization for energy production and fatty acid synthesis together with triglyceride deposition. When there is a shift from use of glucose to fatty acids predominantly, there is a decrease in RQ. For instance, the RQ decreases to 0.7 during fasting in the house sparrows (*Passer domesticus*), hummingbirds, and chickens during the nocturnal fast from $\sim$ 0.9 to $<$0.7 (see Table 25.1). 15.6 $\pm$ 0.24 (247)

25.2 Carbohydrate chains in glycoproteins

Sugar chains consisting of monosaccharides such as galactose and *N*-acetylneuraminic acid (sialic acid) play critical roles in the functionality of proteins. Egg albumen proteins are glycosylated in the magnum with this being employed to produce glycosylated proteins in transgenic chicken expression systems (Mizutani et al., 2011). Further examples of the functionality of the carbohydrates (sialyl-galactose) chains is in colonic epithelial cells that bind viruses (quail and chicken: Guo et al., 2007). Similarly, sialyl-galactose linkages affect binding of viruses to the chick embryo amnion and allantois (Ito et al., 1997).

TABLE 25.1 Examples of respiratory quotients reported in birds.

Species	RQ	Reference
Chicken (*Gallus gallus*) fed	~1.0 or 1.1 or greater	Brackenbury and El-Sayed (1985); Geelissen et al. (2006)
Chicken exercising	0.97	Brackenbury and El-Sayed (1985)
Chicken fasted	0.7	Boshouwers and Nicaise (1981)
House sparrow (*Passer domesticus*) fed	0.9 or ~1.0	Walsberg and Wolf (1995)
House sparrow fasted	0.7	Walsberg and Wolf (1995); Khalilieh et al. (2012)
Rufous hummingbirds (*Selasphorus rufus*) or Anna's hummingbirds (*Calypte anna*) feeding on nectar	1.0	Welch et al. (2007); Suarez et al. (2011)
Rufous or Anna's hummingbirds fasted	0.7	Suarez et al. (1990, 2011); Welch et al. (2007)
Carnivorous birds: Sparrow hawks (*Falco sparverius*), long-eared owls (*Asio otus*), saw whet owl (*Aegoliusa cadicus*)	0.74–0.78	Gatehouse and Markham (1970)

25.2.1 Glucose

Glucose is a simple sugar, specifically a hexose. It is a major carbohydrate in the circulation of birds (discussed in section 25.2.1). It is transported into cells by glucose transporters (GLUTs) (see section 25.6) and after phosphorylation is metabolized by glycolysis (section 25.7.2) and then the aerobic tricarboxylic cycle pathway (see section 25.7.3). Alternatively, glucose can be converted to fatty acids (in lipogenesis predominantly in the liver) or into glycogen in the liver and muscles (see section 25.4).

25.2.1.1 Circulating concentrations of glucose across avian species

25.2.1.1.1 Introduction: circulating concentrations of glucose across avian species

The major circulating carbohydrate in birds is glucose. The mean circulating concentration of glucose in birds is 15.6 + 0.24 [standard error of mean (SEM); number of species (n) = 248; Table 25.2]. There are higher circulating concentrations of glucose in *Neognathae* than in the flightless ratites. There are marked differences between circulating concentrations of glucose between birds and mammals, with avian concentrations more than double those in mammals; for instance, plasma concentrations of glucose in fed and fasting rats were, respectively, 7.9 and 4.9 mM (Simon et al., 2011). The control of circulating concentrations of glucose by the pancreatic hormones, glucagon and insulin, is addressed elsewhere in this volume.

In mammals, there is a relationship between circulating concentration of glucose and body weight: the circulating concentration of glucose in mM = 7.6 − 0.44 log body mass in kilograms (Beuchat and Chong, 1998; Braun and Sweazea, 2008). In birds, a similar relationship was reported by Braun and Sweazea (2008): the circulating concentration of glucose in mM = 15.3−0.44 log body mass in kilograms. For birds, the y-intercept of the line at 1 kg is 15.3 mM (or 275 mg/dL) in wild birds (Braun and Sweazea, 2008). The basis for this relationship between circulating concentrations of glucose and body weight is not clearly established. No such relationship was observed by Beuchat and Chong (1998). There is frequently a dichotomy in the literature between research on wild and domesticated species. The analysis of circulating concentrations of glucose included only wild species.

25.2.1.1.2 Domestication and circulating concentrations of glucose

There is conjecture that domestication and intensive selection have influenced glucose metabolism and circulating concentrations of glucose, although there is also some against this theory. The circulating concentrations of glucose in wild turkeys (*Meleagris gallopavo*) are more than 50% greater than those in domestic turkeys (Lisano and Kennamer, 1977; Anthony et al., 1990; see Table 25.3). In contrast, the circulating concentrations of glucose were higher in domestic than wild geese (Gee et al., 1981; Sitbon and Mialhe, 1979; see Table 25.3). A small study directly compared red jungle fowl (*Gallus gallus*, from which chickens are thought to have been domesticated), Asian village fowl, and commercial broiler chickens (Soleimani and Zulkifli, 2010). No differences were found between circulating concentrations of glucose between red jungle fowl and domesticated chickens (Table 25.3). Moreover, there are no discernible differences between the circulating

TABLE 25.2 Circulating concentrations of glucose across the class aves.

Order of birds	Plasma/Serum glucose mM (mmol/L) ± SEM (number of species)
Accipitriformes	17.5 ± 0.71 (23)
Anseriformes	11.6 ± 0.60 (30)
Apodiformes	16.0 ± 0.47 (3)
Charadriiformes	16.9 ± 0.50 (27)
Ciconiiformes	14.7 ± 0.41 (11)
Columbiformes	16.3 ± 0.83 (9)
Coraciiformes	17.7 ± 0.94 (8)
Falconiformes	19.4 ± 1.24 (5)
Galliformes excluding poultry	16.8 ± 0.70 (16)
Gruiformes	14.7 ± 0.71 (14)
Passeriformes	18.0 ± 0.64 (35)
Pelecaniformes	12.0 ± 0.65 (12)
Phoenicopteriformes	11.8 ± 0.53 (4)
Procellariiformes	13.4 ± 1.55 (6)
Psittaciformes	15.0 ± 0.44 (21)
Sphenisciformes	13.3 ± 0.59 (9)
Strigiformes	18.3 ± 0.61 (11)
Trogoniformes	16.7 ± 1.20 (4)
Super-order	
Neognathae	15.7 ± 0.24 (245)
Palaeognathae	10.9 ± 0.84 (4)
Class	
Aves	15.6 ± 0.24 (249)

concentrations of glucose in wild or domestic pigeons or ducks (Table 25.3). At present, there are no comprehensive studies comparing chickens with red jungle fowl or domestic turkeys, ducks and geese with wild turkeys, ducks and geese, respectively. These should encompass multiple ages. Moreover, they should be performed in the same laboratory with circulating concentrations of glucose determined by the same methods to ensure consistency.

25.2.1.1.3 Fasting and circulating concentrations of glucose

In some species of birds, circulating concentrations of glucose are depressed by fasting, such as in chickens (Dupont et al., 2008; Christensen et al., 2013), domestic ducks (*Anas platyrhynchos*; Zhang et al., 2005), domestic geese (*Anser anser*; Sitbon and Mialhe, 1979), house sparrows (*P. domesticus*; Khalilieh et al., 2012), hummingbirds [Anna's hummingbird (*Calypte anna*)], Costa's hummingbird (*Calypte costae*), and ruby-throated hummingbirds (*Archilochus colubris*); Beuchat and Chong (1998), and yellow-legged gulls (*Larus cachinnans*; Alonso-Alvarez and Ferrer, 2001). For instance, circulating concentrations of glucose are depressed by 25.3% in adult house sparrows fasted for 24 h (Khalilieh et al., 2012). Similarly, circulating concentrations of glucose decreased by fasting in late juvenile/adult domestic geese, being decreased by 25.4% in birds fasted for 24 h and by 32.5% in geese fasted for four days (Sitbon and Mialhe, 1979). In contrast, circulating concentrations of glucose were not depressed by fasting in other species/studies, such as black vultures (*Coragyps atratus*; Migliorini et al., 1973), adult ring doves (*Streptopelia risoria*; Lea et al., 1992), Japanese quail (*Coturnix japonica*; Sartori et al., 1996), Adélie penguins (*Pygoscelis adeliae*; Vleck and Vleck, 2002), Emperor penguins (*Aptenodytes forsteri*; Groscolas and Rodriguez, 1981), Garden warbler (*Silva borin*; Totzke et al., 1998), and juvenile herring gulls (*Larus argentatus*;

TABLE 25.3 Comparison of circulating concentrations of glucose in domesticated birds and wild birds of the same species.

Species	Plasma/Serum concentration of glucose (mM)	Reference
Red jungle fowl/chicken (*Gallus gallus*)		
Red jungle fowl	13.3	Soleimani and Zulkifli (2010)
Fed chickens (15 studies)	13.1	Scanes (2008); Simon et al. (2011)
Turkey (*Meleagris gallopavo*)		
Wild Turkey	19.7	Lisano and Kennamer (1977)
Domestic Turkey refed	11.5	Anthony et al. (1990)
Duck (*Anas platyrhynchos*)		
Wild duck or mallard	11.5	Fairbrother et al. (1990)
Domestic duck	10.0	Applegate et al. (1999); Zhang et al. (2005)
Goose (*Anser anser*)		
Wild or Embden goose	12.3	Gee et al. (1981)
Domestic goose	15.6	Sitbon and Mialhe (1979)
Pigeons (*Columba livia*)		
Wild or rock pigeon	15.5	Gayathri et al. (2004)
Domestic or racing pigeon	16.1	Lumeij and de Brujne (1985)

Jeffrey et al., 1985); on the contrary, concentrations were increased in female ring doves (*Streptopelia risoria*; Lea et al., 1992).

25.2.1.1.4 Influence of feeding

As might be expected, circulating concentrations of glucose are influenced by feeding. For instance, plasma concentrations of glucose are depressed at night in chickens when feeding is not occurring (Christensen et al., 2013). Moreover, concentrations of glucose are markedly increased following eating in hummingbirds, with circulating concentrations rising from already high concentrations to >26.5 mM—levels way into the diabetic range in mammals (Fig. 25.1). This is not surprising with the consumption of nectar, which is high in both glucose and fructose. Plasma concentrations of glucose decline rapidly from 41 mM to basal (17 mM) within 1.5 h following feeding in, for instance, Anna's hummingbird (*Calypte anna*) (Beuchat and Chong, 1998). Similarly, oral loading with monosaccharides increases circulating concentrations of glucose in passerine birds (Fig. 25.1) and chickens (Fig. 25.2). Circulating concentrations of glucose return to basal within an hour (Sinsigalli et al., 1987, Fig. 25.2).

25.2.1.1.5 Shifts in circulating concentration with age, reproductive state, and migration

Circulating concentrations of glucose increase markedly during the second half of embryonic development (chickens: Lu et al., 2007; Willemsen et al., 2011) (see Table 25.4).

There is a transient decrease in circulating concentrations of glucose immediately after hatching, followed by a gradual rise over 12 h (chickens: Rinaudo et al., 1982). Circulating concentrations of glucose subsequently decline during posthatch growth and development in chickens (*Gallus gallus*; Sinsigalli et al., 1987, Fig. 25.2). The rate of clearance of glucose after a glucose challenge is slower in older but still juvenile birds, as shown in chickens by Sinsigalli et al. (1987; Fig. 25.2).

There are small sex differences in circulating concentrations of glucose in some birds. For instance, in adult sexually mature quail, there is a small but consistent sex difference in circulating concentrations of glucose, being decreased 6.7% (Itoh et al., 1998) and 17.0% (Scholtz et al., 2009) in females in different reports. In contrast, circulating concentrations of glucose were lower in male than female mallards (Fairbrother et al., 1990).

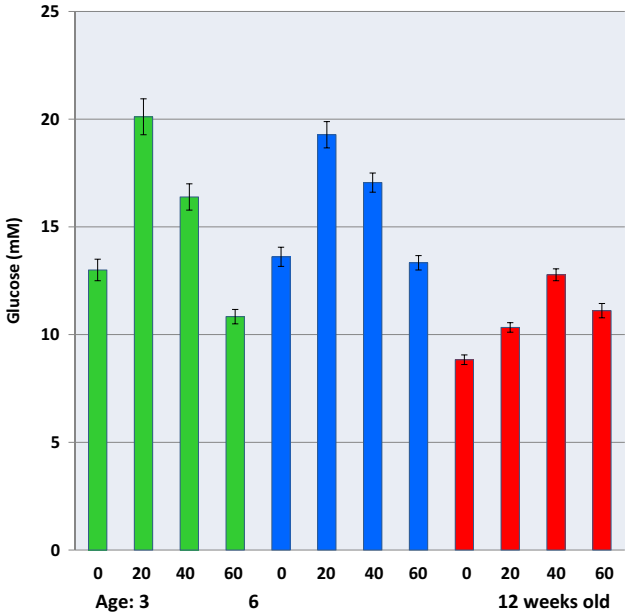

FIGURE 25.2 Effect of glucose load (2 g glucose intubated per kg or 11.1 mmol/kg) on circulating concentrations of glucose at 3, 6, and 12 weeks of age in chickens prior to (0 min) and 20, 40, and 60 min after challenge. *Data from Sinsigalli et al. (1987).*

Some changes have been reported in the circulating concentration of glucose during the breeding cycle. For instance, circulating concentrations of glucose are reduced by 53% in adult pigeons in the middle of period of incubating their eggs, but they recover late in incubation and then rise further after incubation is terminated (Gayathri et al., 2004). Similarly, in ring doves, circulating concentrations of glucose are increased after incubation and when the young squabs are receiving parental care (Lea et al., 1992). A similar reduction in circulating concentrations of glucose is reported in ducks [mallard duck (*Anas platyrhynchos*); Fairbrother et al., 1990].

Prelaying circulating concentrations of glucose correlate well with later reproductive success in raising at least one chick in the greater sage grouse (Dunbar et al., 2005). What is not clear is the physiological basis of the circulating glucose concentrations having a predictive value for reproductive success.

There was little difference in the circulating concentrations of glucose in Canada geese (*Branta canadensis interior*) irrespective of whether it was before or after the

TABLE 25.4 Changes in plasma concentrations of glucose during chick embryonic development and following hatching.

spring migration, during the breeding season, or in the period before the fall migration (Mori and George, 1978). An increase was observed after the fall migration (Mori and George, 1978). In contrast, circulating concentrations of glucose are markedly increased in Emperor penguins undergoing both fasting and molting, increasing from a mean (SEM) of 19.7 + 2.4 mM to 28.4 + 6.5 mM (Groscolas and Rodriguez, 1981).

25.2.1.1.6 Shifts in circulating concentrations of glucose due to disease, toxicants, and husbandry practices

There are pathological changes in the circulating concentration of glucose with glucose being an indicator of health. For instance, there was a negative correlation between plasma concentrations of glucose with body condition score [pale-bellied **t**yrant-manakin (*Neopelma pallescens*) (Azeredo et al., 2016)]. Circulating concentrations of glucose are decreased with infectious disease and increased with exposure to toxicants. In the common pheasant, the circulating concentrations of glucose are depressed by severe infection with spironucleosis (Lloyd and Gibson, 2006). Similarly, in chickens with spiking mortality, there are extremely low circulating concentrations of glucose (Davis et al., 1995).

Environmental toxicants can elevate, depress, or have no effect on circulating concentrations of glucose. There is a marked increase in circulating concentrations of glucose in parakeets receiving the organophosphate insecticide quinalphos (rose-ringed parakeet, *Psittacula krameri*; Anan and Maitra, 1995). Circulating concentrations of glucose were depressed in mallard ducks exposed to the polychlorinated biphenol mixture Aroclor 1254 (Fowles et al., 1997). In contrast, there was no change in circulating concentrations of glucose in ducklings with toxicosis due to furazolidone (Webb et al., 1991).

Force feeding is used in some counties to produce *pate de fois gras* in ducks and geese. Circulating concentrations of glucose are increased by force feeding in geese (Sitbon and Mialhe, 1979) and ducks (Zhang et al., 2005).

25.2.1.1.7 Temperature and circulating concentrations of glucose

There are effects of environmental temperature on circulating concentrations of glucose. Not only does fasting for 16 h depress circulating concentrations of glucose (Boussaid-Om Ezzine et al., 2010) but also the effect is greater in birds exposed to elevated temperatures (32°C for a week in broiler chickens; Boussaid-Om Ezzine et al., 2010). Moreover, glucose plus arginine administration to birds with free access to feed evoked a larger increase in circulating concentrations of glucose in the chickens at a higher environmental temperature (Boussaid-Om Ezzine et al., 2010).

25.2.1.1.8 Issues with the circulating concentrations of glucose

Circulating concentrations of glucose are influenced by physiology but may also be influenced by sampling techniques. For instance, there was a transient increase in plasma concentrations of glucose after capture (Darwin's small ground finch: Clark et al., 2018). Unfortunately, some studies employed determination of glucose concentrations in whole blood and thus as comparison with other studies was not possible, these were not included in the analysis.

25.2.1.2 Glucose concentrations in the cerebrospinal fluid

In birds, the concentration of glucose in the cerebrospinal fluid (CSF) is 286 mg/dL (15.8 mmol/L) (Anderson and Hazelwood, 1969). This is ~20% greater than the plasma concentration of glucose. In contrast in mammals, CSF concentrations of glucose are 10−50% below circulating concentrations of glucose (rabbit 19% lower: Guerra-Romero et al., 1992; human 10−50% lower: Verbeek et al., 2016). Insulin depressed CSF concentrations of glucose (chicken: Anderson and Hazelwood, 1969).

25.2.1.3 Glucose concentrations in muscle

Muscle concentrations of glucose are influenced by physiological state being depressed by the stresses of feed withdrawal for 5 h (chicken: Savenije et al., 2002) and with 3 h of transportation (chicken: Wang et al., 2017).

25.3 Lactate and pyruvate

25.3.1 Introduction

Circulating concentrations of lactate are the result of anaerobic glycolysis (see section 25.7.2) in various tissues. Lactate is readily converted to pyruvate, e.g., in muscle (see section 25.7.2.4). Moreover, lactate is one substrate for gluconeogenesis (see section 25.8).

25.3.2 Circulating concentrations of lactate and pyruvate

Basal plasma concentrations of lactate in various avian species are summarized in Table 25.5. These avian plasma concentrations of lactate tend to be higher than those in mammals (Table 25.5). In addition, circulating concentrations of lactate are elevated by exercise or hypoxia (see Table 25.5). For instance, blood concentrations of lactate are markedly elevated during diving in Emperor penguins (*Aptenodytes forsteri*) and decline after dives returning to baseline within 10 min (Ponganis et al., 1997). Similarly, plasma concentrations of lactate are increased after a short-term flight in Northern bald ibis (*Geronticus eremite*) (Bairlein et al., 2015). While blood concentrations of

lactate are depressed by fasting in chickens while those of pyruvate are increased (Table 25.6).

25.3.3 Muscle concentrations of lactate

There is considerable variation between avian species in the muscle concentrations of lactate (Table 25.7). There is limited evidence that concentrations of lactate in muscle can change. Transportation for 3 h was associated with elevated tissue concentrations of lactate (chicken: Wang et al., 2017). In contrast, there were no changes in the lactate concentration in skeletal muscle (pectoralis) in chickens subjected to feed withdrawal for 5 h (Savenije et al., 2002).

25.4 Glycerol

25.4.1 Introduction

Glycerol is produced when triglyceride is hydrolyzed. It can be phosphorylated by glycerol kinase and is then metabolized (see Fig. 25.3).

The structure of glycerol kinase has been determined from cDNA in multiple avian species, e.g., ostrich (*Struthio camelus*—Genbank XM_009683923.1), crested ibis (*Nipponia nippon*—Genbank XM_009473457.1), and burrowing owl (*Athene cunicularia*—Genbank XM_026846319.1). Glycerol kinase activity is reported in the liver (chickens: Bernardino et al., 2014) and skeletal

muscle of birds (pigeons, chickens, blue tits, pheasant, ducks, and robins—Newsholme and Taylor, 1969). It is assumed that glycerol kinase is not present in adipose tissue.

25.4.2 Circulating concentrations of glycerol

Circulating concentrations of glycerol exhibit marked differences across avian species (see Table 25.8). As might be expected, serum concentrations of glycerol are increased in broiler chickens fed a diet supplemented with glycerol (Romano et al., 2014). Circulating concentrations of glycerol in birds are used as an indicator of mobilization of triglyceride (e.g., Devost et al., 2014). After a migratory flight, circulating concentrations of glycerol are increased in some birds such as flycatchers (*Ficedula hypoleuca*) and garden warbler (*Silvia borin*) but not in European robins (*Erithacus rubecula*) (Jenni-Eiermann and Jenni, 1992). Similarly, plasma concentrations of glycerol are elevated during flight in red knot (*Calidris canutus*) (Jenni-Eiermann et al., 2002) and in bar-tailed godwits arriving from migration (Landys et al., 2005). The appearance rates of glycerol into the circulation per unit fat mass is greater in phase 3 than phase 2 of a fast in king penguins (*Aptenodytes patagonicus*) (Bernard et al., 2002). Circulating concentrations of glycerol are depressed in emperor penguins in phase 2 of fasting in response to glucose infusion indicating decreased lipolysis with there being a concomitant reduction in circulating concentrations of free fatty acids (Bernard et al., 2003a). Conversely, infusion of the lipolytic hormone, glucagon increased circulating concentrations of glycerol and nonesterified fatty acids (Bernard et al., 2003b).

25.5 Glycogen

25.5.1 Introduction

Glycogen is the storage form of glucose and is broken down to glucose at times of need. It consists of a branched polymer of glucose residues with glucose residues linked predominantly by α-1,4-glycosidic bonds but with α-1,6-glycosidic bond at branching points. Granules of glycogen contain about four times as much water as carbohydrate.

In mammals, there is evidence for two types of glycogen:

- Proglycogen (acid insoluble) with a molecular weight of 400,000 and containing 10% protein
- Macro glycogen—with a molecular weight of 10,000,000 and containing 0.35% protein.

(Lomako et al., 1991). There is little information on the structure of glycogen or proglycogen and macro glycogen in avian tissues.

25.5.2 Synthesis and breakdown

Glycogen is synthesized by the enzyme, glycogen synthase (GS). In contrast, glycogen is broken down generating glucose-1-phosphate by the enzymes, glycogen phosphorylase, and glycogen debranching enzyme, working in combination. Glycogen debranching enzyme activity is reported in skeletal muscles *Musculus pectoralis superficialis* and *Musculus quadriceps femoris* (chicken: Ylä;-Ajos et al., 2006). The synthesis and degradation of glycogen is summarized in Fig. 25.6. Glycogenolysis also plays an important role in astrocyte functioning (chicken: Gibbs et al., 2006).

25.5.2.1 Glycogenesis (synthesis)

Glycogenesis is synthesis of glycogen from glucose:

Glucose 6-phosphate → Glucose 1-phosphate.

25.5.2.1.1 Phosphoglucomutase

Glucose 1-phosphate + Uridine triphosphate (UTP) → Uridine diphosphoglucose

25.5.2.1.2 Uridine triphosphate-glucose pyrophosphorylase

Glycogen (n) + Uridine diphosphoglucose → Glycogen (n + 1) + UDP.

25.5.2.1.3 Glycogen synthase

GS is expressed in pectoralis muscle (chicken: Sibut et al., 2008; Simon et al., 2012).

25.5.3 Glycogenolysis (breakdown)

Glycogenolysis is the breakdown of glycogen to glucose 1-phosphate. Glycogen phosphorylase (EC 2.4.1.1) hydrolyzes α-1,4-glycosidic bonds with glycogen debranching enzyme (EC 3.2.1.68) hydrolyzing α-1,4-glycosidic bonds:

Glycogen (n) + ATP → Glycogen (n − 1) + Glucose 1-phosphate.

25.5.3.1 Glycogen phosphorylase

Glycogen phosphorylase is expressed in pectoralis muscle (chicken: Sibut et al., 2008; Simon et al., 2012). Expression of glycogen phosphorylase in the pectoralis is increased with 3 h of transportation with accompanying feed withdrawal (chicken: Wang et al., 2017). There is also a decrease in muscle glycogen (chicken: Wang et al., 2017) presumably concomitant to increased glycogen phosphorylase activity.

25.5.3.2 Glycogenesis (breakdown)

There is little difference in hepatic phosphorylase activity between late avian embryos and newly hatched chicks (turkeys: Rosebrough et al., 1978b). As might be expected, cAMP increases phosphorylase activity in turkey liver tissue (Rosebrough and Von Vleck, 1990). There are increases in AMP-activated protein kinase (AMPK) protein, the expression of regulatory and catalytic AMPK subunits, and phosphorylation of AMPK in the liver and skeletal muscle at the end of embryonic and in early posthatch development (chicken: Walter et al., 2010). There is evidence that the rate of glycogenolysis in pectoralis muscle is increased with 3 h of transportation as evidenced by the elevated tissue concentrations of lactate (chicken: Wang et al., 2017). Glycogen debranching enzyme activity is reported in skeletal muscles *M. pectoralis superficialis* and *M. quadriceps femoris* (chicken: Ylä;-Ajos et al., 2006).

25.5.4 What is the concentration of glycogen in avian hepatocytes?

It is assumed liver is 70% hepatocytes (based on reports from the rat: Dewey, 1960; Regoeczi and Taylor, 1978), and glycogen is only present in hepatocytes (Wong and Cavey, 1992). Moreover, the volume of chicken hepatocyte is $\sim 1000\ \mu m^3$ (Wong and Cavey, 1992). Therefore, 1 gram of liver would contain 7×10^8 hepatocytes assuming the density of liver is 1.0.

The glycogen concentration in the liver has been reported as 167 µmoles glucose equivalent/g in chicks at seven days of age (see Fig. 25.4) (based on data in Zhao et al., 2017, 2018). Assuming all glycogen is proglycogen, then this can be calculated as 83.5×10^{-3} µmoles glycogen/g (83.5 nmoles glycogen/g or 83.5×10^{-9} mol glycogen/g) assuming glycogen has a molecular weight of 360,000 of glucose residues. The concentration of glycogen per hepatocyte is estimated as follows:

- 83.5×10^{-9} mol glycogen/7×10^8 hepatocytes =
  $= 11.9 \times 10^{-17}$ mol glycogen/hepatocyte
  $= 11.9 \times 10^{-17}/6.022 \times 10^{23}$(Avogadro's number).
  $= 1.98 \times 10^6$ molecules of glycogen/hepatocyte = ~2 million molecules of proglycogen per hepatocyte.

Alternatively, assuming all glycogen is *macroglycogen*, then this can be calculated as 3.34×10^{-3} µmoles glycogen/g or 80,000 molecules per cell assuming glycogen has a molecular weight of 10,000,000.

25.5.5 Hepatic concentrations of glycogen

25.5.5.1 Overview

Examples of hepatic concentrations of glycogen are shown in Table 25.9. Hepatic glycogen represents a labile storage form of glucose critically important to the maintenance of circulating concentrations of glucose and, thereby, organ functioning, particularly of the brain.

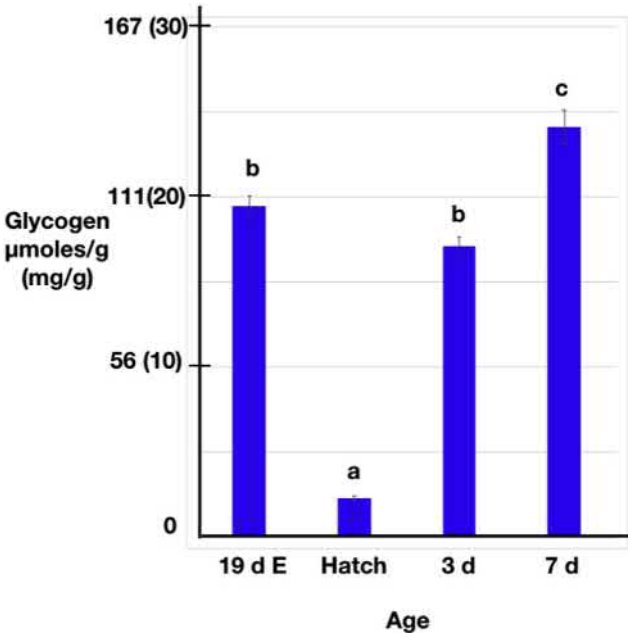

FIGURE 25.4 Changes in hepatic concentrations of glycogen in the perihatch period in chickens. *Based on data in Zhao et al. (2017, 2018).*

25.5.5.2 Effects of nutrition

As would be expected, hepatic concentrations of glycogen are increased following consumption of a carbohydrate meal and decreased with fasting (Tables 25.9 and 25.10).

**Indicates difference with feeding* $p < 0.05$.

25.5.5.3 Developmental changes

Glycogen levels are low in the avian embryo increasing between 15 and ~19 days of embryonic development (chicken: Pulikanti et al., 2010). Large shifts in hepatic glycogen concentrations have been reported in perihatch development. There are increases between 19 days and prior to hatching (chicken: Zhai et al., 2011). There is a large decrease in the glycogen concentrations in the liver at hatching (Fig. 25.4); this reflecting mobilization of stored glycogen. Changes in hepatic glycogen during chicken embryonic development can be summarized as follows:

- Glycogen concentrations increasing threefold between 11 days of embryonic development to a maximum at day 18 (11 to 18 days: Hamer and Dickson, 1987; 16 to 18 days: Willemsen et al., 2011).
- Glycogen content increasing between 18 days of embryonic development to a maximum at day 20 (Kornasio et al., 2011).
- A decrease (58%) in the hepatic glycogen concentration between internal pipping and hatching (chicken, *Gallus gallus*: Willemsen et al., 2011)

After hatching and the onset of feeding, hepatic concentrations of glycogen rise (chickens: Zhao et al., 2017; 2018; turkey: Foye et al., 2006) (Also see Table 25.10; Fig. 25.4).

25.5.5.4 Effects of perihatch nutrition

Feeding newly hatched chicks is followed by increases in liver glycogen (Kornasio et al., 2011) (Table 25.10). It is also possible to manipulate hepatic glycogen concentrations in the embryo. Injection of dextrin and β-hydroxy-β-methylbutyrate into the amniotic fluid is followed increases in the glycogen content of liver on days 19 and 20 of embryonic development (Kornasio et al., 2011). Similarly, intra-yolk sac administration of albumen (200 mg on day eight of embryonic development) was followed by increases in the concentrations of glycogen in both the liver at hatch (Tasharofi et al., 2018).

25.5.5.5 Developmental changes in glycogenesis

The rate of hepatic glycogenesis is very low in avian embryos, but it rises immediately after hatching to achieve a plateau at approximately 2 weeks old (chicken: Goodridge, 1968a, Table 25.4). The rise in glycogenesis does not occur in newly hatched chicks until after feeding (Benzo and DeGennaro, 1974, 1981).

25.5.5.6 Other effects on hepatic glycogen

Hepatic glycogen concentrations are depressed in birds with coccidiosis (chicken: Ruff and Allen, 1982).

25.5.5.7 Muscle concentrations of glycogen

25.5.5.7.1 Overview

Table 25.7 summarizes glycogen concentration in skeletal muscle of avian species. Glycogen concentrations are influenced by physiological state being increased when glucose supplies are abundant and decreased when supplies are limited and/or muscular demand for energy is high.

25.5.5.7.2 Developmental changes

Based on studies in chickens, the glycogen concentration in skeletal muscles exhibits large changes during embryonic development. Pectoralis muscle glycogen increases in late embryo development pattern to that of liver with a 33% increase between days 18 and 20 (Kornasio et al., 2011). There is a reduction in the muscle glycogen concentration at hatching (chicken: Zhao et al., 2017, 2018) (see Fig. 25.4); this presumably reflects glucose utilization by muscles during the process of hatching.

There is a large increase in glycogen concentration in the pipping muscle between 15 and 19 days of embryonic development (chicken: Pulikanti et al., 2010). This is presumably to provide a ready source of easily mobilized glucose for the process of hatching.

25.5.5.7.3 Effects of perihatch nutrition

Pectoralis concentrations of glycogen are increased following the administration of dextrin, and β-hydroxy-β-methylbutyrate into the amniotic fluid is followed increases in the content of pectoralis muscle on days 19 and 20 of embryonic development (Kornasio et al., 2011). Moreover, intra-yolk sac administration of albumen into the yolk sac was followed by increases in the concentrations of glycogen in both muscles at hatch (Tasharofi et al., 2018). With early feeding of newly hatched chicks, muscle glycogen concentrations are increased (Kornasio et al., 2011) (Table 25.10).

25.5.6 Issues with determination of tissue concentrations of glycogen and lactate

There is considerable variation in the concentrations of glycogen and lactate in muscles in various studies (Table 25.7). The bases for these differences are unclear. One possibility is the manner of euthanizing the animals with involuntary convulsions of multiple muscle leading to increased lactate and reduced glycogen (Edwards et al., 1999). There were marked differences in muscle glycogen concentrations between birds killed by cervical dislocation and barbiturate overdose (chicken: Edwards et al., 1999). Another possibility is depletion of glycogen occurs in the times between first handling the birds, euthanasia, and taking tissue samples.

Duration and method of storage of liver affects tissue glycogen and/or glucose concentrations with storage shifts in glucose even when snap frozen and at −70°C (chicken: Cleland and Bannister, 1979). Moreover, there is marked loss of glycogen when tissue is maintained at 4°C for 3 h (chicken: Cleland and Bannister, 1979). Similarly, glucose in muscle with pectoralis muscle glucose concentrations doubles between 7 and 25 min after euthanasia in a poultry processing plant (chicken: Aliani et al., 2013); this reflecting glycogenolysis. Immediate assay after snap freezing is the ideal.

25.5.7 Glycolytic potential

The glycolytic potential can be used as an index of meat quality (e.g., broiler chicken: Berri et al., 2005; domestic turkey: Patterson et al., 2017) and is predominantly due to glycogen in the muscle.

$$\text{Glycolytic potential (expressed in uM of lactate per g of fresh muscle)} = 2[(\text{glycogen}) + (\text{glucose}) + (\text{glucose} - 6 - \text{P})] + (\text{lactate})$$

(Berri et al., 2005). *Postmortem* there is breakdown of glycogen generating lactate.

25.5.8 Glycogen body

The glycogen body is a gelatinous ovaloid organ found in dorsal area of the lumbosacral region of the spinal cord in birds (Watterson, 1949). The glycogen body is functionally separated from the circulatory system due to the blood brain barrier (Möller and Kummer, 2003). The role of the glycogen body is not well established. As its name suggests, it contains glycogen (Lee et al., 2001). Glycogen body cells incubated in vitro incorporate glucose into glycogen suggesting the presence of glycogen synthase (Lee et al., 2001).

It is composed of what was initially described as uniform glycogen body cells (Watterson, 1949). These are astroglial-like cells (Louis, 1959, 1993; De Gennaro, 1993). These cells have a high capacity to store glycogen and contain deposits of glycogen in the cytoplasm (Imagawa et al., 2006a). A second cell type has been identified based on co-incubation of glycogen body cells with cerebellar neurons. These have processes that extend and attach to neurons (Imagawa et al., 2006a). The glycogen body is derived from anterior section of the lumbosacral neural tube (De Gennaro, 1991). The lobes of Lachi have many metabolic similarities to glycogen bodies with glycogen synthase, glycogen phosphorylase, glucose6-phosphate dehydrogenases, and 6-phosphogluconate dehydrogenase together with a lack of glucose 6-phosphatase (Benzo and DeGennaro, 1981).

Glycogen bodies contain multiple metabolic enzyme activities, including the following: glycogen synthase, glycogen phosphorylase, glucose 6-phosphate dehydrogenases, and 6-phosphogluconate dehydrogenase (Benzo and DeGennaro, 1974, 1981). There is lactate dehydrogenase (LDH) activity and LDH-B expression in the glycogen body (Imagawa et al., 2006b). It is suggested that the glycogen body consumes lactate body (Imagawa et al., 2006b). The glycogen level within the glycogen body cells is refractory to both nutritional status, being unchanged by starvation, and by hormones such as insulin, glucagon, and adrenocorticotropic hormone (Imagawa et al., 2006a). There is a small effect of norepinephrine on glycogenolysis with reduced glycogen levels in the glycogen body cells in vitro (Lee et al., 2001). It is suggested that the glycogen body and the lobes of Lachi function to provide precursors via the pentose phosphate pathway for myelin synthesis (Benzo and DeGennaro, 1981).

25.6 Glucose and fructose utilization

Utilization of glucose and fructose can be very high in birds (see Table 25.11). For instance, in foraging hummingbirds, hovering flight is maintained by utilization of ingested sugars in rufous (*Selasphorus rufus*) and Anna's (*Calypte anna*) hummingbirds (Welch and Suarez, 2007). In contrast during migration, fats are employed as the energy source, with the ruby-throated hummingbird (*Archilochus colubris*) losing most of the triglyceride stored in the adipose tissue during a 20 h flight over 960 km (600 miles; Hargrove, 2005). There are very high-respiration rates of mitochondria from skeletal muscles of hummingbirds (7−10 mL O2/cc/min); the rates are twice the maximum found in mammals (Suarez et al., 1991). This may be associated with increased mitochondrial surface area (Suarez et al., 1991). There is an increase in glucose turnover with exercise in

TABLE 25.11 Glucose metabolism in chickens.

Parameter	Age	Method	Estimated glucose metabolism (μmol glucose/min/kg)	Reference
Total body glucose loss (utilization)	Eight days	Disappearance of radioactive deoxyglucose from the blood	102	Calculated from Tokushima et al. (2005)
Total body glucose utilization	Four weeks	Heat produced	174	Calculated from Buyse et al. (1993) [a]
Total body glucose utilization	Five weeks	Heat produced	112	Calculated from Buyse et al. (1993) [a]
Total body glucose disappearance	Five −Six months	Disappearance of radioactive glucose from the blood	79.4	Belo et al. (1976)
Average			116	

[a]*This assumes that the respiratory quotient (RQ) of 1.0 with glucose being utilized for energy rather than either fats or amino acids. Geelissen et al. (2006) reported RQ in similar-aged animals of 1.1 or greater. Data are calculated based on body weights of the same aged birds in the same laboratory (Buyse et al., 2004) and on catabolized energy from carbohydrate = 16.7 kJ/g substrate (3008.67 kJ per mole glucose) with RQ of 1.00 (Walsberg and Wolf, 1995).*

chickens (Brackenbury and El-Sayed, 1985). There are marked differences in glucose uptake by different organs (summarized in Table 25.12). The highest uptake is by the brain and heart. Insulin induced large increases in glucose uptake by the liver and some skeletal muscles. In contrast, glucose uptake is depressed in the brain of the chicken (Tokushima et al., 2005). There are marked changes during the day in glucose uptake by tissues in chickens on a 12 h light/12 h dark cycle (Karaganis et al., 2009).

25.6.1 Developmental changes

There is little glucose utilization for lipogenesis (fatty acid synthesis) in the liver of avian embryos and at hatching. They rise to a substantial plateau level within eight days after hatching due to feeding, as shown in chickens (Goodridge, 1968a,b; Table 25.13). Glucose oxidation in chick embryos is increased when incubated at elevated temperatures (Molenaar et al., 2013).

TABLE 25.12 Comparison of glucose uptake by different organs by chickens.

Organ	Glucose uptake (nmol/min/g)
Brain	315
Heart	223
Kidney	146
Small intestine	100
Skeletal muscle	38 (25−55)[a]
Adipose tissue	18.5
Liver	12.3

[a]*Range of different muscles.*
Data calculated From Tokushima et al. (2005) based on radioactive (3H). 2-deoxyglucose uptake in 8-day-old chickens fasted for 12 h.

25.6.2 Fasting and glucose utilization

There is reduced glucose utilization during fasting in birds. For instance, irreversible glucose turnover is depressed 32% by fasting (either associated with breeding or forced starvation) in Emperor penguins (*Aptenodytes forsteri*; Groscolas and Rodriguez, 1981):

- Fed 44.2 μmol/min/kg
- Fasted 30.1 μmol/min/kg

Similarly, there is a 57.6% decrease in glucose utilization in Japanese quail (*C. japonica*) fasted for two days (Sartori et al., 1996) and 64% in chickens fasted for one day (Belo et al., 1976). The decrease in glucose utilization is due to the following:

- Reduced glucose utilization by peripheral tissues such as skeletal muscles (Table 25.14)
- Reduced glucose utilization by the liver for:
  - Lipogenesis, with as little as 2 h fasting (Fig. 25.5). Rates of fatty acid synthesis are further decreased to 6.4% of control with one day fasting and to 0.2% of control with three days starvation [data from Yeh and Leveille (1971a, b)]. Expression of genes for enzymes in lipogenesis is depressed by fasting in chickens (Désert et al., 2008; Sherlock et al., 2012).
  - Glycolysis (Goodridge, 1968a).

TABLE 25.13 Changes in hepatic utilization of glucose for glycolysis, glycogenesis, and lipogenesis during early posthatch development in the chicken.

	Glucose utilization[a] (as percentage of plateau level)

25.7 Glucose transporters

25.7.1 Introduction to avian glucose transporters

Glucose enters cells due to GLUTs. GLUTs are facilitative hexose transporters that are found in cell membranes. They have molecular weights of 45−55 KDa and have been identified across bacteria, fungi, plants, invertebrate animals, and vertebrates (Wilson-O'Brien et al., 2010). There are three classes of GLUT: 1, 2, and 3. Class 1 and 2 GLUT are distinct clades that are only found in metazoan animals (Wilson-O'Brien et al., 2010; Byers et al., 2017). In contrast, class 3 is not a distinct clade (Wilson-O'Brien et al., 2010). In mammals and birds, there are respectively 14 and 13 GLUT genes/proteins namely:

- Class 1 GLUT
  - GLUT1: Solute carrier family 2 facilitated GLUT member 1 (SLC2A1) (e.g., Anna's hummingbird: Genbank XM_008503695.1; chicken: Genbank L07300.1; house sparrow: Genbank)
  - GLUT2: SLC2A2 (e.g., Anna's hummingbird: Genbank XM_008501315.2; Bengalese finch: GenBank: 021549987.1; chicken: GenBank Z22932.1; mallard: Genbank KJ011857.1; pigeon: GenBank: JN887480.1)
  - GLUT3: SLC2A3 (e.g., Canary: Genbank XM_009102684.3; chicken: Genbank M37785.1; golden-collared manakin: Genbank XM_029 964892.1: zebra finch: Genbank XM_002190755.4)
  - GLUT4: Presumed to be absent in birds
  - GLUT14: SLC2A14 (e,g., chicken: Gene bank NM_205511.1)
- Class 2 GLUT
  - GLUT5: SLC2A5 (e,g., chicken: Gene bank CGNC ID1764; zebra finch: Genbank XM_002187376.3)
  - GLUT7: SLC2A7
  - GLUT9: SLC2A9 (e,g., Anna's hummingbird: Genbank XM_008496129.2; golden-collared manakin: Genbank XM_029958571.1)
  - GLUT11: SLC2A11 (e,g., chuck-will's-widow: Genbank XM_010162948.1); golden eagle GenBank: XM_011592834.1; golden-collared manakin: Genbank XM_018081931.3)
- Class 3 GLUT
  - GLUT6: SLC2A6 (e,g., Anna's hummingbird: Genbank XM_008497303.2)
  - GLUT8: SLC2A8 (e,g., chicken: Genbank AB083371.1)
  - GLUT10: SLC2A10 (e,g., Anna's hummingbird: Genbank XM_008498009.1)
  - GLUT12: SLC2A12 (e,g., Anna's hummingbird: Genbank XM_008494039.2; chicken: Genbank XM_419733 Coudert et al., 2015)
  - GLUT13: SLC2A13 (INT4 or H + *-myo*-inositol transporter) (e,g., Anna's hummingbird: Genbank XM_008493093.1; rifleman: Genbank: XM_009071059.1)

25.7.2 Insulin-dependent glucose transporters

There does not appear to be a homolog of the mammalian insulin-dependent GLUT4 in birds (chickens: Seki et al., 2003; house sparrows *P. domesticus*: Sweazea and Braun, 2006). There is evidence that GLUT12 expression is controlled by insulin as administration of antisera to insulin is accompanied by decrease in expression of GLUT12 in both pectoralis and thigh muscle (Coudert et al., 2015). Moreover, there are effects of both feeding and antisera against insulin of the amount of GLUT12 in cell membranes from leg muscles with more in fed than fasted consistent with elevated insulin levels and also increases with insulin administration (Coudert et al., 2015). Although GLUT1 is insulin-independent in mammals, insulin

TABLE 25.15 Comparison of citrate synthase activity between hummingbirds and chickens.

Species	Citrate synthase activity (nmol/min/g wet wt)	Reference
Hummingbird	448	Suarez et al. (2009)
Chicken	21	Azad et al. (2010)

stimulates glucose uptake along with both GLUT1 expression and protein content in avian myoblasts (chicken: Zhao et al., 2012). An insulin-dependent GLUT8 is expressed in the chicken (high: adrenal, brain, kidney, lung, pancreas, spleen, and testis; low: adipose tissue, liver, heart, and skeletal muscle; chickens: Seki et al., 2003; Kono et al., 2005) (Table 25.15).

25.7.3 Tissue expression of glucose transporters

There is high expression of GLUT1 in adipose tissue (chicken: Kono et al., 2005), brain (chicken: Kono et al., 2005), and skeletal muscle (chicken: Shimamoto et al., 2016) together with fibroblasts (Wagstaff et al., 1995). High GLUT2 expression is only found in the liver and kidneys (chicken: Kono et al., 2005; Lee et al., 2006), with low expression in the small intestine (chickens: Duarte et al., 2011). Epidermal growth factor decreases GLUT2 protein levels in chicken hepatocytes (Lee et al., 2006; Franssens et al., 2016). There is high GLUT3 expression in skeletal muscle (chicken: Shimamoto et al., 2016), brain (chicken: Kono et al., 2005) with chicken fibroblasts also expressing GLUT3 (Wagstaff et al., 1995) and all tissues expressing GLUT3 in house sparrows (Sweazea and Braun, 2006). There is also expression of GLUT8 in skeletal muscles (chicken: Shimamoto et al., 2016). GLUT9 is expressed in the liver (perihatch chickens: Franssens et al., 2016). GLUT12 expression exhibits the following pattern: skeletal muscle > heart = brain > liver = adipose tissue (Coudert et al., 2015).

25.7.4 Physiological control of glucose transporters

GLUT expression decreases during the development of the avian erythrocyte (chicken: Johnstone et al., 1998) with only 200 copies of GLUT1 per mature erythrocyte (pigeon: Diamond and Carruthers, 1993). There is high expression of GLUT2 in the liver of the young chickens, together with some expression of both GLUT1 and GLUT3 (Humphrey et al., 2004). Skeletal muscle also exhibits high expression of GLUT3, with some expression of GLUT1 but no detectable expression of GLUT2 (Humphrey et al., 2004).

25.8 Intermediary metabolism

25.8.1 Glucose phosphorylation and dephosphorylation

Glucose 6-phosphate plays a major role in the control of metabolism (Fig. 25.6). There are rapid increases in hepatic concentrations of glucose 6-phosphate after hatching (turkeys: Rosebrough et al., 1979).

25.8.1.1 Glucose phosphorylation to glucose 6-phosphate

Glucose is phosphorylated to glucose 6-phosphate catalyzed either by glucokinase or hexokinase:

$$\text{Glucose} + \text{ATP} \rightarrow \text{Glucose 6-phosphate}$$

25.8.1.1.1 Enzyme: glucokinase/hexokinase

Glucokinase has been partially characterized both from chickens and mule ducks with 99% identity (Berradi et al., 2005, 2007). There is increased expression in the liver of mule ducks with overfeeding (Berradi et al., 2004) and feeding in chickens (Berradi et al., 2007). Fasting depresses glucokinase expression by 66% in chickens (Dupont et al., 2008). Low Michaelis constant (Km) hexokinase activity is present in the chicken liver and reduced with fasting (O'Neill and Langlow, 1978; Klandorf et al., 1986). High Km hexokinase activity is found in the mitochondria of the liver (chicken: Borrebaek et al., 2007). Hexokinase is present also in the muscles of hummingbirds (Suarez et al., 1990).

25.8.1.2 Glucose 6-phosphatase

Glucose 6-phosphatase plays a critical role in glucose homeostasis:

$$\text{Glucose 6-phosphate} \rightarrow \text{Glucose} + \text{Phosphate}$$

There are markedly higher levels of glucose 6 phosphatase in the carnivorous bird, the black vultures (*C. atratus*) presumably reflecting the greater gluconeogenesis (Migliorini et al., 1973).

Glucose 6-phosphatase activity is present in the avian liver (chicken: O'Neill and Langlow, 1978). Thus, glucose 6-phosphate generated from glycogenolysis and gluconeogenesis is released from the liver into the circulation for peripheral use. There does not appear to be glucose 6-phosphatase in skeletal muscle; hence, muscle glycogen

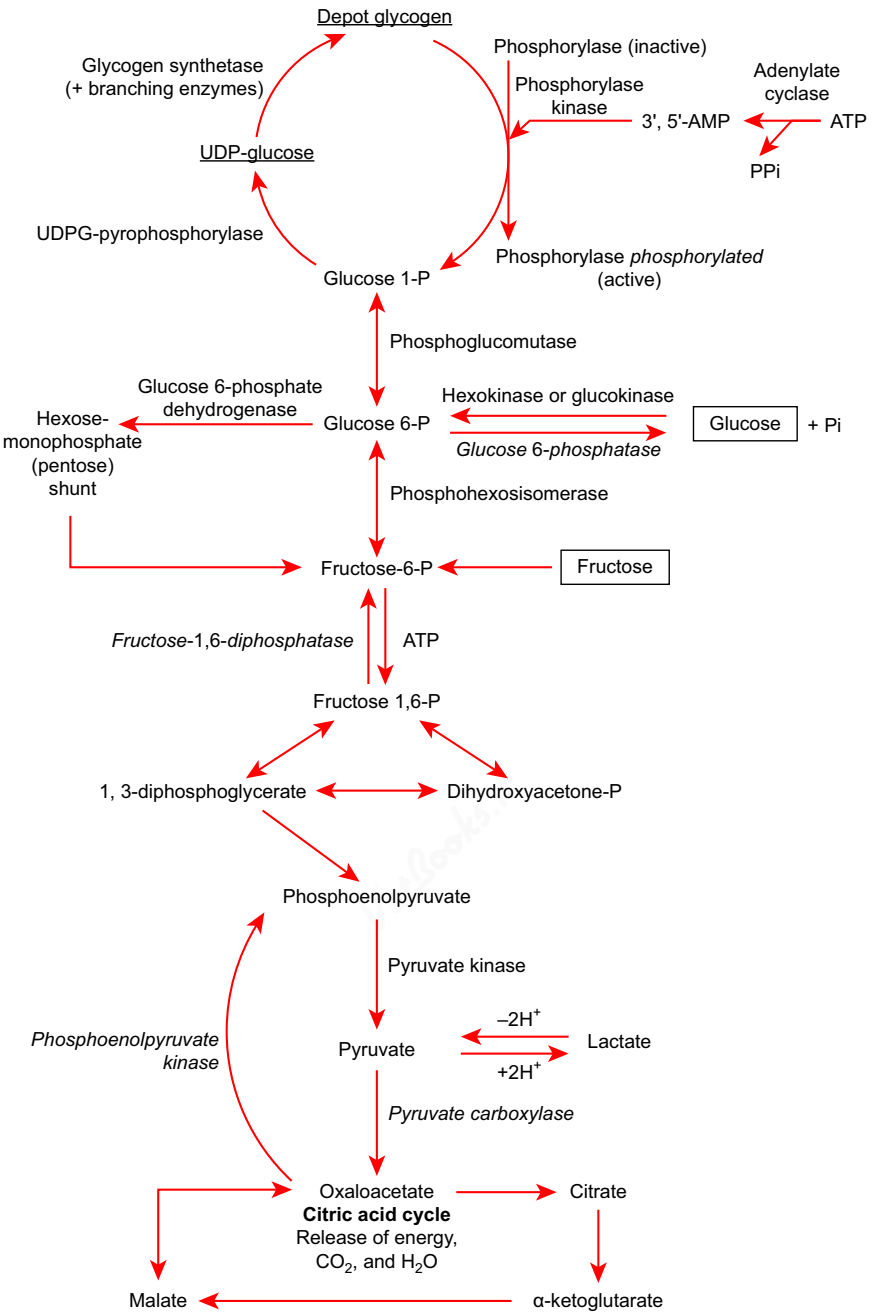

FIGURE 25.6 Overview schematic diagram of carbohydrate metabolism (glucose phosphorylation/dephosphorylation, glycolysis, glycogenesis, glycogenolysis, and pentose phosphate shunt).

is not a source of circulating glucose. Along with elevated glycogenolysis and glucogenesis with fasting, there is increased glucose 6-phosphatase activity in the liver (chicken: O'Neill and Langlow, 1978).

25.8.2 Glycolysis

Glycolysis is summarized in Fig. 25.6. The glycolytic pathway precedes carbohydrate metabolites entering the citric acid cycle and also allows the anaerobic metabolism of glucose.

25.8.2.1 Developmental changes

There are low rates of hepatic glycolysis in the liver of avian embryos, rising quickly after hatching to a plateau level achieved after about a week (chicken: Goodridge, 1968a, Table 25.13).

25.8.2.2 Physiological effects

The posthatch increase in glycolysis is induced by feeding (chicken: Goodridge, 1968b). Hepatics rates of glucose utilization for glycolysis and conversion to carbon dioxide are depressed by fasting. For instance, in young chickens, rates of glucose oxidation to carbon dioxide by liver slices are decreased by the following (Goodridge, 1968b):

- One day: 59.5% of control
- Three days: 17.5%

Expression of genes for enzymes in the glycolytic pathway is depressed by fasting in chickens (Sherlock et al., 2012). There is evidence that the rate of glycolysis in pectoralis muscle is increased with 3 h of transportation as evidenced by the elevated tissue concentrations of lactate (chicken: Wang et al., 2017).

25.8.2.3 Erythrocytes

Glycolysis and pentose phosphate shunt are the pathways to obtain energy from glucose in the erythrocyte (pigeon: Kalomenopoulou and Beis, 1990). Phosphofructokinase activity, pyruvate kinase (PK) activity, and hexokinase activity are present in the erythrocyte (pigeon: Kalomenopoulou and Beis, 1990).

25.8.2.4 Lactate dehydrogenase

LDH catalyzes the conversion of lactate to pyruvate and vice versa. Plasma/serum LDH activities are included by the biochemical reference ranges for birds [e.g., kakapo (*Strigops habroptilus*): Low et al., 2006] (see Fig. 25.7).

There are three genes for LDH in birds, respectively, ldha, ldhb, and ldhc, these encoding LDH-A, LDH-B, and LDH-C. There are tissue differences in expression of LDH such as the following:

- LDH-A expression is breast muscle = liver > kidney = heart with some expression in the brain and glycogen body (chicken: Arias et al., 2000; Imagawa et al., 2006a,b).
- LDH-B expression is kidney = heart >> breast muscle = liver with marked expression in the brain and some in the glycogen body (chicken: Arias et al., 2000; Imagawa et al., 2006a,b).

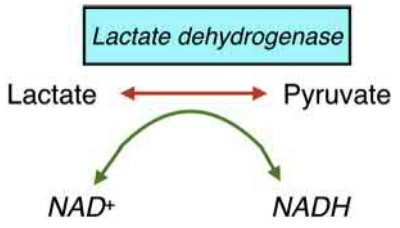

FIGURE 25.7 Conversion of lactate to pyruvate and vice versa.

- A novel LDH-B is reported in chicken testes (Arias et al., 2000).

Moreover, splice variants of LDH C chain mRNA are found in the testes (pigeon: Huang et al., 2012).

There are shifts in LDH with physiological state. Both plasma and pectoralis muscle LDH is increased after short-term transportation with consequent withholding of food (chicken: Wang et al., 2017; Xing et al., 2017). Plasma LDH activity is increased by exercise [red-tailed hawks (*Buteo jamaicensis*) Knuth and Chaplin, 1994]. There are developmental shifts in LDH enzyme activity with declines during postembryonic development (chicken: Seebacher et al., 2006). There is evidence that temperature influences LDH activity with increase in LDH concentrations in the supernatants from chicken myocardial cells exposed to elevated temperatures (Xu et al., 2017).

25.8.3 Citric acid or tricarboxylic acid cycle

25.8.3.1 Overview

Fig. 25.8 summarizes the citric acid or tricarboxylic acid cycle. There were increases in mitochondrial capacity [citrate synthase (CS) activity] at the end of embryonic and in early posthatch development (chicken: Walter et al., 2010). CS and PK activities are found in skeletal muscle from chukar, pheasant, domestic turkey, and wild turkey (Shea et al., 2007). CS activity in hummingbirds is similar to that in mammalian mitochondria (Suarez et al., 1991) but higher than that of the chicken (Table 18.9). PK has been identified by proteomics in pectoralis muscle with dietary protein deprivation (chicken: Corzo et al., 2006).

25.8.3.2 Erythrocytes

The citric acid cycle is absent in erythrocytes (pigeon: Kalomenopoulou and Beis, 1990).

25.9 Gluconeogenesis

The gluconeogenic pathway is summarized in Figs. 25.4 and 25.6. The major organs for gluconeogenesis in birds are the liver and kidneys (see below). There appears to be marked gluconeogenic potential for the yolk sac in the developing embryo, with high expression of fructose 1,6-bisphosphatase and phosphoenolpyruvate carboxykinase together with glucose 6-phosphatase (chicken: Yadgary et al., 2011). Muscle- and liver-type phosphofructokinase-1 (PFK-M and PFK-L) have been characterized in the chicken (Seki et al., 2006). There is hepatic expression of regulatory enzymes of the gluconeogenesis, specifically phosphoenolpyruvate carboxykinase 1 and 2 (PCK1 and 2)

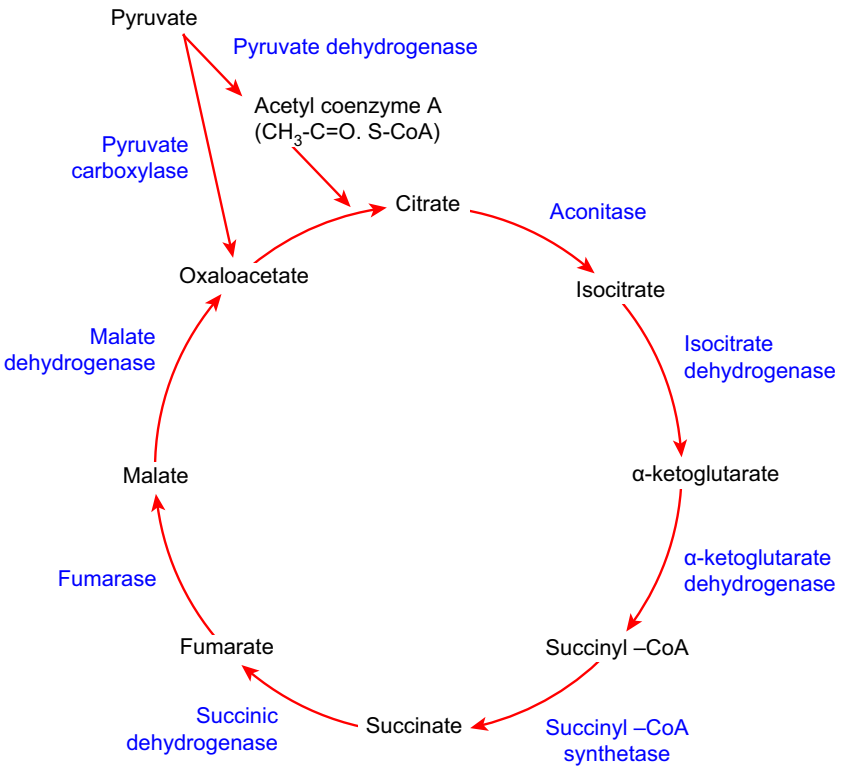

FIGURE 25.8 The citric acid or tricarboxylic acid cycle.

or fructose-1,6-biphosphatase 1 (FBP1) (perihatch chickens: Franssens et al., 2016). Chicken PFK-L is expressed at a low level in the liver, skeletal muscle, and brain (Seki et al., 2006). Chicken PFK-M is expressed in skeletal muscle (Seki et al., 2006). Basal rates of gluconeogenesis is markedly greater in carnivorous birds, black vultures (*C. atratus*) than chickens (Migliorini et al., 1973).

25.9.1 Gluconeogenesis and fasting

Fasting increases gluconeogenesis in some but not all birds. There is greatly increased net release of glucose from both the liver and kidneys (Table 25.14), together with elevated hepatic glucose 6-phosphatase, phosphoenolpyruvate carboxykinase, alanine aminotransferase, and aspartate aminotransferase activities (chickens: Veiga et al., 1978). There are marked increases in gluconeogenesis during fasting in the Japanese quail (*C. japonica*), with increases in the rate of glucose formation from ^{14}C bicarbonate in vivo (Sartori et al., 1996, 2000). Moreover, with two days fasting (phase 2), there were increases in the activity of cytoplasmic phosphoenolpyruvate carboxykinase in the kidney (Sartori et al., 2000). Similarly, fasting increases gluconeogenesis in duckling liver-based perfusion studies in which the medium contains the gluconeogenic precursor, lactate (Bedu et al., 2001). Expression of genes for enzymes in the gluconeogenic pathway is increased by fasting (chicken: Désert et al., 2008; Sherlock et al., 2012). However, gluconeogenesis is depressed in fasted carnivorous birds (black vulture *C. atratus*: Veiga et al., 1978).

25.9.2 Relative importance of the liver and the kidney

Gluconeogenesis occurs in both the liver and kidneys. The relative contribution is estimated from arteriovenous differences in fed and fasted birds, with the liver producing about 70% of the glucose and kidney about 30% in the fasted state (chicken: Tinker et al., 1986, Table 25.14). In fed carnivorous birds, there is high rates of gluconeogenesis (black vulture *C. atratus*: Veiga et al., 1978). There is likely to be some hepatic gluconeogenesis in graniferous birds. This is supported by studies of arterial-venous differences in glucose and lactate (Table 18.8). It is presumed that much of the lactate originates from gastrointestinal tract, with 37% of glucose converted to lactate in the chicken gastrointestinal tract (Riesenfeld et al., 1982).

25.10 Carbohydrate digestion and absorption

Carbohydrate digestion and absorption will be discussed in three parts: starch digestion, disaccharide digestion, and glucose absorption (Fig. 25.9).

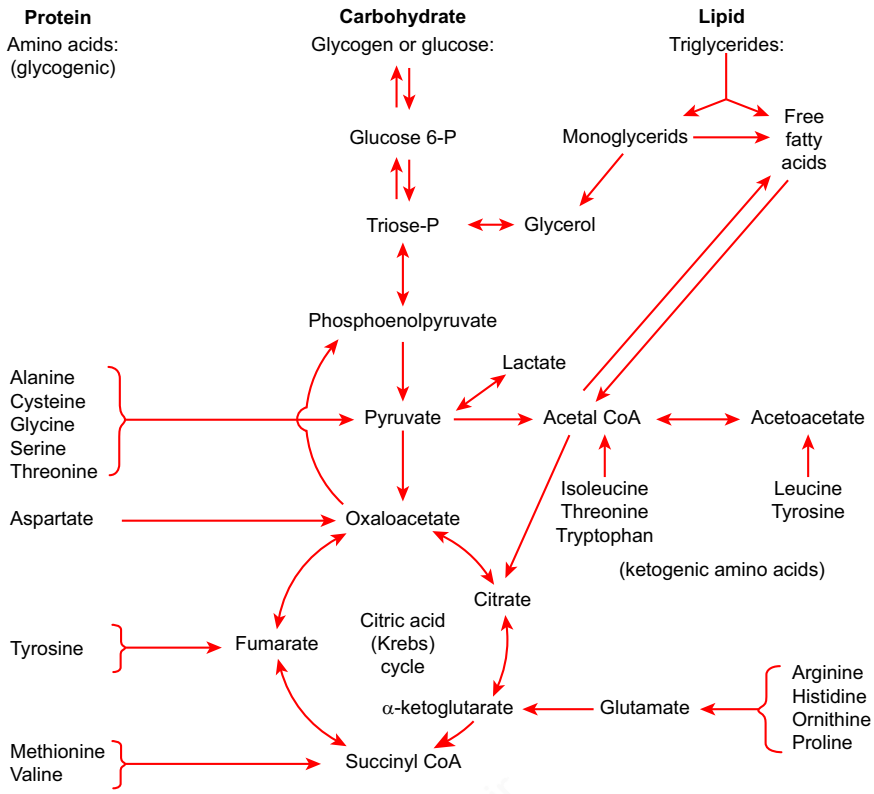

FIGURE 25.9 Overview schematic diagram of the relationships between lipid and protein metabolism with carbohydrate metabolism.

25.10.1 Starch digestion

Starch is digested by amylase, which is produced by the small intestine (see Table 25.16) and exocrine pancreas (chicken: Osman, 1982). About 97% of corn starch in the diet is digested in the chicken (Riesenfeld et al., 1980). The sites of starch digestion in the chicken small intestine are the following (calculated from Riesenfeld et al., 1980):

- Duodenum 63%
- Jejunum 19%
- Ileum 12%

However, there is markedly higher proportion of digestion of other starches, for instance from legumes, in both the duodenum and ilium of chickens (Weurding et al., 2001).

TABLE 25.16 Enzymatic activities in the chicken small intestine.

Enzyme	Duodenum	Jejunum
Amylase	13.4	19.0
Maltase	1.5	4.8
Sucrose	1.4	3.2

Based on Liu et al. (2008).

TABLE 25.17 Changes in liver glycogen with meal feeding in the chicken, allowing determination of the rate of glycogenolysis.

Time relative to feeding	Meal fed	Liver glycogen (mmole glucose equivalents)
	Once daily	3.5
+12 h following meal	Once daily	7.7
Prior to feeding	Once on alternate days	6.9
+24 h following meal	Once on alternate days	15.9

From De Beer et al. (2007).

There is secretion of amylase in the upper gastrointestinal tract and from the liver reported in some birds: from salivary glands (e.g., spotted dove (*Streptopelia chinensis*) and house crow (*Corvus splendens*)), the proventriculus [e.g., house sparrow (*P. domesticus*)] (Bhattacharya and Ghose, 1971) and from the liver in bile (chicken: Farner, 1943).

TABLE 25.18 Changes in liver glycogen with meal feeding in the chicken, allowing determination of the rate of glycogenolysis.

Time relative to feeding	Total liver glycogen (mmole glucose equivalents)	Feed as starch content in the crop (mmole glucose equivalents)
Meal fed daily		
Prior to feeding	4.0	
Immediately after feeding 0		83.1
12 h after feeding	14.1	21.5
24 h after feeding	7.8	6.5
Delta 0 to 12	*NA*	*61.6*
Delta 12 to 24	*6.3*[x]	*15.0*
Meal fed alternate days		
Prior to feeding	6.5

25.10.2 Disaccharide digestion

25.10.2.1 Maltose

Maltase cleaves the disaccharide maltose into its two constituent glucose moieties. There is maltase activity in the duodenum and jejunum (chicken: Liu et al., 2008) but somewhat lower expression of isomaltase in the jejunum then duodenum (Liu et al., 2008). While, there are little changes in expression of isomaltase during embryonic development (Yadgary et al., 2011), both isomaltase and aminopeptidase activities increase in the brush border of the jejunum in late embryonic development (chicken: Uni et al., 2003). Moreover, there are marked increases in maltase activity in the jejunum in the first week of posthatching life (domestic ducks: Tangara et al., 2010). In contrast. there were little changes in the expression of maltase during embryonic development and posthatching development in another avian species (pigeons: Xie et al., 2020).

25.10.2.2 Sucrose

Sucrose cleaves the disaccharide sucrose into its two constituent monosaccharide moieties, glucose and galactose. There is sucrase activity in the duodenum and jejunum (chicken: Liu et al., 2008) with a similar distribution to maltose along the small intestine (Meynard et al., 1999). Similarly, there is somewhat lower expression of isomaltase in the jejunum then duodenum (Liu et al., 2008). There are marked increases in sucrase activity in the jejunum in the first week of posthatching life (domestic ducks: Tangara et al., 2010) but little changes in the expression of sucrase during embryonic development and posthatching development in another avian species (pigeons: Xie et al., 2020).

Sucrose is a major component in nectar. In ruby-throated hummingbird (*Archilochus colubris*), sucrose is digested by sucrase to fructose and glucose prior to absorption (McWhorter et al., 2006). Exogenous fructose or glucose can supply, respectively, 88 and 82% of energy needs of hovering hummingbirds (Chen and Welch, 2014).

25.10.2.3 Lactose

Lactose is poorly utilized by growing chick resulting in diarrhea (Rutter et al., 1953), presumably due to failure of lactose digestion and osmotic effects. In contrast, galactose is well utilized (Rutter et al., 1953).

25.10.3 Glucose absorption

25.10.3.1 Overview

There is active absorption of glucose in the small intestine, cecum, and colon of birds (chickens: Riley et al., 1986; Vinardell and Lopera, 1987; Moreno et al., 1996; De La Hora et al., 1998, 2001). The major site of glucose absorption is the duodenum, accounting for more than 80% of glucose absorbed in young chickens fed a diet high in glucose (Riesenfeld et al., 1980). The very high glucose absorption from the intestines of hummingbirds is due to active, mediated transport [rufous (*Selasphorus rufus*) and Anna's (*Calypte anna*) hummingbirds] (McWhorter et al., 2006). Similarly, honey eaters have a high rates of glucose absorption (Nicolson and Fleming, 2014).

Glucose absorption from the lumen of the gastrointestinal tract into enterocytes is achieved by active transport, predominantly by sodium D-glucose and galactose co-transporter 1(SGLT1). The SGLT1 protein has a high affinity for glucose (Gal-Garber et al., 2000) and is exclusively found in the brush border of enterocytes (chickens: De La Hora et al., 1998; Barfull et al., 2002). Expression of SGLT1 is high in the small intestine, being greatest in the jejunum as seen from the following values for the chicken (calculated from Gilbert et al., 2008, with expression shown as a percentage of that in the jejunum):

- Duodenum 77%
- Jejunum 100%
- Ileum 65%

Jejunal expression of sodium GLUT1 is increased in fasted chickens (Gal-Garber et al., 2000; Duarte et al., 2011) and further elevated with refeeding (Gal-Garber et al., 2000). During embryonic development, there are increases in both expression and activity of SGLT1 (chicken: Uni et al., 2003; Yadgary et al., 2011; pigeon: Dong et al., 2012). During growth, the surface area increases but expression of SGLT1 declines (Barfull et al., 2002). Aldosterone influences expression of SGLT1 (chickens: De La Hora et al., 2001). There is also expression of sodium independent glucose (galactose and fructose) transporter 2 (GLUT2) in the small intestine. Jejunal expression of GLUT2 is unaffected by either fasting or refeeding in young chickens (Duarte et al., 2011).

25.10.3.2 Noncarrier uptake of glucose

Noncarrier uptake of glucose can occur across the tight junctions between enterocytes. There is marked noncarrier uptake of glucose (occurring across tight junctions between enterocytes) during migration stop-overs in blackcaps (*Sylvia atricapilla*) (Tracy et al., 2001). Similarly, noncarrier uptake of glucose is found in nectarivorous birds such as rufous hummingbirds (*Selasphorus rufus*) and Anna's hummingbirds (*Calypte anna*) with glucose or fructose flowing down a concentration gradient from the nectar (McWhorter et al., 2006).

25.10.4 Glucose digestion in frugivorous birds

Frugivorous birds consume fruits; these having fructose and glucose. Table 25.19 summarizes the digestibility of glucose and fructose in frugivorous birds from different types of fruits. While digestibility of glucose and fructose was high (>97.5%) from *Vitis* type fruits (Witmer and Van Soest, 1998). In contrast, digestibility of fructose from *Lindera* type fruits was lower while digestibility for glucose was approximately 30% lower (Witmer and Van Soest, 1998).

TABLE 25.19 Digestive efficiencies of glucose and fructose in frugivorous birds (Witmer and Van Soest, 1998).

Type of fruit and bird species	Digestive efficiencies	
	Glucose	Fructose
***Vitis* (e.g., grapes)**		
American robin (*Turdus migratorius*)	98.1	99.2
Wood thrush (*Hylocichla mustelina*)	98.1	99.1
Cedar waxwing (*Bombycilla cedrorum*)	97.9	99.0
***Lindera* (spicewood and spicebushes)**		
American robin (*Turdus migratorius*)	24.3	52.3
Wood thrush (*Hylocichla mustelina*)	29.7	62.7
Cedar waxwing (Bombycilla cedrorum)	55.3	86.8

25.10.5 Gastrointestinal storage of ingesta

There is temporary storage of feed in the crop and gizzard of at least some graniferous birds (e.g., in the order *Galliformes*). For instance, substantial stores of feed are found in crop of in sexually immature meat-type chickens adapted to either daily or alternate day meal feeding (De Beer et al., 2008) (Fig. 25.10). In chickens, feeding is restricted to the hours of light (day). There is a marked peak in consumption prior to lights-off, with concomitant filling of both the crop and gizzard (Scanes et al., 1987; Buyse et al., 1993, Fig. 25.10). Nocturnal energy needs are accommodated by reduced metabolic rate and the release of the stored ingesta (Buyse et al., 1993, Fig. 25.11).

25.10.6 Intestinal fermentation

Limited information is available on gastrointestinal fermentation in birds.

25.10.6.1 Cellulose

25.10.6.1.1 Foregut

A neotropic bird, the hoatzin (*Opisthocomus hoazin*), is said to be unique in having foregut fermentation (Grajal et al., 1989). The microbial communities in the muscular crop have been characterized and include methanogens as in the mammalian rumen (Wright et al., 2009; Godoy-Vitorino et al., 2012).

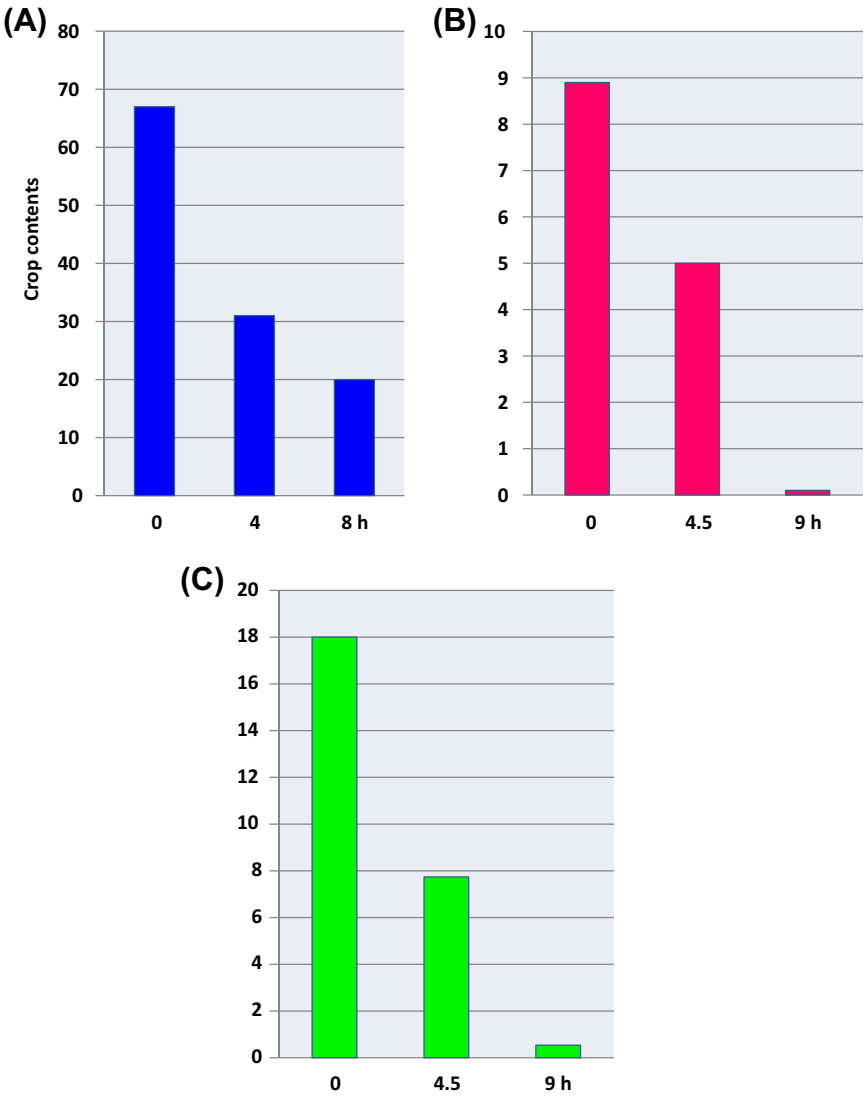

FIGURE 25.10 Mechanical storage of ingesta in the crop (g) of chickens. (A) Following meal feeding in broiler breeder pullets (sexually immature females) (De Beer et al., 2008) and (B) during the night following increased feeding prior to lights-off in young broiler chickens (Buyse et al., 1993) and during the night following increased feeding prior to lights-off in laying hens Scanes et al. (1987).

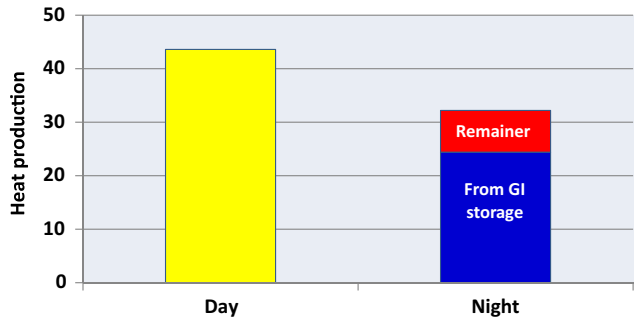

FIGURE 25.11 Comparison of heat production/energy consumption (kJ kg0.75 h) during the day and night in young chickens. Also shown are the contributions of ingesta held (short-term stored) in the crop, gizzard, and proventriculus for nocturnal needs. *Data from Buyse et al. (1993).*

25.10.6.1.2 Hindgut

Cellulose fermentation to volatile fatty acids in the ceca has been demonstrated in a galliform bird, rock ptarmigan (*Lagopus muta*) (Gasaway, 1976a, 1976b, 1976c).

25.10.6.2 Starch

There is evidence for fermentation of starch in the crop of domestic poultry. During the nocturnal storage of feed in the crop, there are marked increases in lactate acid concentrations but little increase in volatile simple fatty acids, except valeric and caproic acids (turkey: Johannsen et al., 2005). About 37% of glucose converted to lactate in the chicken gastrointestinal tract (Riesenfeld et al., 1982).

25.11 Putative roles of other monosaccharides

25.11.1 Sorbitol

The presence of sorbitol in the feed did not influence body weight gain or feed to gain ratio of broiler chickens but did depress circulating concentrations of glucose and adiposity (Furuse et al., 1991). In contrast, sorbitol prevented the reduction in growth in broiler chickens challenge with *Escherichia coli* lipopolysaccharide (LPS) endotoxin (Takahashi et al., 2001).

25.11.2 Xylitol

Feeding broiler chickens with a diet containing xylitol prevented the growth retardation following *E. coli* LPS endotoxin challenge (Takahashi et al., 2002). Moreover, the antibody response to sheep erythrocytes was increased in chicks receiving xylitol in the feed compared to glucose (Takahashi et al., 2005).

25.12 Conclusions

25.12.1 Overview

Fig. 25.12 summarizes glucose flow in the metabolism in birds. Although carbohydrate metabolism in birds is similar in mammals, there are distinct differences:

1. There are marked differences between circulating concentrations of glucose between wild birds and mammals, with avian concentrations double those in mammals.
2. Birds are very resistant to diabetes, with neither pancreatectomy nor insulin administration evoking large changes in circulating concentrations of glucose. However, chickens received passive immunization with antisera to insulin exhibit diabetic-like shifts in metabolism, with circulating concentrations of glucose of 747 mg/dL reported 5 h after antisera administration (Dupont et al., 2008; Simon et al., 2012). Identical extremely high concentrations of glucose are observed

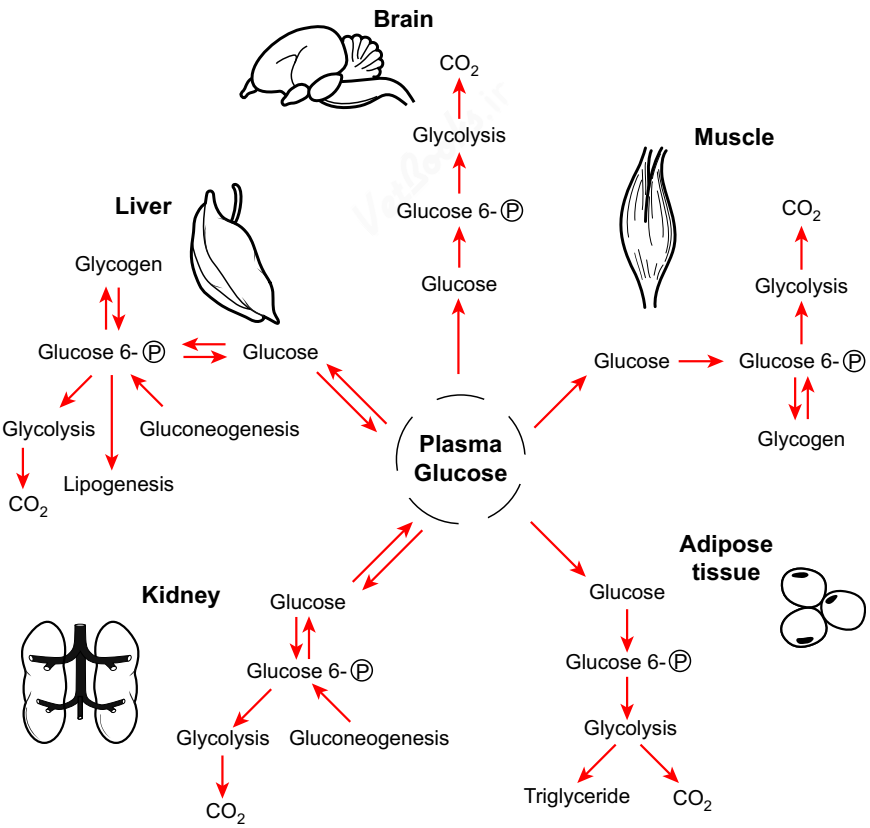

FIGURE 25.12 Overview schematic diagram summarizing the flow of glucose to and from plasma to major organs.

following feeding in hummingbirds without adverse effects (Beuchat and Chong, 1998).
3. The glucose transporter GLUT4 is missing in birds.
4. The principal site of lipogenesis is the liver (compared with adipose tissue in mammals).

25.12.2 Starvation and metabolism

It is assumed that there are four metabolic phases:

- An absorptive phase following feeding, until ingesta carbohydrates in the gastrointestinal tract are completely depleted
- A postabsorptive phase or short-term fasting
- Phase 2 starvation: protein sparing and utilization of fatty acids
- Phase 3 starvation: fatty acids depleted and a shift to amino acids.

The absorptive phase is when glucose and other simple carbohydrates are being absorbed. It encompasses both the passage of ingesta with digestion, and any storage of ingesta in the foregut (crop, gizzard, and proventriculus) prior to digestion/absorption (Fig. 25.11). In at least chickens and turkeys, there is nocturnal foregut storage of ingesta (laying hen: Scanes et al., 1987; young chicken: Buyse et al., 1993). This has been calculated to meet over 70% of energy requirements (Fig. 25.12).

It has been generally assumed that, during the postabsorptive phase, glycogen is employed as the energy source. In contrast, during phase 2 starvation, there is protein sparing and fatty acids from the breakdown of adipose triglyceride used. During phase 3 starvation, there is a shift to muscle and other protein catabolism using amino acids for gluconeogenesis as triglyceride stores are exhausted (Goodman et al., 1980; Bernard et al., 2002).

During the postabsorptive phase, together with phase 2 and 3 starvation, there is a progressive decrease utilization of glucose for glycolysis, such as by muscle (see Table 25.17) and hepatic lipogenesis (Fig. 25.5). The decrease precedes the end of absorptive phase as, for instance, the metabolic rate is decreased 26% in chickens during the nocturnal period (Fig. 25.11), when feeding has essentially stopped. Hepatic glycogenolysis only meets a small proportion of body glucose during the postabsorptive phase. Table 25.17 shows hepatic glycogen contents in meal-fed chickens; it was assumed that the hepatic glycogen contents approach maximal in chickens fed meals either daily or on alternate days. Hepatic glycogenolysis in the postabsorptive phase between meals was calculated as follows:

- 6 μmol/min/kg

This compares with

- 55 μmol/min/kg total glucose utilization (Belo et al., 1976) or 116 μmol/min/kg total glucose utilization (Table 25.18)
- Maximal rates of glucose from ingesta transiting out of the crop is 21 to 27 mmol of glucose/hour.

Thus, only about 10% of whole-body glucose utilization comes from hepatic glycogenolysis. This would indicate that hepatic gluconeogenesis is increased and hepatic glycolysis and lipogenesis are decreased during the postabsorptive phase and phase 2 starvation. Evidence for an immediate increase in gluconeogenesis and/or a decline in hepatic glycolysis comes from the observed reduction in the hepatic concentration of lactate with 2 h fasting (chicken: Yeh and Leveille, 1971b). The glycogen content in both the liver and muscle decline during fasting, being depressed by, respectively, 78 and 53% with six days of starvation in the chicken (see Table 25.13; Tinker et al., 1986).

The conceptual framework for phases 2 and 3 starvation is supported in king penguins (*Aptenodytes patagonicus),* where body fat reverses are almost exhausted with markedly decreased circulating concentrations of fatty acids (Bernard et al., 2002). Evidence for increased gluconeogenesis comes from the increase in circulating concentrations of uric acid (Bernard et al., 2002). Moreover, in chickens, starvation for six days is accompanied by increased net release of glucose into hepatic and renal veins (Tinker et al., 1986); indicating elevated gluconeogenesis (see Table 25.14). This is calculated as gluconeogenesis providing 70 μmol glucose/min/kg.

VLDLy yolk-targeted very low-density lipoproteins

26.1 Introduction

The presumed predominant function of adipose tissue is to maintain energy homeostasis. In times of feed excess, energy is stored as hydrophobic triglyerides or triacylglycerols (TAGs) in expansive lipid droplets within the adipocytes. TAGs are very well suited for this as they contain a large amount of energy per unit of weight. In times of feed deprivation, however, adipocyte TAGs are mobilized (lipolysis), and the generated fatty acids are subsequently oxidized by various tissues to yield chemical energy. Adipose tissue is the most variable carcass component and the amount that is deposited depends on genetic as well as on exogenous factors. However, it has been become clear that adipose issue is more than only a storage buffer for energy as it also functions as an important endo- and paracrine tissue involved in many bodily processes.

26.2 Development of adipose tissue

Adipose tissue development at the cellular level consists of an increase in cell number (hyperplasia) on the one hand and of an increase in cell volume (hypertrophy) on the other hand (e.g., Wang 2019). Both adipocyte number and volume increase with age and are positively correlated with fat pad weight and with body mass (Cartwright, 1991). Hence, both hyperplasia and hypertrophy of adipose cells contribute to the accumulation of fat in the chicken. However, the magnitude of the contribution of each of these two factors to the final size and weight of the distinct fat tissues is not equal.

At younger age, increases in weight of fat depots would be mainly attributable to an increase in fat cell number whereas at later ages, lipid accumulation in fat cells would be the major determinant. Literature data are not consistent about the age at which hypertrophy becomes the most important contributor to adipose tissue growth. It was first observed that in broiler chickens of a commercial strain, the number of abdominal adipocytes increased until about 12 to 14 weeks of age whereas adipocyte volume only increased slowly. After this age, the filling of the existing adipose cells was then the predominant factor responsible for the increase in weight of the abdominal fat pad (Hood, 1982; March et al., 1984; Cartwright, 1991). In contrast, more recent studies revealed that at about seven weeks of age, increases in fat deposition were primarily due to adipocyte hypertrophy in broiler chickens (Guo et al., 2011). Still, new adipocyte formation is possible even when a positive energy balance is maintained after hypertrophy, at least in mammals and probably also in birds; then hyperplasia resumes and a greater than normal number of adipose cells is developed. Moreover, adipocytes have also been reported to dedifferentiate: mature adipocytes loose then their lipid filled morphology and assume a fibroblast-like appearance and regain preadipocyte characteristics (Kokta et al., 2004).

The modern, growth-selected meat-type chickens are proportionally fatter compared to randombred, unselected, or even growth-selected chickens of some decades ago. Therefore, it is reasonable to assume that the age at which hypertrophy becomes the major determinant for body fat accumulation is shifted to younger age and even to a lower

Sturkie's Avian Physiology. https://doi.org/10.1016/B978-0-12-819770-7.00015-3

degree of maturity. Fast-growing chickens will probably also attain their genetically determined final number of fat cells earlier than slower-growing chickens. Furthermore, sex (Hood, 1982), nutritional status (March et al., 1984; Cartwright, 1991), and surely (in)direct divergent selection for fatness (Hood and Pym, 1982; Guo et al., 2011) all affect the age- or body weight−dependent developmental pattern of adipose cellularity. As a consequence of the increase in adipocyte number and size but with a different velocity, a bimodal frequency distribution (proportional number of cells per diameter class) is present in the abdominal fat pad of broilers by seven weeks of age. With increasing age up to 22 weeks, the number of fat cells in the population of "large" cells increased slowly and the mean diameter shifted to larger values. In contrast, the number of cells in the population of "small" cells increased more rapidly but the mean cell diameter remained unchanged (March et al., 1984). A same phenomenon was observed by Merkley and Cartwright (1989) for abdominal, thigh, back, and neck fat pads. It can be concluded that differences in fatness between populations, even when considered on a same body weight basis, are attributable to both the number and size/volume of adipocytes whereas reductions in body fat content by, e.g., dietary manipulations, are mainly caused by delipidation of adipocytes (hypotrophy).

26.3 Structure, cellularity

The first step in adipogenesis is the differentiation of chicken embryonic stem cells into white preadipocytes, a process that is induced by insulin and dexamethasone (Li et al., 2011). The resulting adipocyte precursors are present in the stromal-vascular fraction of adipose tissue. These preadipocytes proliferate and then undergo differentiation to multilocular immature white adipocytes. When becoming filled with lipids, unilocular mature adipocytes appear which are characterized by distinct morphological and metabolic features (Butterwith, 1988; Evans, 1977). A mature avian fat cell (average diameter of 150 μm) is characterized by the presence of a large lipid droplet which occupies more than 80% of the total cell volume. As a consequence, all other cell organelles are displaced to the periphery where the cytoplasm appears as a narrow rim. Another morphological feature of avian adipocytes is the presence of microfilaments at the interface between cytoplasm and lipid droplet and which may provide structural support to the adipocyte (Evans, 1977; Hood, 1982).

Most of the studies concerning adipogenesis were done using cell culture systems with cell lines from mammalian and to a much lesser extent from avian (chicken and duck) origin (Wang, 2019) and were mainly focused on its endocrine regulation. It was observed that the proliferation of chicken preadipocytes grown in culture was stimulated when insulin was added to the medium. When the medium was supplemented with 10% dialyzed chicken serum or when insulin was deleted from the medium, proliferation was retarded. Moreover, it was found that chicken preadipocyte proliferation in vitro was stimulated by insulin-like growth factor (IGF)-I and −II, fibroblast growth factor-1 and -2, epidermal growth factor, transforming growth factor-α and −β, and platelet-derived growth factor (Butterwith, 1997). On the other hand, most of these growth factors also inhibit preadipocyte differentiation. These data suggest that these growth factors may be important autocrine/paracrine/endocrine regulators of preadipocyte proliferation and differentiation although species-dependent differences have to be taken into account (Wang et al., 2012a,b,c; Wang, 2019). In addition, glucose (Qi et al., 2012), dexamethasone, and insulin (Ramsay and Rosebrough, 2003) also stimulate preadipocyte differentiation. Furthermore, in a recent review, Wang (2019) summarized that exogenous fatty acids (especially oleic acid for lipid droplet deposition) are critical factors in chicken and duck preadipocyte differentiation. At the molecular level, transcription factor such as peroxisome proliferator-activated receptor-γ (PPARγ), CCAAT/enhancer binding proteins (C/EBPs), and Sterol response element-binding proteins (SREBP) are important regulators of preadipocyte differentiation through modulation of expression and activity levels of relevant genes (summarized by Wang, 2019).

26.4 Body composition

The modern meat-type chickens contain between 150 and 220 g of lipids per kg body weight at commercial slaughter age. Adipose tissue is distributed over several fat depots of which the abdominal fat pad is the largest, followed by neck, thigh, back, and gizzard fat pads. These fat depots represent about 20% of the total body fat content. The skeleton and the skin contain, respectively, 15% and 19% of the total body lipid content whereas several smaller fat depots represent about 8% of the total body fat content. The rest of the carcass contains then about one third of the total body lipid content. As avian striated muscle is characterized by only small amounts of inter- and intramuscular fat (1.5%), the remaining lipids must be located in the intestines, lungs, kidneys, glands, etc (Nir et al., 1988).

The abdominal fat pad weight is highly positively correlated with total body fat content and as it is rather easy to dissect it quantitatively, abdominal fat pad weight has been used extensively as an excellent estimator of total body fat content (Sonaiya, 1985). Indeed, selection against fatness in meat-type chickens by means of selection against abdominal fat content has been proven to be very successful (Leclercq, 1984; Baéza and Le Bihan-Duval, 2013).

The growth of higher vertebrates is not simply an increase in weight but consists also of changes in body

conformation and composition due to the differential growth rate of the constituent parts and of their functional abilities (Pálsson, 1955). The relationship between the weight of a part (Y) of the body in relation to total body weight (X) can be described by the Huxley equation:

$$Y = aX^b$$

Or after logarithmic transformation:

$$\ln Y = \ln a + b \ln X$$

The regression coefficient b is also referred to as the allometric coefficient. When $b = 1$, the weight of the dependent variable Y increases proportionally with the weight of the independent variable X (isometric). When $b \neq 1$, the proportionality of absolute weights is not maintained, but the ratio between the relative growth rates of both Y and X remains constant during the growth trajectory.

As in mammals, the allometric coefficient for the growth of body fat in relation to body weight is also greater than unity in avian species. However, not all adipose tissues, including intramuscular and physiologically necessary fat, mature at the same rate as reflected in their different allometric coefficients. Merkley and Cartwright (1989) reported greater weight gains in abdominal and back fat than neck and sartorius fat depots between 8 and 16 weeks of age of commercial female broilers. Nir et al. (1988) observed that in broiler lines selected for or against abdominal fat content, the allometric coefficients (pooled for both lines) of several fat depots increased in the following order: sartorial ≈ neck fat (0.83) < gizzard fat (1.030) < abdominal fat (1.17) < mesenteric fat (2.51). The allometric coefficients were higher for the high fat line chickens (average 1.24) compared to the low fat line chickens (average 1.02). From our studies on commercial broilers reared under continuous illumination, the following allometric coefficients were calculated: sartorial fat (1.137) ≈ scapular fat (1.171) < heart fat (1.284) < abdominal fat (1.615) ≈ stomach fat (1.623). It can also be concluded that the abdominal fat pad is relatively more affected by (non)genetic factors than other fat depots and even the fat deposited in the rest of the carcass. However, the mechanisms involved in the differential allometric growth of adipose tissues and in the regulation of the discriminative effects of genetic and exogenous factors according to their location in the body, remain to be elucidated further.

26.5 Functions of adipose tissue

26.5.1 Energy reservoir

In chickens, lipids, and especially TAGs are stored in hepatocytes, growing oocytes (for laying hens), and adipocytes (Alvarenga et al., 2011). Lipid storage in the oocytes is associated with vitellogenesis (Walzem et al., 1994), while excessive fat accumulation in the liver causes hepatic steatosis and fatty liver haemorrhagic syndrome in laying hens (Alvarenga et al., 2011). Adipose tissue (fat) is a form of loose connective tissue composed of adipocytes, able to store large quantities of excess TAGs, which can be released for oxidation (primarily by skeletal muscle) for the synthesis of ATP. Although variable between fat depots, the hydrophobic lipid content of adipocytes can mount up to 90% of the fresh tissue weight (Evans, 1977; Nir et al., 1988). Taking into account the high-energy content of lipids (±39 kJ/g) compared to protein (±23 kJ/g) and carbohydrates (±18 kJ/g), adipose tissue is indeed an appropriate reservoir of energy. In addition, fat tissue (e.g., subcutaneous fat) can play a role in insulation, is important in thermoregulation, and can act as a protective shield for internal organs. More recent studies however have revealed that adipose tissue is also involved in numerous other processes and biological functions such as appetite regulation, reproduction, angiogenesis, coagulation, fibrinolysis, vascular tone control, and immunity.

26.5.2 Adipokines

Adipose tissue is not just equal to a sum of adipose cells. In adipose tissue, 90% of adipose mass may account for roughly 25% of total cell population, the other cells being fibroblasts, blood cells, endothelial cells, pericytes, mesenchymal cells, preadipocytes, nerve tissue and immune cells, all being targets for an extensive autocrine-paracrine cross-talk with each other and involved in adipogenesis (Frühbeck and Gómez-Ambrosi, 2005). Hence adipose tissue is a multifunctional organ rather than a passive organ for the storage of excess energy in the form of fat. Indeed, fat cells are able to secrete a large number of hormones, growth factors, cytokines, and matrix proteins collectively termed adipokines or adipocytokines. At the same time, adipocytes have receptors (see Section 26.5.3) for many of these adipokines as well as for several systemic hormonal factors (e.g., pituitary and pancreatic hormones).

26.5.2.1 Leptin

The existence of avian leptin was finally confirmed by Seroussi et al. (2016). The leptin gene sequence is extremely rich in guanine-cytosine (GC) content (about 70%); there is a low sequence of conservation for both the nucleic and amino acid sequences (≤30%), and low expression level (Friedman-Einat and Seroussi, 2019). Indeed, leptin expression in adipose tissue ranges from unexpressed in wild chicken red junglefowl to low levels of expression, which is unaffected by feed deprivation (Bornelöv et al., 2018), selection for fast or slow body growth (Resnyk et al., 2017), or lean or fat genotype (Resnyk et al.,

2015). Therefore, it is assumed that adipose tissue in chicken is not signaling the amount of fat stores via leptin. Moreover, it is hypothesized that leptin requires other proteins than the leptin receptor to interact with for its functioning, that may be another role than acting as an adipostat signaling molecule (Friedman-Einat and Seroussi, 2019). To better understand the function of leptin in birds, studies at the protein level are needed.

26.5.2.2 Adiponectin

Adiponectin as well as its receptors (ADIPOR1 and ADIPOR2) are expressed in many tissues, including adipose tissue in the chicken (Hendricks et al., 2009; Ghazanfari et al., 2011; Mellouk et al., 2018a), and the expression of the adiponectin system in adipose tissue (and muscle) depends on the gender and age of the animals (Zhang et al., 2017). Plasma adiponectin, especially the plasma heavy molecular weight adiponectin isoform, and adiponectin mRNA levels in adipose tissue are inversely related to abdominal fat pad weight in chicken (Hendricks et al., 2009; Tahmoorespur et al., 2010). In adipose tissue and muscle, adiponectin seems to limit lipid deposition (Mellouk et al., 2018a), and it is suggested that it may stimulate feed intake (Sintubin et al., 2014).

26.5.2.3 Visfatin

Visfatin is another adipokine hormone involved in chickens in the regulation of muscle growth, metabolism, feed intake, and reproductive functions (Mellouk et al., 2018a). Chicken visfatin is 92−94% homologous to mammalian visfatin and mainly expressed in skeletal muscle rather than in abdominal and subcutaneous fat in chicken; therefore it is rather a myokine than an adipokine (Krzysik-Walker et al., 2008; Li et al., 2012). Nevertheless, fat-line chickens selected for high abdominal fat have a higher expression of visfatin in adipose tissue compared to their lean line counterparts (Cogburn et al., 2011). In line with these results, Li et al. (2017) showed that visfatin is more expressed in adipose tissue of a fast growing broiler line compared to a slow growing one, suggesting a potential role as a marker of fat accumulation.

26.5.2.4 Chemerin

Chemerin is an adipose cytokine that is expressed in chicken and turkeys in the liver, heart, adipose tissue, muscles, and ovarian cells (Diot et al., 2015; Mellouk et al., 2018b). In broiler hens, plasma chemerin levels are negatively correlated with the fattening state, and feed restriction decreases the mRNA levels of chemerin in liver and adipose tissue (Mellouk et al., 2018b). Further research is needed to determine the role of chemerin in metabolism and reproduction (Mellouk et al., 2018a).

26.5.2.5 Other adipokines

Tumor necrosis factor-α (TNFα), interferon-ɣ and interleukin-6, three prominent adipokines in mammals that operate in concert with leptin to control appetite, insulin resistance, and inflammation, are expressed at low levels in chicken in visceral fat (Bornelöv et al., 2018). In addition, TNFα is not affected by feed deprivation (Bornelöv et al., 2018).

As several adipokines, known in mammals to signal on energy stores in adipose tissue, do not play such role in birds, it is suggested that adipose tissue in birds may have a different endocrine role (Friedmain-Einat and Seroussi, 2019). More research is needed to determine their potential role in the endocrine control of metabolic and reproductive functions in chickens (Mellouk et al., 2018a)

26.5.3 Receptors

The chicken leptin receptor (LEPR) gene was discovered in 2000 as the first LEPR in nonmammalian vertebrates. The sequences of bird LEPRs have a normal GC content (∼45%) and a higher similarity than leptin to the corresponding mammalian orthologs (∼60%) (Friedman- Einat and Seroussi, 2019). As the expression of LEPR in the pituitary is more than 100-fold higher than in any other tissues, it may suggest that the role of leptin is rather in reproduction and stress response than on appetite (Friedman-Einat and Seroussi, 2019). In mammals, there are six different isoforms of the LEPR, the short forms of LEPR controlling clearance, transport, and stabilization of circulating leptin. In birds, the predominant form is the long form of LEPR (Seroussi et al., 2016), suggestion rather a paracrine/autocrine role (Friedman-Einat and Seroussi, 2019). There is controversy as to the leptin receptor expression in chicken adipose tissue. According to Wang et al. (2007), no leptin receptor expression in chicken adipose tissue was found, whereas Hausman et al. (2012) reported leptin receptor expression in broiler adipose tissue.

As previously mentioned, the expression of the adiponectin receptors ADIPOR1 and ADIPOR2, in adipose tissue are age and gender dependent (Zhang et al., 2017). Fasting in chicken is known to decrease adiponectin receptor expression in adipose tissue (Ghazanfari et al., 2011). For more information on adiponectin and its receptors in other tissues, we refer to the review of Mellouk et al. (2018a).

So far, no visfatin receptor has been identified in chickens (Mellouk et al., 2018a).

Three chemerin receptors are found in chickens and turkeys, i.e., chemokine-like receptor 1, G protein-coupled receptor 1, and chemokine (C−C motif) receptor-like 2, and expressed in liver, heart, adipose tissue, and ovarian cells (Diot et al., 2015; Mellouk et al., 2018b).

26.6 Lipid metabolism

26.6.1 Lipogenesis and lipolysis

Fat tissue is central in energy substrate partitioning as it acts as a reservoir, as a result from lipogenesis on the one hand and lipolysis on the other hand. In energy balance equilibrium, there is still lipogenesis and lipolysis going on continuously making fat tissue a rather dynamic tissue with a turnover rate that is relatively high [e.g., half-life of depot lipids in rodents is about eight days (Frühbeck and Gómez-Ambrosi, 2005)]. In avian species, the liver is the main tissue of de novo fatty acid synthesis, followed by adipose tissue (Leveille et al., 1975; Hermier, 1997) (Figure 26.1). The synthesis of TAGs, lipogenesis, in adipocytes requires a steady supply of free fatty acids. This supply occurs through the delivery of TAGs by lipoproteins. In chickens, fatty acids for TAG synthesis and adipose tissue expansion are acquired from plasma VLDL and portomicrons (see Section 26.6.4). There are indications that the role of the liver in lipogenesis might be overestimated and that the contribution of other tissues (e.g., bones, skin, and intestines) must also be reconsidered (Griffin and Hermier, 1988; Nir and Lin, 1982).

Acetyl-CoA, formed from pyruvate by pyruvate dehydrogenase, plays a central role in the de novo fatty acid synthesis. Nonlipid precursors are carbohydrates from dietary origin or from glycogenolysis or gluconeogenesis from glucogenic or ketogenic amino acids and metabolites such as lactate and glycerol. Acetyl-CoA is then irreversibly converted to malonyl-CoA. This reaction is catalyzed by Acetyl-CoA carboxylase (ACC), and this step is considered to be rate-limiting for fatty acid synthesis. Elongation of malonyl-CoA is catalyzed by the multienzyme complex fatty acid synthase (FAS). The newly formed fatty acids are then esterified with glycerol 3-phosphate to form TAG.

Lipolysis in chicken adipose tissue is realized by a lipase (adipose triglyceride lipase or ATGL) exclusively found in subcutaneous and abdominal fat (Lee et al., 2009), and this lipase is highly present after hatching and before feed is given. This enzyme catalyzes the first rate-limiting step of lipolysis to release a fatty acid and diacylglycerol (DAG) (Zimmerman et al., 2004). Hormone-sensitive lipase and monoglyceride lipase [catalyze fatty acid removal from DAG and monoacylglycerol, respectively (Wang et al., 2012a,b,c)]. After lipolysis in adipose tissue, the mobilized nonesterified fatty acids (NEFAs) are transported by the blood (bound to albumen), and are then taken up by diverse cell types for subsequent β-oxidation to generate ATP (Figure 26.1). In most cases, uptake of NEFA is much faster than their oxidation except during heavy and/or prolonged exercise. The NEFA used in muscle for oxidation come for 80−90% from plasma NEFA (coming from the diet and fat tissue) while only ± 10% comes from muscle lipid itself. The major proteins involved in cellular NEFA transport in mammals are CD36/FAT (fatty acid translocase), fatty acid transport proteins, and fatty acid binding proteins, which have also been described in avian adipose tissues (Wang et al., 2012a,b,c; Qi et al., 2013).

26.6.2 Lipoprotein metabolism

26.6.2.1 Portomicrons

In the digestive tract, after hydrolysis, simple sugars (hexoses and pentoses) and amino acids are transported by active or diffusion processes from the lumen of the small intestine into the blood circulation. Dietary lipids are emulsified by bile salts, hydrolyzed by lipases and the resulting free fatty acids are absorbed by the mucosal cells. Within the enterocytes, most fatty acids are re-esterified with glycerol to form new TAG. These TAG are then

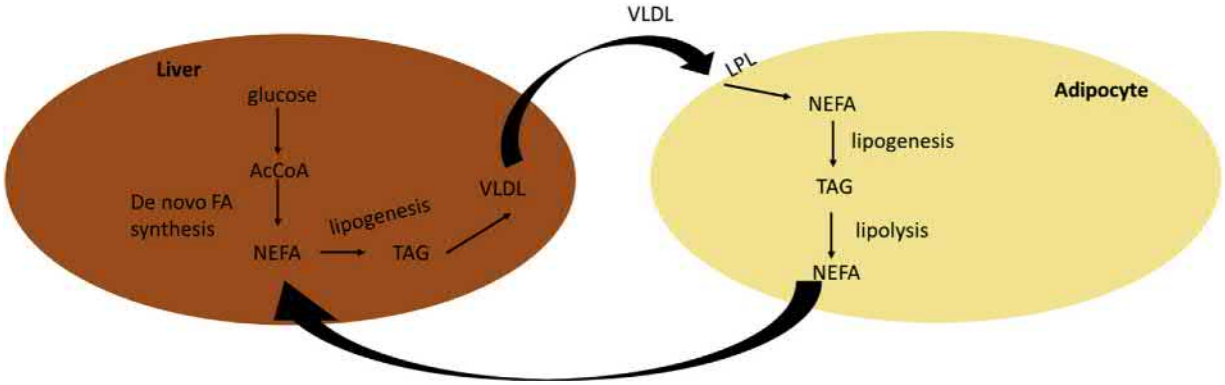

FIGURE 26.1 In the liver, de novo fatty acid (FA) synthesis starts from Acetyl-CoA to synthesize nonesterified fatty acids (NEFAs). They are esterified with glycerol during lipogenesis to form triacylglycerol (TAG). TAG are transported in very low-density lipoproteins (VLDL) that will go in the blood circulation. Activated lipoprotein lipase (LPL) at the luminal surface of the blood capillaries of adipose tissue, hydrolyzes TAG after which the NEFAs are taken up by the adipocyte. NEFAs are again incorporated in TAG during lipogenesis for storage. After lipolysis of TAG in adipose tissue, NEFA mobilization is followed up by its uptake by diverse cell types for β-oxidation.

associated with phospholipids, cholesterol (esters), and specific apolipoproteins (mainly apoB100) to form lipoproteins. In mammals, these lipoproteins are transported via the lymphatic system and are therefore termed chylomicrons. In birds however, the lymphatic system is poorly developed, and these newly formed lipoproteins are released into the portal vein. It was therefore proposed to term these lipoproteins (average diameter of 150 nm; a lipid composition of 90% TAG) from dietary origin as portomicrons (Bensadoun and Rothfeld, 1972). However, the re-esterification of the dietary free fatty acids is not complete and the NEFAs are also released to the portal system, bound to albumin, and carried to peripheral tissues. The portomicron concentration in the blood is mainly dependent on the nutritional status of the bird and of the dietary fat content (Griffin and Hermier, 1988). After the portomicrons are released into the portal vein, they are transported to the liver (Figure 26.2). However, they are not metabolized by the liver [probably because they are too large to penetrate the cellular sieve of the hepatic capillary bed (Hermier, 1997)] but pass through the liver to the extrahepatic tissues where they are partially hydrolyzed by lipoprotein lipase. The resulting portomicron-remnants are taken up by the liver, probably by an apoB100-dependent lipoprotein remnant receptor as apoE is lacking in chickens (Sato et al., 2009). The endocytosed TAG can then be used to resynthesize new TAG-rich lipoproteins (see Section 26.6.2.2).

26.6.2.2 Other lipoproteins

The TAG, from de novo fatty acid synthesis or from the portomicron-remnants, are then assembled with phospholipids, cholesterol (esters), and specific apolipoproteins (mainly apo- B100) to form very low-density lipoproteins (VLDLs). The newly synthetized VLDLs are then stored in vesicles and released into the bloodstream (Figure 26.2). VLDLs have a diameter of 30 to 90 nm and are denser than portomicrons, owing to a greater proportion of proteins. Plasma VLDL concentrations are highly positively correlated with total body fat content and can be used successfully as selection criterion for or against fat deposition in broiler lines (Whitehead, 1988; Guo et al., 2011).

As the hydrolysis of the TAG from the lipoproteins progresses (see Section 26.6.2.3), apolipoproteins are also lost and the lipoproteins decrease in size but increase in density. The partially metabolized VLDL can be recovered from chicken plasma as intermediate density lipoproteins (IDL or VLDL-remnants). The IDL is remodeled in cholesterol-rich low-density lipoproteins (LDLs). The remaining VLDL-remnants and portomicron-remnants are substrate for hepatic lipase. LDLs are taken up by receptor-mediated endocytosis in the liver and other tissues. Premature HDL probably originate in liver and intestines and receive cholesterol and phospholipids from VLDL and after interaction with LDL. As in mammals, HDLs are considered to be the main transporters of cholesterol and phospholipids in avian species. They are the smallest lipoproteins (approximately 10 nm), and comprised of 57% protein (Alvarenga et al., 2011).

As for mammals, many apolipoproteins have already been identified in birds, but there is a difference between mammals and birds in the content and function of several apoproteins (Sato et al., 2009; Alvarenga et al., 2011). VLDL mainly contains apo B-100, and HDL mainly apo A-I (Alvarenga et al., 2011). It is worthy to note that lipoproteins of birds have no apoB48 and apoE (Walzem, 1996). Moreover, chickens express an ApoVLDL-IV in liver and intestine, an apoprotein that has no mammalian counterpart, but regions of similarity with rabbit ApoC-IV (Nikolay et al., 2013). Still, many aspects regarding lipoprotein metabolism and apoproteins in birds remain unclear.

26.6.2.3 Lipoprotein lipase: a key enzyme

TAG-rich lipoproteins from the intestine (portomicrons) and from the liver (VLDL) secreted in the bloodstream are substrates for several lipase enzymes of which lipoprotein lipase (LPL) is by far the most important. LPL is synthesized by fat and by muscle cells and migrates to the luminal

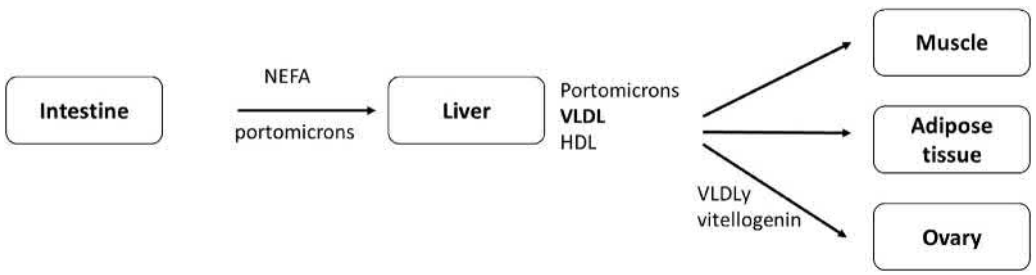

FIGURE 26.2 Nonesterified fatty acids (NEFAs) and portomicrons are released in the portal system and transported to the liver. The liver assembles very low-density lipoproteins (VLDL) and high-density lipoproteins (HDL) and releases these lipoproteins and the portomicrons into the systemic blood circulation. In laying hens, the liver synthesizes yolk-targeted VLDL (VLDLy) and vitellogenins to the ovary for yolk formation of the developing oocytes.

surface of the surrounding blood capillaries where it becomes functional after being anchored to the capillary wall by heparin and must be activated by specific apolipoproteins (apoC) on the surface coat of the lipoproteins (Butterwith, 1988; Griffin and Hermier, 1988). In mammals, apoCII is transferred from high-density lipoproteins (HDLs) to VLDL and then activates LPL. In birds, however, the equivalent activator of LPL needs to be identified (Walzem, 1996) but is present on VLDL from immature hens and portomicrons from (im)mature hens and HDL (Griffin et al., 1982). LPL hydrolyzes TAG from the core of the lipoprotein after which the liberated free fatty acids are taken up by the cells. In muscle cells, fatty acids are then oxidized to yield energy whereas in adipocytes, fatty acids are again incorporated in TAG for storage. As some of the fatty acids stored in the adipose tissue come from the diet, in nonruminant species, the fatty acid composition of the diet has a direct bearing on the fatty acid profile of lipids stored in adipose tissue. LPL activity is influenced by age and to some extent by nutritional state of the bird and is under the major stimulatory control of insulin (Griffin and Hermier, 1988).

26.6.2.4 Lipoproteins in laying hens

Plasma lipoprotein metabolism in laying hens differs substantially compared to immature hens or male chickens. As the ovary has very little capacity for lipid synthesis, all egg yolk lipids are synthesized mainly by the liver (stimulated by steroid hormones estrogens and progesterone) and transported to the ovary in special yolk-targeted TAG-rich VLDL (VLDLy) and in phospholipid-rich lipoproteins termed vitellogenins (Walzem, 1996, Figure 26.2). VLDL is the major lipoprotein responsible for the transport of lipids from the hen's liver to the oocytes and accounts for 60% of the dry yolk mass, while vitellogenin accounts for 24% (Speake et al., 1998). Compared to immature hen and normal VLDL, laying hen VLDLy are 50% smaller in size (30 nm), contain relatively more TAG and phospholipids but lower proportions of cholesterol(esters), have an unusual apoprotein composition (only apoB and apoVLDLII) and are sparely hydrolyzed by peripheral intravascular LPL (Griffin et al., 1982; Griffin and Hermier, 1988). Vitellogenin forms a very HDL and is carried to the developing oocyte, where it is broken down to form phosvitin and lipovitellin, which are proteins found in egg yolk (Hermier et al., 1989). The sequence leading to the incorporation of lipoproteins into the oocytes starts with passing through to the pores of the granulosa basal lamina (acts as a sieve to exclude larger lipoproteins) and ends with the uptake of the lipoproteins into the developing oocytes by receptor-mediated endocytosis (oocyte-specific apoB receptor in contrast to the somatic apoB receptor), followed by post-endocytotic modifications (Mann et al., 2008). Apparently, apoB acts as the ligand and not apoVLDLII (Walzem, 1996). This oocyte-specific VLDL/vitellogenin receptor or LR8 receptor was then identified as a member of the LDL receptor superfamily (Bujo et al., 1994). In this way, only lipids of hepatic origin (except for polyunsaturated fatty acids) can be deposited in the egg yolk. Besides its role in mediating the diameter of VLDLy, it has been shown that the estrogen-dependent apoVLDLII act as an inhibitor of LPL activity and in this way prevents TAG from VLDLy to be hydrolyzed by LPL (Schneider et al., 1990).

26.6.3 Endocrine control of lipid metabolism

26.6.3.1 Insulin

Adipose tissue metabolism in the chicken is regulated by energy status, and to a lesser extent by insulin. Indeed, insulin has minimal effect on glucose uptake in chicken adipose tissue, which is in contrast with mammals (Tokushima et al., 2005). In addition, insulin does not inhibit lipolysis in chicken adipose tissue, but avian pancreatic polypeptide, somatostatin (also from the pancreas), and gut glucagon-like immunoreactivity have antilipolytic effects (Dupont et al., 2012). Insulin also stimulates hepatic lipogenesis mainly by stimulating the synthesis of lipogenic enzymes, and stimulates VLDL synthesis, while thyroxine, glucagon, and epinephrine have opposite effects. In addition, insulin may increase the hydrolysis of VLDL at the adipocyte level by stimulation of LPL activity (Simon, 1989). Insulin signaling cascade in chicken adipose tissue, although similar in its downstream components (Dupont et al., 2012), is quantitatively markedly different from that operating in mammals. It has been shown that levels of insulin-receptor (IR) and IR-substrate protein (IRS-1) in chicken are lower compared to mammals (rat), contributing to a certain insulin insensitivity or refractoriness. Glucagon is the primary lipolytic hormone in birds (Scanes, 2009), in contrast to mammals where catecholamines play this role.

In addition to pancreatic hormones, two major axes can be identified: the somatotrophic axis and the thyrotrophic axis. These two axes seem to be very much interrelated in birds and especially in the determination of growth and body composition. In addition, signaling interactions between muscle and adipocytes affect relative fat and lean deposition, and the efficiency of energy utilization.

26.6.3.2 Somatotrophic hormones

The pituitary hormone, growth hormone (GH) is a potent stimulator of growth in mammals. In the young, its promotes overall body growth and in the adult, it stimulates the growth of the extremities. Therefore, it was obvious to suppose that this hormone had also a primary effect on growth in poultry (Scanes et al., 1984). The anabolic effects

of GH in relation to its pulsatile secretory pattern are discussed elsewhere (Buyse and Decuypere, 1999).

Based on these observations, it became clear that GH is not the only determinant of growth and body composition in poultry. Also, other endogenous regulatory substances such as thyroid hormones and IGF must be considered. There is ample evidence for a positive relationship between plasma GH and IGF-I levels which are known to stimulate several anabolic processes. Moreover, IGF-I stimulates adipogenesis while it inhibits the GH-induced lipolysis. Continuous administration of IGF-I reduces abdominal fat content (Buyse and Decuypere, 1999). Data on plasma IGF-II concentrations are scarce, and its biological significance is unclear, except that IGF-II administration to broilers augmented fat deposition (Buyse and Decuypere, 1999). This also holds for the role of IGF-binding proteins in avian growth, development, and body composition.

Various sources of GH have been reported to affect lipolytic activity of chicken adipose tissue explants in vitro. GH alone stimulates glycerol release but is also known to inhibit glucagon-induced lipolysis although by different cellular mechanisms (e.g., Campbell and Scanes, 1988). The physiological importance of the observed effects of GH on lipolysis in vitro can be linked with a homeostatic role of GH in nutrient metabolism.

26.6.3.3 Thyroid hormones

There is abundant evidence that thyroid hormones are not only important for embryogenesis but also for normal posthatch growth in birds. Thyroid hormones also affect body composition and fatness. A hyperthyroid status in chickens is associated with a decreased fat content while in hypothyroid chickens, fat deposition is greatly enhanced (Decuypere and Buyse, 1988). Triiodothyronine has been shown to increase basal lipolytic activity and glucagon-induced lipolysis in cultured broiler adipocytes (Harden and Oscar, 1993). In addition, triiodothyronine stimulates hepatic malic enzyme activity, and hence lipogenesis.

26.6.3.4 Other hormones

There is ample evidence that adrenal glucocorticoids (mainly corticosterone in birds) depress body weight and increase fat deposition in birds as glucocorticoids exert a direct catabolic action and stimulate lipogenic activity in avian hepatocytes.

The pituitary hormone prolactin is also known to be a lipogenic effector and a possible temporal synergistic effect between corticosterone and prolactin on fat deposition has been demonstrated in broilers and wild-type birds (Decuypere and Buyse, 1988). The role of sex steroids in the hormonal control of growth in birds is not well established except that estrogens stimulate lipogenesis whereas testosterone has the opposite effect.

Interestingly, local Agouti Signaling Peptide and Melanocortin receptor expression were found in chicken adipose tissue, as well as Pro-opiomelanocortin (Yabuuchi et al., 2010) and Neuropeptide Y (Hausman et al., 2012), indicating that hypothalamic regulatory pathways for feed intake regulation, also in birds, may also play a role, locally, in adipose tissue metabolism. In mammals, treatment with NPY leads to obesity (Kuo et al., 2007). Similarly, NPY promotes adipogenesis in chicken adipose cells in vitro, which may occur slightly differently than the mechanisms found in mammals (Zhang et al., 2015; Shipp et al., 2016).

26.6.4 Transcription factors

Several transcription factors orchestrate adipocyte development (Wang et al., 2012a,b,c). Below, we describe some studies that specifically focused on birds. For a general description of transcription factors, the reader can consult Wang et al. (2012a,b,c).

PPARγ is a central regulator of adipogenesis and is expressed in fat tissue and even more in liver but not in muscle. Its importance in birds is confirmed by a report that the suppression of PPARγ mRNA by small-interfering RNA inhibited differentiation and promoted proliferation of chicken preadipocytes (Wang et al., 2008). Moreover, a single intraperitoneal injection of troglitazone, a synthetic PPARγ ligand, to newly hatched broiler chicks resulted in a reduction of the absolute and proportional abdominal fat pad weight at 48 days of age (Sato et al., 2008). Levels of PPARγ are affected by nutrition and are also higher at the onset of egg laying in layers in liver and ovary, while it is then decreased in adipose tissue (Sato et al., 2004). Krüppel-like transcription factors (KLFs) and SREBP are other transcription factors that facilitate adipocyte maturation. In chicken preadipocytes, KLF7 was shown to enhance proliferation and suppress differentiation (Zhang et al., 2013). SREBP1 and SREBP2 chicken genes are nearly perfectly conserved compared to their mammalian homologs (Assaf et al., 2003). SREBP1 is linked to FAS protein content or activity in adipose tissue and/or liver. Therefore, SREBPs are key regulators in lipogenesis both in mammals and avian species, and their differential expression in different tissues is a major determinant for the site of fatty acid synthesis in the body (Gondret et al., 2001; Yen et al., 2005). GATA binding protein 2 is a preadipocyte-specific factor that promotes preadipocyte activity as its overexpression inhibited chicken preadipocyte differentiation (Zhang et al., 2012).

26.7 Factors affecting fat metabolism and deposition

26.7.1 Dietary factors

Nutrition has a major impact on animal performance and body composition. Nutrition is a very broad term and includes quantitative (e.g., ad libitum vs. feed restriction programs) and qualitative [e.g., metabolizable energy (ME), macro- and micronutrients, toxins] aspects as well as feeding programs (e.g., sequential feeding, "skip-a-day" feeding).

26.7.1.1 Quantitative strategies

It is common knowledge that feed deprivation/refeeding cycles are associated with fluctuations in intermediary metabolism induced by endocrine factors such as thyroid hormones, GHs, and pancreatic hormones (Buyse et al., 2001). During feed deprivation, hepatic lipogenic activity is drastically reduced, and the release of NEFA from adipose tissue is stimulated whereas the opposite is true after refeeding. The reader is referred to recent elegant studies for detailed information of feed deprivation/refeeding schedules on the dynamics of hepatic mRNA levels of lipogenic genes and transcription factors (e.g. Wang et al., 2012a,b,c; Richards et al., 2003; Saneyasu et al., 2013). In addition, such feeding schedules have also a marked effect on hypothalamic (an)orexigenic neuropeptides and lipogenic genes such as FAS and ACC (Higgins et al., 2010; Song et al., 2013). A discussion of the relevance of these findings in the framework of the control and regulation of voluntary feed intake of avian species is however beyond the scope of this chapter.

26.7.1.2 Qualitative strategies

With respect to diet quality, the impact of ME levels and macronutrient (lipids, carbohydrates, and proteins) ratio's on performance and body composition has been widely investigated mainly with broiler chickens. In general, diets with high ME levels (but normal protein levels) promote fat deposition in broiler chickens, but genetically determined body weight gain is rather maintained. This augmented fat deposition is the result of an excess in energy intake ("luxus" energy consumption) relative to the energy needed for maintenance and production. This "luxus" energy is then largely diverted to body fat deposition though also dissipated as heat to some extent (Buyse et al., 1992). Widening of the ME: protein ratio due to a reduction in protein level results in not only in a higher fat deposition but also in a reduced growth rate. The higher fat deposition is caused by an enhanced hepatic lipogenesis (demonstrated in vivo and in vitro) as reflected in the increased expression and activity of lipogenic enzymes such as malic enzyme, ACC, and FAS (e.g., Donaldson, 1985; Adams and Davis, 2001; Rosebrough et al., 2011). The reader is referred to the work of Rosebrough, Richards, and coworkers with respect to short-term adaptations in hepatic lipogenesis when switching from high to low-protein diets and vice versa (Rosebrough et al., 2011). The underlying causal mechanisms at the biochemical level of the hepatic intermediary metabolism are discussed in detail elsewhere (Swennen et al., 2007a).

Diets with a relative protein shortage also induce marked endocrine alterations (reviewed by Buyse et al., 2001; Rosebrough et al., 2011). Indeed, protein-restricted chickens are characterized by an enhanced pulsatile GH secretion, lower plasma IGF-I and thyroxine levels, but higher 3,3′,5-triiodothyronine concentrations. Feeding broilers with diets with a too high-protein content (above requirements) will result in lean broilers (decreased de novo lipogenesis and expression and activity of lipogenic enzymes). Several studies show that an increase in dietary protein decreases abdominal fat, enhances body weight gain and increases breast meat yield (Temim et al., 2000; Alleman et al., 2000; Jlali et al., 2012). Alternatively, growth could be stunted because of the energetic costs of nitrogen waste excretion. Interestingly, female broiler breeders that are fed according to their body weight curve have an increased proportional abdominal fat weight when fed a reduced protein, isoenergetic diet (Lesuisse et al., 2018). Furthermore, dietary amino acids can play a role on lipid metabolism and fat deposition (Wang et al., 2012a,b,c).

The effects of dietary fat level on body fat accretion and lipid metabolism are less unambiguous (Swennen et al., 2007a). The interpretation of studies focusing on dietary fat level is sometimes complicated by the fact that it is not clearly indicated whether the dietary fat is iso-energetically substituted with protein or carbohydrates or both. In general, an increase in dietary fat is associated with an increased abdominal fat and increasing the dietary fat level will reduce hepatic lipogenic activity probably due to the inhibitory effect of long chain acyl-CoA on ACC activity (Leveille et al., 1975). Besides the dietary fat level, the source of fat also affects body fat deposition. For example, a diet containing sunflower oil, rich in unsaturated fatty acids, decreases abdominal fat compared to animals fed tallow or lard (richer in saturated fatty acids) (Sanz, 1999), with reduced lipogenesis in the liver and an enhanced β-oxidation in the heart (Sanz et al., 2000). Both the degree of saturation and the chain length are associated with different metabolic functions of fatty acids in chickens and can regulate transcription factors (Wang et al., 2012a,b,c).

For example, conjugated linoleic acid, a mixture of mainly cis-9, trans-11 and trans-10, cis-12 fatty acid isomers reduced total body fat in chickens (Du and Ahn, 2002), increased saturated fatty acids and decreased monounsaturated fatty acids in abdominal fat of chickens (Chamruspollert and Sell, 1999), and decreased PPARɣ mRNA abundance in chicken abdominal fat (Ramiah et al., 2014).

Finally, high-carbohydrate levels in broiler diets will enhance glycolysis and hence provide plenty reducing equivalents for hepatic fatty acid production (Tanaka et al., 1983). However, these dietary fat and carbohydrate-induced changes in hepatic lipogenic activity do not necessarily result in changed body fat accretion (Swennen et al., 2007a).

26.7.2 Genetics

Intensive selection of broiler chickens for high-growth rate and feed efficiency has resulted in a tremendous progress in body weight gain and feed efficiency (direct selection response). However, several adverse indirect selection responses such as augmented fat deposition, leg problems, and metabolic diseases such as ascites and sudden death syndrome have also occurred. In addition, excessive fat is economically uninteresting, can hinder processing and is not desired by the consumers (Wang et al., 2012a,b,c). Havenstein and coworkers (Havenstein et al., 1994a,b) have elegantly assessed the differential impact of selection for growth rate and of diet regimen by comparing a typical 1957 broiler strain (Athens−Canadian randombred control strain) with a modern 1991 broiler strain (Arbor Acres) and both fed on a typical 1957 or a 1991 diet. A similar comparative study was done between the randombred 1957 strain and a commercial 2001 (Ross 308) strain and both fed on a typical 1957 or 2001 diet (Havenstein et al., 2003). These studies clearly revealed that genetics were the major contributing factor for the progress in performance and yield of carcass parts but also that carcass fat content increased due to selection for growth rate. In view of this augmented fat deposition and associated negative consequences, divergent experimental fat and lean broiler lines were established in several poultry research institutes. Different selection strategies were used: divergent selection for or against abdominal fat content (France, Israel); selection for high body weight gain (fat line) or feed efficiency (lean line) (The Netherlands, Denmark, USA); divergent selection for high (fat line) or low (lean line) plasma VLDL concentration (UK). Detailed information on heritability estimates, genotypic and phenotypic correlations as well as performance characteristics, energy, lipid, and protein metabolism, endocrine profiles and intermediary metabolism and breeder performance are provided elsewhere (Leclercq, 1988; Whitehead, 1988; Buyse et al., 1999; Baéza and Le Bihan-Duval, 2013). It is clear that either direct or indirect selection resulted in fat and lean broiler lines. With respect to lipid metabolism, all fat line broilers were characterized by a higher hepatic lipogenic capacity compared to their lean line counterparts, irrespective of the selection criteria. However, some indirect selection responses as well as the underlying endocrine mechanisms were different according to the selection strategy. Indeed, lean broilers produced by selection for feed efficiency had a higher basal as well as glucagon-stimulated lipolytic activity compared to their fat counterparts selected for high-body weight gain. Low feed efficiency-selected broilers had a higher expression of lipid synthesis genes and lower expression of triglyceride hydrolysis and cholesterol transport genes (Zhuo et al., 2015). In contrast, direct selection for high or low-abdominal fat content had apparently no effect on the lipolytic capacity of adipose tissue. Differentially expressed genes in these fat and lean chicken lines are rather associated with hemostasis, endocrine function, and metabolic syndrome in mammals (Resnyk et al., 2015). These differences in lipolytic activity, among other parameters, according to the selection strategy can be related to the differential selection-induced alterations in endocrine profile. Indeed, direct selection rather triggered the thyrotrophic axis and pancreatic hormones whereas indirect selection primarily affected the somatotrophic axis (Buyse et al., 1999). Another interesting genetic model to study the regulatory mechanisms of lipid metabolism is the selection model for high (R+: fat line) or low (R-lean line) residual feed intake of laying hens, which markedly differ in appetite, heat production including diet-induced thermogenesis, body conformation and composition, and hypothalamic transcriptome (Bordas et al., 1992; Swennen et al., 2007b; Jehl et al., 2019).

26.8 Summary and conclusions

Adipose tissue is the most variable carcass component and is traditionally being considered as a rather inert storage tissue for energy under the form of lipids. Most of the fat in chickens is located in adipose depots, which are all late maturing. At the cellular level, preadipocyte differentiation and proliferation is under the control of multiple hormones and transcription factors. The growth of fat tissue is initially due to hyperplasia followed by hypertrophy of the mature adipocytes, and the amount of fat deposited depends on genetic and nutritional factors.

Recent research has however revealed that adipose tissue must now be regarded as a dynamic tissue, which secretes a considerable number of adipokines and hence plays a role in a multitude of bodily processes.

Chapter 27

Protein metabolism

Colin G. Scanes[1,2] and Sami Dridi[2]

[1]Department of Biological Sciences, University of Wisconsin, Milwaukee, WI, United States; [2]Center of Excellence for Poultry Science, University of Arkansas, Fayetteville, AR, United States

27.1 Introduction

27.1.1 Protein metabolism: overview

Proteins play critical roles in birds, as in other animals, including in the following: as structural elements, such as keratin in skin and feathers; collagens in connective tissue; cellular proteins (e.g., those of the cell membrane, cytoskeleton, protein synthetic machinery); DNA-associated proteins (e.g., histones); as contractile elements in muscles (see Chapter 23); as oxygen-binding proteins, such as hemoglobin in erythrocytes and myoglobin in muscle; as receptors; as hormones, cytokines, and other messengers; as antibodies; as transporters; as nutrients for embryonic development in the yolk and egg albumin proteins (see Chapter 35); and as enzymes.

Proteins represent a major component of birds with proteins comprising the following:

- Adult verdin (*Auriparus aviceps*) with 24.5% protein
- Seven week-old domestic geese
  - Carcass 18.3% protein
  - Skin 10.6% protein
  - Feathers 54.5% protein.

Table 27.1 summarizes the composition of young chicken, adult mallards, and bald eagles as estimated by dissection and correction for muscles and associated connective tissue adhering to bone.

27.1.2 Physiological effects on protein concentrations

There are physiological effects on the protein and weights of the liver and intestine. For instance, the weights of both the liver and intestine are decreased in pied flycatchers and in willow warblers following long migrations (Schwilchet al., 2002). This is due to amino acids from protein degradation supplying some of the energy needs of flight during migration.

Diet can influence the protein metabolism of the liver and intestine. For instance, feeding a diet that is high in fiber for four weeks is followed by marked hypertrophy (2.3-fold increase) of the gizzard in Japanese quail (Starck and Rahmaan, 2003). This is explicable for the following reason: there is a marked increase in the amount of feed consumed due to its lower nutritional density compared to the high-fiber diet, and this increase results in mechanical stretching of the gizzard by the volume of ingesta.

27.1.3 Amino acids and proteins

Proteins are synthesized from amino acids. The essential or indispensable amino acids in avian diets for protein production and other functions are as follows:

- Arginine, histidine, isoleucine, lysine, methionine (with a higher requirement if cysteine is not present), threonine, tryptophan, and valine.

Other important amino acids (dispensable or in dispensable under specific conditions) for protein production are the following:

- Alanine, aspartate, asparagine, cysteine, glutamate, glutamine, glycine, leucine, proline, phenylalanine, serine, and tyrosine.

Lysine and methionine are the first limiting amino acids for growth (Bornstein and Lipstein, 1975). Amino acids are synthesized in birds, predominantly in the liver. There is interconversion of some amino acids. For instance, glutamate can be converted to glutamine, catalyzed by glutamine synthase, while glutamine can be converted to glutamate by glutaminase. There are also extranutritional effects of amino acids (see Section 27.11), with amino acids converted to glucose in gluconeogenesis (see Chapter 25), to purines, to uric acid, to neurotransmitters, and to pigment (see Section 27.10).

27.1.4 Posttranslational modification of amino acids

Posttranslational modification of amino acids in proteins occurs, including:

- Methylation: Histidine residues in myofibrillar proteins (e.g., actin and to a less extent myosin) are methylated (see Table 27.2).
- Phosphorylation: Phosphorylating serine, threonine, or tyrosine residues is essential for activating or deactivating enzymes.
- Glycosylation: This is to form glycoproteins.
- Acetylation with the addition of fatty acids: This results in the formation of lipoproteins.
- Sulfation.

27.2 Major proteins

27.2.1 Collagen

27.2.1.1 Overview

Collagen is major protein in the extracellular matrix of skin, tendons, and bone but is also present in other tissues including skeletal muscle. Collagen molecules are in the form of long fibrils. Collagen is said to the most abundant protein in the animal kingdom (Lodish et al., 2000). It is not readily possible to estimate the collagen content of whole bird with a degree of accuracy.

TABLE 27.2 Quantitative importance of feathers in birds.

Organ	Feathers	
	Weights as % body weight	Protein as % of body weight
Bald eagle[a]	16.6	14.1[f]
Chicken (one-week-old broiler type)[b]	1.4	1.2
Chicken (three-week-old broiler type)[c]	1.3	1.1
Chicken (10-week-old broiler type)[b]	5.5	4.7
Chicken (one-week-old layer type)[b]	2.7	2.3
Chicken (10-week-old layer type)[b]	8.3	7.1
Domestic geese (seven-week-old)[d]	8.3	4.5
Mallard ducks[e]	7.9	6.7

[f]*Assumes feathers are 85% protein (e.g., Peng et al., 2019).*

27.2.1.2 Quantitative aspects

The available evidence supports collagen being the predominant protein in birds. The collagen percentages have been reported for the following:

- Chicken bone is 15.7% (Kettawan et al., 2002; Cansu and Boran, 2015)
- Chicken muscle is 3.0% (Laurent et al., 1978b, 1978c); Reddy et al., 2016; Maharjan et al., 2019)

Based on these percentages and organ composition in Table 27.1, the amounts of collagen in these tissues are the following:

- Chicken bone has 5.9 g collagen per 100 g body weight
- Chicken muscle has 0.9 g collagen per 100 g body weight

What is missing is estimates of collagen in high collagen containing tissues such as the following:

- Keel cartilage—35% collagen (De Araújo Cordeiro et al., 2002)
- Feet—9.1% collagen (Liu et al., 2001)

Thus, collagen represents over 6.8 g per 100 g body weight in, at least, chickens. Is there another protein that can compete with collagen to be the most abundant in

birds? Keratin is a possible. Table 27.2 summarizes feather weights as a percentage of body weight together with protein/keratin per 100 g body weight. It is noted that estimates of the protein/keratin composition of feathers varies considerably, for instance—45% (Nitsan et al., 1981) and 85% (Peng et al., 2019). Irrespective of this, keratin is in contention for the most abundant protein in birds without including estimates of keratin in claws, beak, scales, and keratocytes.

27.2.1.3 Chemistry of collagen

The types of collagen include the following:

- Type I is found in skin, tendons, and bone consisting of three polypeptide chains (see Fig. 27.1):
  - Two α1
  - One α2
- Type II (found in cartilage) consisting of three α1 chains (see Fig. 27.1)
- Type III (found in blood vessels) consisting of three α1 chains (see Fig. 27.1).

There are three domains in procollagen, respectively, the globular N terminal, the triple helical region of collagen, and the globular C terminal (see Fig. 27.1). After trimerization including formation of disulfide bridges, procollagen is cleaved by N- and C-proteases to yield collagen. Collagen is composed of repeating amino acid residue triplets: GlycineXY with X and Y likely to be proline or possibly alanine or glycine (see Fig. 27.2). Multiple of proline residues are hydroxylated (Fig. 27.2).

27.2.1.4 Functions of collagen

Not only are collagen fibers essential to organ integrity and to movement, but also collagen has other roles. For instance, collagen fibers, in quasi-ordered parallel arrays in the dermis, are one basis for skin coloration (Prum and Torres, 2003).

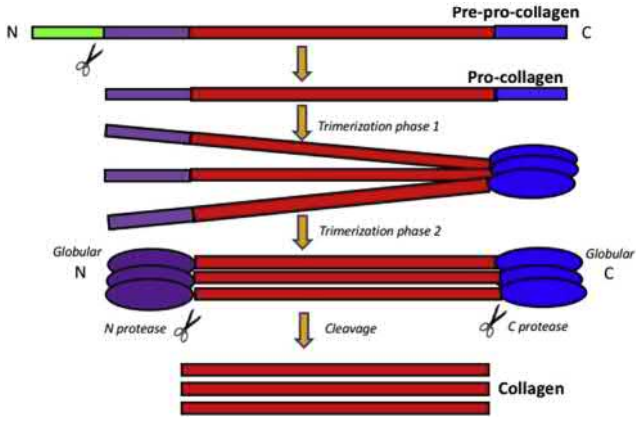

FIGURE 27.1 Processing of chicken pre-pro-collagen to procollagen and then to collagen. *Adapted from Canty and Kadler (2005).*

27.2.1.5 Control of collagen synthesis

Collagen synthesis is considered in section 26.6 below. Collagen synthesis is influenced by physiological and pathological factors. Expression of collagen in the small intestine is increased by lysolecithin (chickens: Brautigan et al., 2017). Synthesis of insoluble collagen in muscles increases during growth while that soluble collagen decreases (chicken: Maharjan et al., 2019). Collagen synthesis was reported to be increased with myopathy (chicken: Maharjan et al., 2019).

27.2.2 Keratins

27.2.2.1 Overview

Keratin is the major or sole protein in epidermal tissues and appendages including: scales, claws, and beaks (reviewed e.g., Greenwold et al., 2014). Keratins have multiple β-pleated sheets and are therefore resistant to proteolysis.

27.2.2.2 Keratin genes

Members of the α keratin gene family are found throughout the vertebrates while the β keratin gene family is only found in reptiles and birds (reviewed e.g., Greenwold et al., 2014). The keratin gene family in birds consists of the following:

1. α keratin gene family with 26 to 38 genes in birds consisting of the following:
   - Type 1 α keratin gene subfamily (10 to 18 genes in different avian species)
   - Type II α keratin gene subfamily (11 to 22 genes in different avian species)
2. The β keratin gene family (in the same 5′ to 3′ order on microchromosome 25) composed of the following gene subfamilies:
   - Feather β keratin gene subfamily (85% of β keratin genes)
   - Claw β keratin gene subfamily
   - Scale β keratin gene subfamily
   - Keratinocyte β keratin gene subfamily

(reviewed e.g., Greenwold and Sawyer, 2013; Greenwold et al., 2014). The number of β keratin genes varies from 6 in barn owls to 149 genes in zebra finch with 133 in chickens (Greenwold et al., 2014). There are also specialized forms of keratin, for instance, otokeratin (keratin, type II) in cochlea (Heller et al., 1998).

27.2.2.3 Keratin expression and protein

Both α- and β-keratin are expressed in skin appendages include beaks, feathers, scales, and claws (chicken embryo: Wu et al., 2015). However, the ratio between these varies markedly (chicken embryo: Wu et al., 2015).

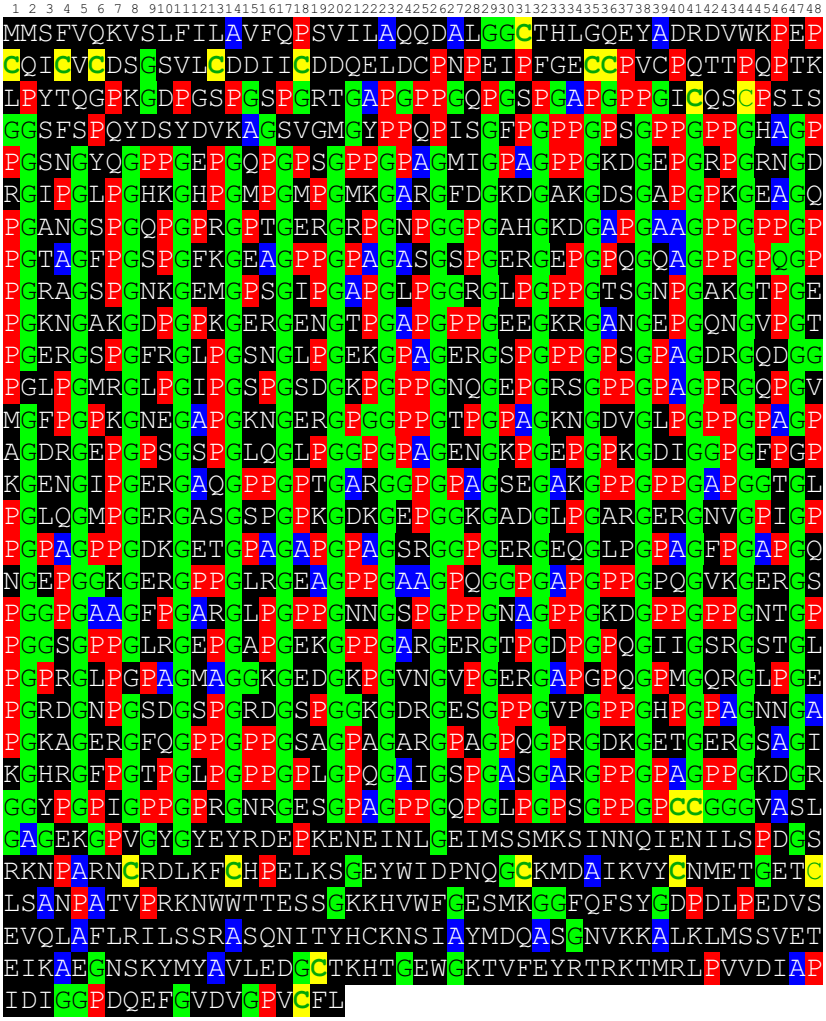

FIGURE 27.2 Structure of example of chicken pre-pro-collagen [collagen type III alpha 1 chain (COL3A1), based on cRNA (Genbank accession NM_205380 XM_421847)] showing sequences in N and C globular domains and a central collagen domain containing repeating GXY triplets.

Feathers are made of α and β-keratins. The proteins of the rachis of chicken feathers have a high content of the following four amino acids.

- Glycine: 13.5%
- Proline: 11.9%
- Cysteine: 9.7%
- Leucine: 8.3%

[In chickens, turkey, emu, white-crowned sparrow, and pygoscelid penguins (Harrap and Woods, 1967; Murphy et al., 1987; King and Murphy, 1987)]. There are differences in the relative concentrations of the amino acid residues in barbs versus rachis plus calamus (e.g., Harrap and Woods, 1967). Moreover, the proportion of barbs varies markedly between different avian species from 70% in white-crowned sparrows (*Zonotrichia leucophrys*) (King and Murphy, 1987) to 35% in penguins (calculated from Murphy et al., 1990).

A mutation in the krt75 gene (encoding an α collagen) results in defective rachis in frizzle feather chicken (Ng et al., 2012).

27.2.2.4 Feather dynamics

There are high rates of keratin synthesis. Keratin synthesis can be estimated as follows:

- Broiler chickens 1.67 g/d
- Layer type chickens 0.85 g/d
- White-crowned sparrows (*Zonotrichia leucophrys*) 75 mg/d

[Values for chickens calculated from data in the sources: chicken (7 days to 10 weeks old) Plavnik and Hurwitz (1983) using feathers as 85% protein (Peng et al., 2019)] (Murphy and Taruscio, 1995).

This replacement of feathers after losses (accidental or during molting) is critically important for flight. Rapidity of feather growth has been linked to feather abnormalities (Vágási et al., 2012). Feathers scale with the body weight of birds by 0.32 power, while feather growth rate increases across species by much less, 0.17 power of body weight (Rohwer et al., 2009).

27.2.2.5 Control of keratin synthesis

The relative weights of feathers and consequently keratin is influenced by physiological factors. There is an increase in the relative weight of feathers during growth in chickens (Plavnik and Hurwitz, 1983) (Table 27.2). Nutritional restriction decreased the overall weights of feathers from 8.45% of body weight on ad libitum feeding compared 7.74% receiving 50% feeding (chickens: Plavnik and Hurwitz, 1983).

There are shifts in feather growth in wild birds. Feather growth is followed increased in a simulated molt when feathers were removed in starlings by plucking (Romeroa et al., 2003). Hormones influence feather growth with, for instance, corticosterone depressing feather growth based on studies with implanted white-crowned sparrows (Romeroa et al., 2003).

27.3 Muscle proteins

27.3.1 Overview

Over 20% of the wet weight of skeletal muscles is protein (equivalent to 7.6% of body weight). The major proteins are myosin and actin of the thin and thick filaments, together with sarcoplasmic proteins.

Thin filaments:

- Actin
- Tropomyosin
- Troponin

Thick filaments:

- Myosin.

The physiology of myosin, actin, and other muscle proteins is considered in chapter 23. In addition to its role in muscle contract, actin has other roles. For instance, there are intracellular actin fibers (e.g., Perrin et al., 2010). Profilins (PFN) are actin binding proteins. PFN2a is expressed ubiquitously in avian tissues and plays a role in cell adhesion, spreading, and movement (chicken: Murk et al., 2009). Moreover, actin fibers are found in the avian cochlea (Tilney et al., 1992).

27.3.2 Actin and myosin genes

The distribution of actin in the body of birds can be estimated by use of 3-methyl histidine as a surrogate. About 11.8% of actin is methylated (chicken: calculated from Johnson et al., 1967) (Table 27.3). Methylated histidine residues are also found in myosin (chicken: calculated from Johnson et al., 1967) (see Table 27.3).

TABLE 27.3 Importance of various Organs to total 3-Methyl-Histidine in young chickens.

Organ	3-Methyl-Histidine as % of total body	
	Chicken	White-crowned sparrow
Skeletal muscle (and associated connective tissue)	84.0	84.1
Bone[a]	1.6	NA
Gastrointestinal tract	9.8	10.2
Skin and feathers	1.7	NA
Liver	1.0	1.0
Heart	1.4	1.3
Kidneys	0.0	0.3
Lung	0.2	0.2
Brain	0.1	NA

NA not available.
[a]*Corrected for muscle and other soft tissues adhering to bones.*
Calculated from data in Jones et al. (1986); Taruscio and Murphy (1995).

Multiple forms of myosin are expressed with differences between fiber types and during embryonic development and posthatch growth (Rosser et al., 1996, 1998). For instance, in adult chickens, pectoralis expresses fast myosin heavy chain (MyHC1), with slow myosin heavy chain (MyHC2) expressed in tonic muscles (Crew et al., 2010).

Actin genes include the following:

- α cardiac-actin (expressed in cardiac muscle)
- α skeletal-actin (expressed in skeletal muscle)
- α smooth-actin (expressed in smooth muscle)
- β cyto-actin (expressed in ubiquitously)
- γ smooth-actin (expressed in cardiac muscle)
- γ cyto-actin (expressed in ubiquitously)

(Chang et al., 1984; Perrin et al., 2010).

27.4 Other proteins

27.4.1 Blood proteins

Using data across avian species (see chapter on Blood 17), the major blood proteins are the following:

- Hemoglobin represents 1.15% of body weight
- Serum albumen represents 0.71% of body weight

27.4.2 Mucins

Another example of a family of genes/proteins are the mucin proteins. Mucin is produced by goblet cells in the gastrointestinal tract. It is a gel consisting of heavily glycolylated proteins in solution. There are multiple Muc genes in birds:

- Genes for transmembrane mucins—Muc4, Muc13, and Muc16 transmembrane mucins
- Genes for gel forming mucins—Muc2, Muc5ac, Muc5b, and Muc6

(Chicken: Lang et al., 2006). Mucin glycoproteins can be neutral or acidic sialiated or acidic sulfated (chicken: Biasato et al., 2019). Greater mucin staining is reported in both the villi and crypts in the ileum than duodenum with the jejunum being intermediate (Biasato et al., 2019).

The mucin layer is important to both gastrointestinal integrity and functioning. When young chickens receive increased dietary lysine but decreased protein, jejunal expression of MUC2 is increased (Lee et al., 2020). Moreover, jejunal expression of mucin genes is influenced by *Clostridium perfringens* with the following:

- MUC2 ↓
- MUC5AC ↑
- MUC13 ↓

(Forder et al., 2012).

27.4.3 Egg protein

Egg yolk proteins as 0.22% of body weight per day while egg white proteins as 0.23% of body weight per day (this discussed in more detail in chapter 35).

27.5 Digestion of proteins

27.5.1 Overview

Proteins, in the diet, provide animals with amino acids (both indispensable and dispensable) that a vital to maintenance, growth, feathers, and reproduction of all animals. The impact of feeding an extremely low-protein diet is shown in Table 27.4. Chicks on a very low-protein diet lost weight compared to those on a 10% protein feed demonstrating the need for protein even for maintenance. A 10% protein diet allows some growth, but this was accelerated with a 20% protein diet.

Proteins are digested in the gastrointestinal tract to amino acids and dipeptides together with some tripeptides.

TABLE 27.4 Effect of dietary protein between 7 and 17 days old in Leghorn chicks.

	Dietary protein as %			
	0	10	20	SEM
Body weight				
Change g	−16.3[a]	57.5[b]	90.8[c]	1.4
Liver				
Weight g	1.96[a]	3.61[b]	4.27[c]	0.15
DNA mg	5.3[a]	8.3[b]	8.6[b]	0.8
Protein mg	289[a]	577[b]	785[c]	33
Protein fractional synthesis rate %/d	46.8[a]	66.0[b]	91.4[c]	3.9

[a,b,c]*Different superscript letter indicates difference $P < .05$.*
Data from Kita et al. (1996).

27.5.2 Protein digestion in the gizzard and proventriculus

27.5.2.1 Overview

The digestion of proteins is initiated in the gizzard and proventriculus in birds by the following methods:

- Mechanical grinding by the gizzard
- Chemical denaturation by the low pH
- Enzymatic proteolysis by pepsin

27.5.2.2 Pepsinogen

There are multiples pepsinogen genes including the following:

- Pepsinogen A
- Progastricsin (pepsinogen C or pepsinogen II) encoded by PGC gene [e.g., chicken (Genbank accession number: NM_204877)]
- Embryonic pepsinogen [e.g., chicken Hayashi et al. (1988a); accession number: NM_204877; golden eagle (*Aquila chrysaetos*) XM_030000984; emperor penguin (*Aptenodytes forsteri*)—XM_009290607; American crow (*Corvus brachyrhynchos*)—XM_008638001].

Gastric aspartic proteinases consist of pepsin A and gastricsin (pepsinogen C or pepsinogen II) in posthatching birds. These are expressed and secreted from the mucosal cells in the chicken proventriculus (Sakamoto et al., 1998).

They are synthesized as pepsinogens with the zymogen has been activated by acid conditions (chicken: Bohak, 1969).

The embryo specific or embryonic pepsinogen exhibits homology to calf prochymosin or rennin (Foltmann, 1992). Expression of embryonic pepsinogen by endodermal tissue is a marker of differentiation of proventriculus epithelium (Hayashi et al., 1988b).

Avian pepsinogen is proteolytically activated to pepsin at low pH (Keilova et al., 1977) (Table 27.4).

27.5.3 Protein digestion in the small intestine

27.5.3.1 Overview

The predominant site of protein digestion is the small intestine (Pisano et al., 1959; Hurwitz et al., 1972) (Table 27.5). The digested protein (amino acids and dipeptides together with some tripeptides) is absorbed in the small intestine (Table 27.5). There is high digestibility/absorption of amino-acids as reflected by ileal digestibility (Table 27.6).

Proteins undergo enzymatic digestion in the small intestine by the serine proteases, trypsin, and chymotrypsin. These are produced by the pancreas as inactive zymogens (respectively, trypsinogen and chymotrypsinogen) and transported to the small intestine in the pancreatic secretions. In the small intestine, both trypsinogen and chymotrypsinogen are activated by proteolytic cleavage:

- Trypsinogen → trypsin
- Chymotrypsinogen → chymotrypsin.

In addition, there are peptidases that hydrolyze peptides generated by trypsin and chymotrypsin.

27.5.3.2 Trypsin

Trypsinogen gene family consists of the following:

- Trypsinogen I (cationic trypsin isoenzymes) subfamily six genes
- Trypsinogen II (anionic trypsin isoenzymes.) subfamily three genes

TABLE 27.5 Protein digestion and absorption in the regions of the chicken small intestine.

Protein	Digestion (%)	Protein absorption (%)
By end of duodenum	60	7
By end of jejunum	85	70
By end of ileum	93	83

Based on Hurwitz et al. (1972).

Amino acid	Mean % ileal digestibility + SEM
Cysteine	76.2 ± 1.8
Threonine	79.7 ± 1.7
Lysine	89.8 ± 0.6
Methionione	94.4 ± 0.5
Arginine	97.5 ± 4.2

Source: Fagundes et al. (2020).

(Chicken Wang et al., 1995). In addition, the structure of ostrich trypsinogen II is deduced from mRNA (Genbank accession: AY601749) (Szenthe et al., 2005).

Trypsinogen genes are expressed in the pancreas along with the liver, spleen, and thymus (Wang et al., 1995). Trypsinogen is proteolytically cleaved either by enterokinase or autocatalytically (ostrich: Szenthe et al., 2005). This proteolytic cleavage results in the formation of an active protease, trypsin. Concentrations of trypsin in the pancreas show little change during embryonic development and posthatching development [pigeon (*Columba livia*): Xie et al., 2020].

Trypsin-like activity is reported in amniotic fluid together with some in the allantoic fluid and egg albumen (chicken: Da Silva et al., 2017). There are increases in this trypsin-like activity during embryonic development (chicken: Da Silva et al., 2017).

27.5.3.3 Chymotrypsinogen

5wAvian chymotrypsinogen has been isolated from pancreas (ostrich: van der Westhuizen et al., 1989; Japanese quail: Hou et al., 1990). The structures of chymotrypsinogen have been deduced in multiple avian species from mRNA including the following: chicken (*Gallus gallus*) chymotrypsinogen A-like (Genbank XM_025154258) and B-like (NM_001277636), mallard (*Anas platyrhynchos*) (XM_027466372), tufted duck (*Aythya fuligula*) (XM_032195902), rock pigeon (*C. livia*) (XM_005504777), Anna's hummingbird (*Calypte anna*) (XM_030457979.1), peregrine falcon (*Falco peregrinus*) (XM_005233498), bald eagle (*Haliaeetus leucocephalus*) (XM_010584290), barn owl (*Tyto alba*) (XM_033001843), New Caledonian crow (*Corvus moneduloides*) (XM_032121949), zebra finch (*Taeniopygia guttata*) (XM_012570273), lance-tailed manakin (*Chiroxiphia lanceolate*) (XM_032700994), Swainson's thrush (*Catharus ustulatus*) (XM_033069904), and great tit (*Parus major*) (XM_015640042).

Chymotrypsinogen is activated to chymotrypsin in the small intestine by proteolytic cleavage, for instance by trypsin. The structure is maintained by disulfide bridges.

27.5.3.4 Aminopeptidases

27.5.3.4.1 Overview

Aminopeptidases are membrane-bound proteins in enterocytes. Most of the enzyme protein is extracellular, with a single transmembrane domain and a small intracellular domain. An avian aminopeptidase has been partially characterized (chicken: Gal-Garber and Uni, 2000), but its complete structure deduced from mRNA [e.g., chicken (*Gallus gallus*) (Y17105.1), ostrich (*Struthio camelus*) (AJ577158), turkeys (*Meleagris gallopavo*) (AJ296745.1), and zebra finch (*Taeniopygia guttata*) (XM_002194583.5)].

27.5.3.4.2 Expression of aminopeptidases

Not only is there high expression of aminopeptidase in the duodenum, jejunum, and ileum but also in the ceca (chicken: Gal-Garber and Uni, 2000; Miska et al., 2015). Aminopeptidase is also expressed in the yolk sac [e.g., rock dove (*C. livia*) (Shbailat and Aslan, 2018) and chicken: Miska et al., 2015].

Expression of aminopeptidase is influenced by physiological status. There is increased expression of aminopeptidase in the brush border of the ileum of high growth rate chickens (Miska et al., 2019). Expression of aminopeptidase is markedly depressed in young chickens challenged with *Eimeria maxima* infection (Miska and Fetterer, 2018). Administration of threonine *in ovo* was accompanied by increased ileal expression of aminopeptidase at hatching (chicken: Moreira Filho et al., 2019).

27.5.4 Amino acid absorption in the small intestine

27.5.4.1 Overview

Amino acids are absorbed in the small intestine (chicken jejunum and ileum: Tasaki and Takahashi, 1966) (discussed in detail in chapter 21). There is greater absorption of methionine in the ileum than in other regions of the small intestine (Hurwitz et al., 1972) (also see Fig. 27.3). Methionine is absorbed at the highest rate, followed by isoleucine, valine, and leucine, and glutamate is absorbed at the lowest rate, followed by aspartate, glycine, and arginine (Tasaki and Takahashi, 1966; Riley et al., 1986). There are series of amino acid transporters (10 in chickens) expressed in the enterocytes of the small intestine, with predominantly increases progressing down the small intestine from the duodenum, jejunum, and ileum (chickens: Gilbert et al., 2007). Moreover, there are increases in the expression of many amino acid transporters during the period of growth and development posthatching (chickens: Gilbert et al., 2007).

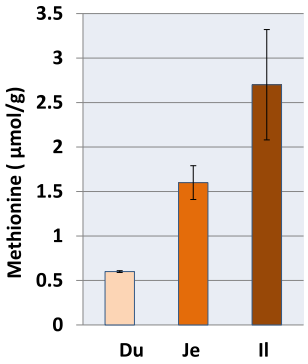

FIGURE 27.3 Absorption of methionine by different regions of the chicken intestine *in vitro*. *Du*, duodenum; *Je*, jejunum; *Il*, ileum; vertical lines, standard error of the mean. *Data from Knight and Dibner (1984).*

There is moderately high expression of the H^+-dependent peptide transporter-1 (PepT1) throughout the small intestine, with marked increases in the posthatch period (Gilbert et al., 2007). PepT1 functions to transport both dipeptides and tripeptides into the enterocyte.

27.5.4.2 Turnover times for small intestine mucosal cells

Not only are proteins in the ingesta digested with the resultant amino acids and small peptides absorbed but also mucosal intestinal cells are sloughed off and then digested. The turnover times for mucosal cells in the small intestine are estimated as the following in the chicken (calculated from data in Imondi and Bird, 1966):

- Duodenum: 111 h
- Jejunum: 55 h
- Ileum: 89 h.

27.5.5 Colon and protein digestion

There is a lack of definitive information on the roles of the colon in protein and amino acid digestion and absorption. Most of the proteins in the ingesta are digested by the time the ingesta reaches the colon (Table 20.5). There are populations of proteolytic bacteria in the colon of birds (chicken: King et al., 2009). The impact of these proteolytic bacteria is not known. Interestingly, there is absorption of the methionine analog, 2-hydroxy-4-(methylthio) butanoic acid (Alimet), in the colon as well as the small intestine (chicken: Knight and Dibner, 1984; Dibner et al., 1988).

27.5.6 Ceca and protein digestion

The ceca appear to play some role in nitrogen metabolism. Ileal protein digestibility is depressed in cecectomized

chickens (Choct et al., 1992). Moreover, there are increases in endogenous losses of nitrogen and both indispensable and dispensable amino acids in feed deprived cecectomized ducks (Ragland et al., 1999) and endogenous losses of nitrogen in chickens following cecectomy either on a low protein or on low protein plus urea diet (Kang et al., 1999). There are also decreases in uric acid excretion in cecectomized birds (duck: Ragland et al., 1999; chickens: Son et al., 1997; Kang et al., 1999). Uric acid, arginine, glycine, glutamic acid, and, to a less extent, alanine are metabolized by cecal microorganisms releasing ammonia (Karasawa et al., 1988; Karasawa, 1989). Similarly, bacterial degradation of uric acid is reported in the ceca, e.g., Gambel's quail (*Callipepla gambelii*) (Campbell and Braun, 1986).

27.6 Protein synthesis

27.6.1 Whole-body synthesis and degradation

Whole-body net protein synthesis can be estimated by nitrogen balance. For instance, Kino and Okumura (1987) estimated nitrogen balance in 14–21 day-old chickens as 0.29 g/day. Alternatively, whole-body protein net synthesis (accretion) or net degradation can be estimated by difference between determined body protein at multiple ages.

Whole-body protein synthesis can be determined by infusing a radioactive form (or equivalent stable isotopes) of a nonmetabolized amino acid such as phenylalanine or tyrosine or proline (for collagen synthesis). Combining net protein synthesis and whole-body protein synthesis allows indirect calculation of rates of protein degradation (Table 27.6).

$$\text{Whole} - \text{body protein net synthesis (accretion)} = \text{Whole} - \text{body protein synthesis} - \text{Whole} - \text{body protein degradation}$$

Where whole-body protein losses include in proteins in eggs or molted feathers. If negative, whole-body protein net synthesis is whole-body protein net degradation.

27.6.2 Fractional protein synthesis in different organs

Proteins are synthesized from the intracellular amino acid pool in the organs. There is interchange between amino acids in this pool and the plasma but markedly lower concentrations of, for instance, in the intracellular pool (Table 27.7).

The highest fractional rate of protein synthesis reported in young chickens is 172%/d for the pancreas (Muramatsu et al., 1987a). High rates are also reported in the bursa Fabricius (67%/d), spleen (46%/d), ceca (63%/d), and small intestine (see Table 27.8) (Muramatsu et al., 1987a).

TABLE 27.7 Effect of reduced dietary lysine on plasma and muscle concentrations of lysine and on muscle degradation as reflected by 3-Methyl Histidine.

	Free amino acid concentrations	
	Diet 1 (control diet meeting lysine requirement)	Diet 2 (low lysine 90% of requirement
Lysine		
Plasma (nmol/mL)	187	103[a]
Intramuscular (nmol/g)	69	42[a]
3-Methyl histidine		
Plasma (nmol/mL)	22.6	26.1[a]
Intramuscular (nmol/g)	24.2	35.5[a]

[a]*Difference with replete diet $P < .05$.*
Based on Watanabe et al. (2020).

TABLE 27.8 Comparison of fractional synthesis rates in various organs in young chicks (Muramatsu et al., 1987a; Nieto et al., 1994) with those in adult female chickens (Yuan et al., 2016; Miao et al., 2017; Vignale et al., 2015).

	Fractional synthesis rates %/d	
Organ	Young chickens	Adult female chickens
Liver	95.1	11.3
Jejunum	65.7	6.9
Skin	43.4	–
Skeletal muscle (breast/*pectoralis*)	22.2	4.7

Fractional rates of rates of protein synthesis are lower in the brain (32% of liver) (Sayegh and Lajtha, 1989) and skeletal muscle (see Table 27.8).

Protein synthesis in the liver is high (see Table 27.8), representing 11% of all protein synthesis in the bird. Similarly, gastrointestinal protein synthesis is disproportionately high compared to in other tissue. For instance, in the young chick, 18.9% of protein synthesis occurs in the small intestine plus the pancreas and ceca (calculated from Muramatsu et al., 1987a). This is in contrast to the gastrointestinal organs, which represent 5.2% of the protein in the bird or 5.9% of the body weight (Table 27.9).

TABLE 27.9 Comparison of collagen and noncollagen components in chicken muscle.

	Noncollagen	Collagen
Protein content % wet wt.

[b]*USDA Nutrient database.*
[c]*Determined in young chickens by Maharjan et al. (2019).*

27.6.3 Fractional protein synthesis in muscle

There are very similar rates of protein synthesis for sarcoplasmic and myofibrillar proteins in skeletal, heart, and smooth muscle:

- *Anterior latissimus dorsi*: 16% per day
- *Posterior latissimus dorsi*: 7% per day
- Heart: 14% per day
- Gizzard: 11% per day

(Chicken: Laurent et al., 1978a). Connective tissue makes up a significant proportion of muscle. Fractional synthesis rates for collagen are considerably lower than for myofibrillar and sarcoplasmic proteins (also see Table 27.9) (adults: Laurent et al., 1978b, 1978c; young chickens: Maharjan et al., 2020) (Table 27.11).

27.6.4 Ribosomal protein S6 and ribosomal protein S6 kinase (S6K1) and protein synthesis

Ribosomal protein S6 (RPS6) and RPS6 kinase (S6K1) play important roles in the initiation of protein synthesis (see Fig. 27.4). Protein kinase B/mechanistic (or mammalian) target of rapamycin (mTOR) pathway control activation and expression of S6K1 (see section 27.8.2 and Fig. 27.4).

Nutritional and endocrine states influence S6K1 activity (see Fig. 27.4). Phosphorylation of S6K1 in skeletal muscle is depressed with fasting in chickens (Saneyasu et al., 2019). In a reciprocal manner, arginine supplementation is followed by increases in S6K1 activity in the liver (Yuan et al., 2016) and small intestine in chickens (Miao et al., 2017). In addition, in vitro, L methionine increases phosphorylation of S6K1 (chicken myoblasts: Métayer-Coustard et al., 2010). Similarly, endocrine status influences S6K1 activity with marked increases in skeletal muscle after insulin administration (chicken: Bigot et al., 2003). Moreover, the glucocorticoid, dexamethasone, reduces both protein synthesis and phosphorylation of S6K1 (chicken: Wang et al., 2019). In addition, expression of RPS6K in breast muscle is increased following administration of 25-hydroxycholecalciferol (chickens: Vignal et al., 2015).

TABLE 27.10 Effects of age on breast muscle protein synthesis and degradation in young chickens.

27.6.5 Other factors influencing protein synthesis

There is intriguing evidence that hydrogen sulfide plays a role in stimulating protein synthesis. Hydrogen sulfide is produced from cysteine and homocysteine catalyzed by cystathionine γ-lyase and cystathionine β-synthase. Phosphorylation of S6K1 in muscle is increased following injection of sodium hydrogen sulfide (chicken: Wang et al., 2019). Moreover, L-cysteine overcame the inhibitory effect of glucocorticoid on protein synthesis (chicken myoblasts: Wang et al., 2019).

27.7 Protein degradation

27.7.1 Overview

Proteins are degraded generating the amino acids in intracellular pool of the organs. There is interchange between amino acids in this pool and the plasma. Amino acids are then available for reuse. An exception is 3-methylhistidine which is excreted. As would be expected there are higher concentrations of the 3-methylhistidine in the intracellular pool than in plasma (Table 27.7).

Plasma amino acid pool ↔ Organ amino acid pool ↔ Organ protein

27.7.2 Autophagy

27.7.2.1 Overview

Autophagy ("self-eating") is the intracellular process of degradation of misfolded, unfolded, or damaged proteins together with organelles. Proteins are damaged (oxidized) by reactive oxygen species (ROS) in oxidative stress (reviewed: Bottje, 2019). Autophagy is accomplished the damaged protein associating with the autophagosome followed by fusion of autophagosomes and lysosome and subsequently proteolysis by lysosomal degradation pathway. Fusion is accomplished by soluble NSF attachment proteins (SNARE) proteins as with exocytosis.

27.7.2.2 Autophagy-related genes

There is both tissue and gender differences in the expression of autophagy-related genes with, for instance, higher expression of autophagy genes (Atg) including Atg 9 in breast muscle and brain and Atg 13 in liver and brains in females (chicken: Piekarski et al., 2014). Moreover, expression of Atg 7 and Atg16L1 in breast muscles of high than low-feed efficiency broiler type chickens (Piekarski et al., 2018a). Intracerebroventricular administration of leptin increased hypothalamic expression of autophagy-related genes including Arg 5, Atg 7, and Beclin 1

together with microtubule-associated protein 1 light chain (LC), LC3a, LC3b, and LC 3c (chicken: Piekarski et al., 2018).

27.7.3 Ubiquitin and protein degradation

27.7.3.1 Overview

There are two ubiquitin systems critical to protein degradation:

- Ubiquitin−proteasomal system
- Ubiquitin-like system.

The ubiquitin-proteosome proteolytic pathway plays a critical role in protein degradation. Proteins to be degraded undergo tagging with ubiquitin allowing recognition by autophagy receptors. Ubiquitin is small protein with 76 amino acid residues and that is ubiquitous in cells. Proteins to be degraded can be tagged by post-translational modification, specifically ubiquitination, of lysine residues. Fig. 27.5 summarizes the role of ubiquitination in autophagy (Fig. 27.6).

27.7.3.2 Atrogin-1/MAFbx and protein degradation in birds

Atrogin-1/MAFbx is a muscle-specific ubiquitin ligase. There is expression of Atrogin-1/MAFbx in skeletal, cardiac, and smooth muscle with markedly higher expression in smooth muscle (chicken: Nakashima et al., 2013). Fasting would be expected to increase catabolism with degradation of protein and, not surprisingly, expression of Atrogin-1/MAFbx is increased following fasting in skeletal muscle (chickens: Nakashima et al., 2006) and gizzards (chicken: Nakashima et al., 2013). Similarly, administration of the synthetic glucocorticoid, dexamethasone, is followed by catabolism in the skeletal muscle and increased expression of Atrogin-1/MAFbx (chickens: Nakashima et al., 2016). Moreover, expression of atrogin-1 (E3 ubiquitin ligase muscle atrophy F box) by muscle fibroblasts is depressed by insulin or the amino-acid, methionine (Japanese quail: Tesseraud et al., 2007).

Expression of Atrogin-1/MAFbx is reduced in broiler chickens compared to the red jungle fowl due to single nucleotide polymorphism (Li et al., 2019). This may be a

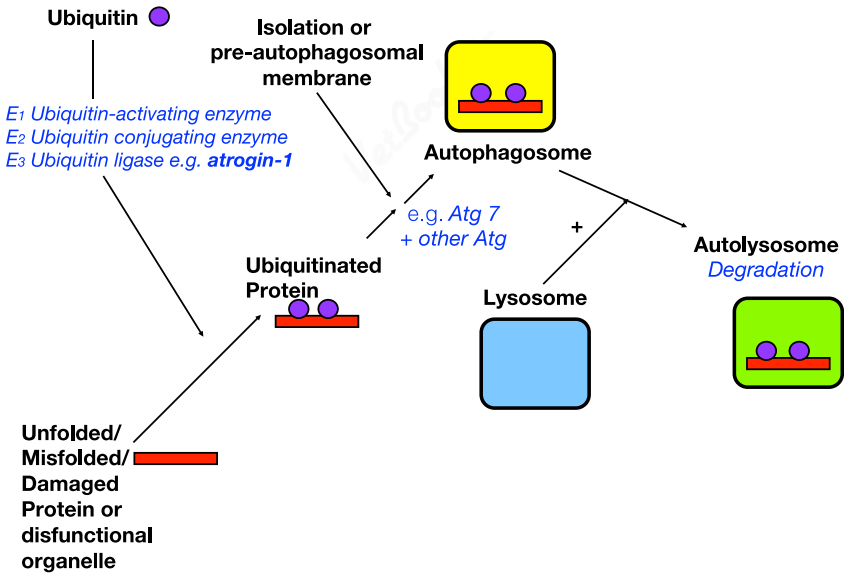

FIGURE 27.5 Simplified schematic of autophagy (degradation of damaged proteins and organelles) including ubiquitination of proteins, formation of autophagosomes, and fusion of these with lysosomes and hence enzymatic degradation.

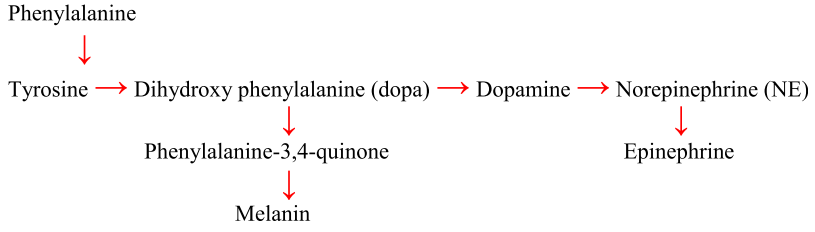

FIGURE 27.6 Synthesis of melanin, dopamine, norepinephrine, and epinephrine from phenylalanine or tyrosine.

causative factor in the lower degradation rates in broiler chickens than wild red jungle fowl.

27.7.4 Lysosomes and protein degradation

27.7.4.1 Overview

Lysosomes play a critical role in autophagy degrading unfolded, misfolded, or oxidized proteins together with damaged organelles (Fig. 27.5). Lysosomal enzymes include proteases, e.g., cathepsins (see Table 27.12) together with glycosidases, sulfatases, nucleases, and phosphatases.

27.7.4.2 Lysosomal proteases

Proteases responsible for proteolysis reported in avian tissues include the following:

- Caspases
- Cathepsins

27.7.4.2.1 Caspases

Physiological status influences expression of caspase (CASP). For instance, fasting increases the expression of the protease, CASP 3, is increased in the gizzards of fasting chickens reflecting catabolism (chicken: Nakashima et al., 2013). Moreover, administration of T2 toxin induces a series of changes in splenic cells including increases in the following: apoptosis and ROS together with expression of CASP: CASP 3 and CASP 9 (chicken: Chen et al., 2019). In contrast, dexamethasone did not influence expression of cathepsin B in muscles (chickens: Nakashima et al., 2016).

27.7.4.2.2 Cathepsins

There are multiple cathepsins in birds. Table 27.12 summarizes cathepsins in chickens. In addition to degrading damaged, misfolded, and unfolded proteins, cathepsins exert other important roles. There is evidence that cathepsin D plays a role in yolk deposition catalyzing hydrolysis of vitellogenin (VTG) in the oocyte (Ritzek et al., 1992; Sheng et al., 2013).

There is tissue-specific expression of cathepsins with expression of cathepsin E-A-like (similar to nothepsin) solely in the liver of sexually mature female birds (chickens: Bourin et al., 2012) with expression induced by estrogen and the estrogen receptor β (chicken: Zheng et al., 2018). There was markedly higher expression of cathepsin D in the uterus than magnum (chickens: Bourin et al., 2012).

27.7.5 Whole body determination of protein degradation

Degradation of muscle myofibrillar proteins can also be measured in vivo by excretion of 3-methylhistidine or in vitro by release of 3-methylhistidine (Hillgartner et al., 1981; Saunderson and Leslie, 1983). When muscle proteins are broken down, 3-methyl-histidine is released but is not reutilized. Whole-body muscle protein degradation can be measured by the excretion of 3-methyl-histidine (see Table 27.3). Rates of 3-methylhistidine excretion are increased in dystrophic chickens (Hillgartner et al., 1981). Measurement of 3-methylhistidine in avian excreta is problematic with the mixing of feces and urine and the retrograde movement of the mixture into the ceca where microbial degradation may occur.

27.8 Control of protein synthesis and degradation

27.8.1 Overview

There are high rates of both net muscle protein accretion or net protein synthesis and fractional rates of muscle protein

TABLE 27.12 Examples of cathepsins in chickens.

Cathepsin K	NM_204971.2		

synthesis in young birds with optimal nutrition (see below). Fractional rates of muscle degradation are also high in young birds but can be further increased with inadequate nutrition (see below).

27.8.2 Protein kinase B (Akt)/mechanistic (or mammalian) target of rapamycin pathway controlling protein synthesis and degradation

mTOR and the mTOR pathway plays an important role in both protein synthesis and degradation (see Fig. 27.4). Methionine depresses expression of atrogin-1 and RPS6 in muscle fibroblasts with the effects mediated by the protein kinase B (Akt)/mTOR signaling pathway being blocked by the mTOR inhibitor, rapamycin (Japanese quail: Tesseraud et al., 2007). Similarly, in the presence of both methane and rapamycin, expression of Akt is increased (Japanese quail: Tesseraud et al., 2007). Moreover, the mTOR inhibitor, rapamycin, blocks the increased activity of S6K1 induced by amino acids in insulin resistant myoblasts (chicken: Tesseraud et al., 2003).

There are physiological effects on expression of mTOR by avian tissues. For instance, 25-hydroxycholecalciferol administration increased the following breast muscle weight, muscle fractional protein synthesis rate, and muscle mTOR expression (chickens: Vignal et al., 2015). There is higher expression of mTOR in breast muscles of high than low-feed efficiency broiler type chickens (Piekarski et al., 2018a).

27.8.3 Protein synthesis and age/development

Fractional rates of rates of protein synthesis decline markedly with age with much lower rates in adult than young chickens (see Table 27.8). Moreover, there are decreases in fractional synthesis rates for protein in skeletal muscle during posthatch growth (chickens: Lauterio et al., 1986; Tesseraud et al., 2000) (also Table 27.10).

27.8.4 Effects of nutritional deficiencies on muscle protein synthesis and degradation

As might be expected, nutritional status influences the net rate of protein synthesis together both the fractional rates of protein synthesis and degradation. For instance, net protein accretion becomes negative in fasted young chickens (Table 29.11). Moreover, there is a decrease in the fractional rate of protein synthesis and an increase in the fractional rate of protein degradation (Table 29.11). Nutritional deficiencies can be accompanied by decreases in fractional rates of protein synthesis or increases in protein degradation or both. For instance, the fractional rate of protein synthesis is depressed when chicks received either a histidine or sulfur-containing deficient feeds (Table 27.10) (Kino and Okumura, 1987). In contrast, feeding a lysine deficient feed resulted in the following in leg or breast muscles of young chicks:

- Protein accretion: Falls to ~0
- Fractional rate of protein synthesis: remains unchanged
- Fractional rate of protein degradation: markedly increased

(Maruyama et al., 1978).

27.8.5 Effects of stretching on muscle protein synthesis and degradation

During hypertrophy induced by weights stretching the muscles, there are increases in the fractional rate of synthesis for both collagen and noncollagen protein (chickens: Goldspink, 1978; Laurent et al., 1978b, 1978c).

27.8.6 Hormones and muscle protein synthesis

Hormones influence muscle protein with effects on rates of both synthesis and degradation. For instance, corticosterone and other glucocorticoids suppress muscle growth (e.g., Klasing et al., 1987; Mehaisen et al., 2017). This is due to both a decrease in protein synthesis (Wang et al., 2015) and an increase in degradation (Klasing et al., 1987). Based on the limited in vitro studies with myotubes derived from chicken pectoralis satellite cells, insulin and/or insulin-like growth factor 1 (IGF1) stimulate protein synthesis and inhibit degradation (Duclos et al., 1993).

27.8.7 Microorganisms and protein synthesis in liver and gastrointestinal tract

Microorganisms influence protein status with decreases in both the weights of the liver and small intestine and in the rates of protein synthesis in these organs in chickens fed a germ-free diet (Muramatsu et al., 1987a, 1988). This would suggest that microorganisms are stimulating gastrointestinal growth.

27.8.8 Environmental temperature and protein synthesis and degradation

Prolonged high temperatures or chronic heat stress has detrimental effects on protein metabolism with, for instance, reduced breast muscle weights (young chickens: Temim et al., 2000). The adverse effect of elevated temperature is mediated, at least partially, by increase protein degradation; expression of cathepsin L2 being increased with heat stress in chicken muscle (Del Vesco et al., 2015).

27.8.9 Protein synthesis and immune functioning

As might be expected, there are high levels of protein synthesis in immune tissues. Protein synthesis in immune tissues are high (discussed above in section 27.6.3) in young growing chickens. The high rates of protein synthesis in immune tissues are disproportionate to their percentage of the body weight. There are interactions between immune functioning and amino acids with lysine increasing the proliferation of chicken thymocytes (Humphrey and Klasing, 2005).

The cationic amino acid transporter-1 through −3 (CAT1−3) is responsible for the transfer of amino acids across the cell membrane into cells. These are expressed in immune tissues—the bursa of Fabricius, the spleen, and the thymus—from seven-days-old (chicken: Humphrey et al., 2004, 2006). Expression of CAT1-3 is influenced by immune responses. Acute phase reaction, as induced by challenge with *Salmonella typhimurium* lipopolysaccharide (LPS), decreased expression of CAT1 in the bursa of Fabricius and the thymus of 11-week-old chickens (Humphrey and Klasing, 2005).

27.8.10 Other physiological effects on protein synthesis and degradation

27.8.10.1 Overview

Measurement of whole-body muscle protein degradation has not been widely employed in wild birds. An exception is the study of molting (see below).

27.8.10.2 Molt and protein synthesis

Molting influences protein metabolism in tissues not directly involved in the process. Body protein varies during the annual cycle of birds. This encompasses a progression though physiological state in female common eider (*Somateria mollissima*) with a plateau high during overwintering, prebreeding, laying, and the beginning of incubation declining to a nadir at the beginning of molting (with a loss of over 50% protein and weight) but subsequently return to the high as molt progresses (Milne, 1976).

Table 27.13 summarizes changes in protein metabolism in white-crowned sparrows (*Zonotrichia leucophrys*) (Murphy and King, 1985; Murphy and Taruscio, 1995 Taruscio and Murphy, 1995). Surprisingly, fractional rates of protein synthesis in skeletal muscle are elevated during molting (Table 27.13). There is also an increase in whole body protein synthesis (Table 27.13). On the other hand, an increase in protein degradation would be expected as this would supply amino acids for feather regrowth. This is the case with elevated excretion of 3-methyl-histidine during molting (Pearcy and Murphy, 1997).

TABLE 27.13 Effects of molting on protein metabolism synthesis in white crown sparrows.

	Nonmolting	Molting
Liver		
Weight g	0.771	1.011
Protein mg	175.8	237.4[a]
Glutathione mmoles[b]	0.576	1.757[a]
Protein fractional synthesis rate %/d	75	123[a]
Muscle		
Weight g	1.618	1.729
Protein mg	327.8	352.0
Protein fractional synthesis rate %/d	11.8	14.9[a]
Whole body		
Protein synthesis excluding integument fractional synthesis rate %/d	24.5	32.9[a]
Degradation		
3 methyl histidine excretion μmoles/d	0.79	1.23[a]

[a] *Difference with nonmolting $P < .05$.*
[b] *Early morning sampling.*
Calculated from Murphy and King (1985); Murphy and Taruscio (1995), Taruscio and Murphy (1995).

Nutrition influences protein metabolism in molting birds. There is increased excretion of 3-methyl-histidine in molting but not nonmolting white crowned sparrows fed a diet deficient in sulfur amino acids (Pearcy and Murphy, 1997). In contrast, there was decreased excretion of 3-methyl-histidine in molting white-crowned sparrows fed a protein-deficient diet (Pearcy and Murphy, 1997).

27.9 Proteins and reproduction

27.9.1 Female reproduction

There have not been definitive studies of the relative contributions of the reproductive organs to protein synthesis and degradation in birds. However, protein synthesis related to reproduction in the female is high. Birds' eggs are high in protein. For instance, the protein composition of a chicken hen's egg (assuming a 58 g egg) is the following (calculated from Belitz et al., 2009):

- Albumin: 3.6 g
- Yolk: 3.3 g
- Shell: 0.2 g

TABLE 27.14 Characteristics of sexually mature hens.

Parameter	Metric
Body weight (kg)	1.5
Carcass protein %	23.9
Carcass protein g	358
Ovary g	35.5
Oviduct g	47.1
Oviduct protein g	8.2
Liver g	24
Egg production	
Protein requirement in diet g d^{-1}	16.5
Protein taken up in yolk by developing oocyte in the ovary	3.3
Protein secreted in oviduct as egg white g d^{-1}	3.4
Protein secreted in oviduct as membranes/shell g d^{-1}	0.2
Total ***(% of protein requirement)***	7.0 (*42*)
Sexual maturation	
Increase in body weight during sexual maturation	252
Increase in body protein during sexual maturation g d^{-1}	2.2
Increase in ovarian and oviduct protein during sexual maturation g d^{-1}	0.5

From or calculated from Reid (1976), Renema et al. (2001), Belitz et al. (2009).

Egg protein contents are equivalent to 43% of the protein in the diet of the chicken (see Table 27.14). The yolk proteins are synthesized in the liver and are absorbed into the developing oocyte in the follicle (see Chapter 27).

Yolk proteins consist of the following (Moran, 1987):

- Low density (very low-density lipoproteins LDF1 and LDF2): 66%
- Granules (phosvitins and lipovitellins): 23%
- Aqueous α livetin, β livetin, and γ livetin (IgY): 11%

Both phosvitin and lipovitellin are derived from VTGs produced in the liver and secreted into the plasma. The VTG is processed to lipovitellin and phosvitin in the ovary. There are multiple VTG genes in birds (e.g., chicken VTGI, VTGII, and VTGIII: Evans et al., 1988). There is a relationship between the percentage essential amino acid in both VTGI and II with incubation time across avian species (Hughes, 2015).

Estrogens induce expression of VTGS with hepatic expression being only observed in birds either producing endogenous estrogen or receiving exogenous estrogens (chicken: Evans et al., 1988; Japanese quail: Gupta and Kanungo, 1996). Progesterone can inhibit VTGII expression (Japanese quail: Gupta and Kanungo, 1996). Interestingly, possible endocrine disrupters of chemicals such as pesticides can be evaluated using either circulating concentrations of VTG or VTG gene expression in the Japanese quail (Shibuya et al., 2005).

There is limited information on whole-body and specific-organ rates of protein synthesis and degradation in the reproductively mature female. As might be expected, protein synthesis in the oviduct is elevated when the ovulated oocyte is in the magnum (Hiramoto et al., 1990). In photostimulated sexually immature female chicken (17-week-old pullet), the development of the ovary and oviduct occurs over about 28 days (Renema et al., 2001). Oviductal growth is occurring under the influence of estrogen (estradiol) and progesterone with marked increases in protein synthesis (Muller et al., 1970).

27.9.2 Male reproduction

The importance of the male reproductive organs to overall protein metabolism has received little attention in birds. The testes of birds are considerably larger than those of mammals, as can be readily observed from the following: Sexually mature Japanese quail testes: 2.5 g or 2.5% of body weight (Vatsalya and Kashmiri, 2012), sexually mature chicken testes: 33 g (González-Moránet al., 2008).

It is likely that there are high demands for protein synthesis in spermatogenesis. However, protein requirements for seminal fluid are likely to be low as semen volume is modest, for instance, 0.4 mL, with seminal plasma protein concentrations are only 1.9% in turkeys (Kotłowska et al., 2005). There is a lack of information on the protein requirements for epididymal, ductal, phallic, and secondary sexual characteristic development and maintenance in birds.

27.10 Amino acids and metabolism

27.10.1 Amino acid transfer into muscle and other cells

There are transporters transferring amino acids into muscle cells and into the cells of other organs. Amino acid uptake by cells can be determined by uptake of [^{3}H]-amino-isobutyric acid (AIB) or ^{14}C-AIB. This approach prevents the confounding of data as AIB is not incorporated into proteins. Hormones, including IGF1 and insulin, stimulate AIB uptake by muscle cells (Duclos et al., 1993) or heart cells (Guidotti et al., 1968; Santora et al., 1979).

27.10.2 Amino acid transporters

27.10.2.1 Overview

The amino acid transporters expressed in avian skeletal muscle include the following:

- $B^{0,+}AT$ (b(0,+)-type amino acid transporter 1) [Gene—Solute carrier family 7 member A9 (SLC7A9)],
- $B^{0}AT$ (SLC6A19),
- CAT1 (SLC7A1) high affinity cationic amino acid transporters 1,
- CAT2 (SLC7A2) cationic amino acid transporters 2,
- CAT3 (SLC7A3) cationic amino acid transporters 3,
- LAT1 (SLC7A5) large neutral amino acid transporter 1
- LAT4 (SLC43A2) large neutral amino acid transporter 2
- SNAT1 (SLC38A1) sodium coupled neutral amino acid transporter 1
- SNAT2 (SLC38A2) sodium coupled neutral amino acid transporter 2
- SNAT7 (SLC38A7) sodium coupled neutral amino acid transporter 7
- TAT1 (SLC16A10) T type amino acid transporter 1 (Na^{+}-independent transporter of aromatic amino acids)

(e.g., chicken: Humphrey et al., 2004, 2006; Habashy et al., 2017).

27.10.2.2 Amino acid transporters and physiological state

Amino acid transporters are influenced by physiological state. For instance, expression of CAT1−3 is greatly decreased in birds on lysine-deficient diet (Humphrey et al., 2006). Similarly, expression of CAT 1 and 2 in *pectoralis* muscle is suppressed in newly hatched chicks when feeding is delayed (Payne et al., 2019). Acute-phase reaction as induced by challenge with *Salmonella typhimurium* LPS increased expression of CAT1−3 in the pectoralis of 11-week-old chickens (Humphrey and Klasing, 2005). Moreover, heat stress influences expression of amino acid transporters in pectoralis muscle with increases in SNAT1 and $B^{0,+}AT$ and decreases in $B^{0}AT$, SNAT7, and TAT1 (chicken: Habashy et al., 2017).

27.11 Nitrogenous waste

27.11.1 Overview

Nitrogenous waste in birds is in the form of uric acid, urea, and ammonia. The proportion of nitrogen excreted as uric acid and ammonia varies with species with, for instance, more as uric acid in Tristram's grackle (*Onychognathus tristrami*) but about equal amounts in yellow-vented bulbul (*Pycnonotus xanthopygos*) (Tsahar et al., 2005). In the hummingbird (*Archilochus alexandri*), over a quarter of nitrogenous waste is as ammonia (McWhorter et al., 2003).

The proportion of uric acid to ammonia is also influenced by protein concentration in the feed (Tsahar et al., 2005) or temperature in Anna's hummingbirds (*Calypte anna*) (Roxburgh and Pinshow, 2002). In contrast, there is no effect of dietary protein on the concentration of ammonia in pigeon excreta (*C. livia*: McNabb et al., 1972).

27.11.2 Uric acid

The major nitrogenous waste in birds is generally thought to be uric acid (Milroy, 1903) (also see above in section 27.10.1). Infusion of ammonia or glutamine increases circulating concentrations of uric acid in chickens (Karasawa, 1986). The enzymes of the uric acid cycle are found in both the liver and kidney. For instance, phosphoribosyl pyrophosphate amidotransferase and xanthine dehydrogenase activities are present in both avian liver and kidneys (chicken: McFarland and Coon, 1980, 1984). Glutamine is critically important for uric acid formation (see the below). It is not surprising that glutaminase (catalyzing glutamine to glutamate) is either not present or at very low levels in the avian liver (chicken: Wu et al., 1998).

The predominant organ responsible for uric acid formation is the liver. Chicken hepatocytes have been demonstrated to synthesize uric acid in vitro (McFarland and Coon, 1984). The kidney synthesizes only about 17% of the uric acid found in the urine of birds (chicken: Chin and Quebbemann, 1978).

Uric acid formed from the amino acids, glutamine, glycine, and aspartate by the following pathway (based on Stevens, 1996):

1. Ribose + ATP ↔ Ribose-5-phosphate + ADP
2. Ribose − 5 − phosphate + ATP ↔ 5−
   Phosphoribosyl − α − pyrophosphate (PRPP) + AMP
   Pyrophosphokinase
3. PRPP + Glutamine ↔ 5 − β−
   Phosphoribosyl amine + Glutamate
   Phosphoribosylpyrophosphate amidotransferase
   (*Aminophosphoribosyltransferase*)
4. Phosphoribosylamine +
   Glycine ↔ Glycinamide ribotide (GAR)
   [*Phosphoribosylglycineamine*]
   GAR synthetase
5. GAR + N − formyl tetrahydrofolate ↔
   Formylglyinamide ribotide (FGAR)
   [Phosphoribosyl−
   GARtransformase N − formylglycineamine] +
   Tetrahydrofolate

6. FGAR + Glutamine + ATP ↔ Formylglycineamidine ribotide (FGAM) + Glutamate + ADP
   FGAM Synthetase
7. FGAM + HCO_3^{-1} + ATP ↔ Phosphoribosyl-5-aminoimidazole-4 carboxylate + ADP
8. Phosphoribosyl − 5 − aminoimidazole−4 carboxylate + Aspartate + ATP ↔ Inosine monophosphate + Fumarate + ADP
9. Inosine monophosphate ↔ Xanthine + PRPP
   IMP dehydrogenase

PRPP is cycled back to step 3 and hence uric acid cycle or used to generate purines.

10. Xanthine ↔ Uric acid
    Xanthine dehydrogenase

Breast cancer resistance protein (BCRP) and multidrug resistance protein 4 (MRP4) are involved in uric acid excretion. Both BCRP and MRP4 are expressed in liver, kidneys, and the small intestine (chickens: Ding et al., 2019). Moreover, renal expression and concentrations of both BCRP and MRP4 are increased in chickens on a fish meal containing diet (Ding et al., 2019). Chickens on a high-protein diet have elevated serum concentrations of urate and have been proposed as a model for gout (Hong et al., 2020).

27.11.3 Urea

The existence of a urea cycle in birds has been questioned (Stevens, 1996). However, birds have both uric acid/urates as well as urea in their plasma (see Chapter 17).

The urea cycle is as follows:

1. Ornithine + Carbamyl phosphate ↔ Citrulline
2. Citrulline + Asparate + ATP ↔ Argininosuccinate + Fumarate + AMP
3. Argininosuccinate ↔ Arginine
4. Arginine ↔ Urea + Ornithine (and return to step 1)

27.11.4 Glutamine and ammonia detoxification

The primary ammonia-detoxifying enzyme in the avian liver is glutamine synthase. The gene has been characterized (Pu and Young, 1989). Glutamine synthase is expressed in the liver, brain, and retina (chicken: Satoh and Matsuno, 1983; Patejunas and Young, 1987). In contrast to the situation in mammals, there is little zonation of the enzyme in the avian liver (chicken and ducks: Smith and Campbell, 1988). Moreover, while glutamine synthase is cytosolic in mammals, the enzyme is located in the mitochondria in birds (chicken and ducks: Smith and Campbell, 1988).

27.11.5 Amino acids as energy sources

27.11.5.1 Amino acids and metabolism

Multiple amino acids can be deamidated and then be converted to glucose or readily metabolizable carbohydrates in the process of gluconeogenesis (discussed in detail in chapter 25 Carbohydrates). There is also evidence that during migration, birds use both lipid but also metabolize protein with the later catabolism providing water (Gerson and Guglielmo, 2011; Giulivia and Ramsey, 2015).

27.11.5.2 Glutamine as an energy source

Glutamine is a significant energy source for at least some tissues in birds. For instance, it is the major energy source for avian erythrocytes (chicken: Mathew et al., 1993). Glutamine is also employed as a major energy source for enterocytes (chicken: Watford et al., 1979).

27.12 Amino acid derivatives

27.12.1 Overview

There are multiple compounds in the animals that are derived from amino acids via biosynthetic pathways. These include the following:

- Neurotransmitters—dopamine, norepinephrine, and epinephrine from tyrosine (and phenylalanine)
- Epinephrine (hormone) from tyrosine (and phenylalanine)
- Glutamate (neuromodulator)
- Histamine (neurotransmitter and inflammatory response) from histidine
- Melatonin (hormone) from tryptophan
- Melanin (pigment) from tyrosine
- Nitric oxide (signal molecule) from arginine catalyzed by nitric oxide synthase
- Norepinephrine (neurotransmitter and hormone) from tyrosine (and phenylalanine)
- Nucleotides (purines, e.g., adenine, and guanine together with uric acid) from glutamine, aspartate, and glycine
- Serotonin (neurotransmitter) from tryptophan
- Thyroxine and triiodothyronine (hormone) from thyroglobulin (iodinated tyrosine residues)
- Urea from arginine

Phenylalanine and tyrosine are precursors for the synthesis of the neurotransmitters, dopamine, norepinephrine, and epinephrine and for melanin (Fig. 27.6).

27.12.2 Melanin

The melanocytes in the skin synthesize polymeric melanin which is subsequently transferred to feathers. The colors range from red due to phaeomelanin (produced from benzothiazole), black due to eumelanin (made of dihydroxyindole oligomers), and gray (produced from benzothiazine) (reviewed Galván and Solano, 2016) (also see Fig. 27.4). For instance, the orange feathers of the Eastern bluebird have high concentrations of phaeomelanin while the black feathers of penguins have high concentrations of eumelanin (McGraw et al., 2004).

27.13 Extranutritional effects of amino acids

27.13.1 Overview

There is intriguing research supporting amino acids having regulatory roles.

27.13.2 Amino acids in the control of metabolism

27.13.2.1 Glutamine and muscle growth

Glutamine has been proposed to be playing a role in the control of muscle protein synthesis (Wu et al., 1998). Either ammonia or glutamine increases myotubule diameters in vitro (Stern and Mozdziak, 2019) (Table 27.15). In addition, there are decreased levels of free glutamate and glutamine in leg but not pectoralis muscles from starved chickens along with the suppression of protein synthesis in leg but not pectoralis muscles (chicken: Watford and Wu, 2005) (see Table 27.16). Both glutamine synthase and glutaminase activities are reported in avian muscle. There is also much higher activity of glutamine synthase but not glutaminase in leg muscles than in pectoralis muscles (chicken and pigeon (*C. livia*): Watford and Wu, 2005).

TABLE 27.15 Effects of ammonia (ammonium acetate) or glutamine on growth of primary chicken myotubules in culture for 24 h.

	Myotubule diameters mean in μm + SEM	
Treatment	Breast	Thigh
Control	11.4 + 0.4[a]	11.1 + 0.4[a]
Ammonia	24.6 + 1.4[a]	24.2 + 0.6[a]
Glutamine	25.3 + 1.4[a]	19.9 + 0.6[a]

[a]*Different superscript letters indicate difference $P < .05$.*
Based on Stern and Mozdziak (2019).

TABLE 27.16 Effect of Starvation on fractional rate of protein synthesis and amino acid concentrations of different muscles in young chickens. Data shown is mean + (n = 5) SEM.

	Fed	Starved[a]
Fractional protein synthesis rate		
Pectoralis %/d	10.5 + 0.9	10.4 + 0.8
Leg muscle %/d	36.1 + 1.5	13.6 + 0.5[b]
Free glutamine		
Pectoralis μmoles/g	1.41 + 0.04	1.38 + 0.07
Leg muscle μmoles/g	9.45 + 0.64	3.02 + 0.17[b]
Plasma μmoles/mL	1.09 + 0.06	0.94 + 0.03
Free glutamate		
Pectoralis μmoles/g	0.90 + 0.06	0.89 + 0.05
Leg muscle μmoles/g	3.43 + 0.28	1.69 + 0.12[b]
Plasma (μmoles/mL)	0.26 + 0.02	0.32 + 0.01[b]
Free alanine		
Pectoralis μmoles/g	1.20 + 0.08	1.70 + 0.09[b]
Leg muscle μmoles/g	3.21 + 0.15	3.93 + 0.10[b]
Plasma (μmoles/mL)	0.51 + 0.01	0.62 + 0.01[b]

[a]*starved for 48 h.*
[b]*Difference $P < .05$ from fed.*
Based on Watford and Wu (2005).

27.13.2.2 Glutamine and intestinal growth

Supplementing a corn–soybean diet with glutamine increased both duodenal and jejunal mucosal villi height in young chickens despite not impacting growth (Bartell and Batal, 2007). For instance, duodenal villi height was reported to be increased by 41% with glutamine supplementation in the following manner (Bartell and Batal, 2007):

- Controls on corn–soybean diet: 652 μm
- Supplemented with 4% glutamine: 921 μm.

27.13.2.3 Dipeptides

Muscle contains alanine and histidine containing dipeptides:

- Carnosine—β-alanyl L-histidine
- Anserine—β-alanyl -3-methyl-L-histidine.

These are proposed to exert physiological effects. Muscle concentrations of carnosine and anserine are much greater in chickens than hummingbirds (Dolan et al., 2018). Moreover, there is markedly greater concentrations of anserine and carnosine in both breast than thigh muscle and

in slow growing than rapid growth rate young birds (chickens: Barbaresi et al., 2019). Muscle concentrations of anserine are greater than those of carnosine (chickens: Barbaresi et al., 2019).

27.14 Other uses of avian proteins

There are intriguing and, in many cases, novel applications using avian proteins:

1. Paleoproteomics can be performed on the collagens in fossil avian bones (Horn et al., 2019). This approach complements phylogenetics.
2. Recombinant chicken feather keratin is being employed to assay for keratinase activity (Jin et al., 2017).
3. Plasma concentrations of protein and of albumen are depressed with inadequate nutrition (black-necked swan: Artacho et al., 2007). Plasma concentrations of protein have been proposed as an indicator of nutritional status of wild bird populations.
4. The albumen layer of penguin eggs contains an "anti-freeze" like protein, penalbumin [Adélie penguin (*Pygoscelis adeliae*) and emperor penguin (*Aptenodytes forsteri*)] (Feeney, 1982; Osuga et al., 1983). There is a concomitant decrease in the amount of egg albumin with the presence this highly glycosylated protein (Feeney, 1982; Osuga et al., 1983).
5. Expression of actin is used in expression studies as actin is viewed as a house-keeping gene (e.g., Fagundes et al., 2020). LAT4 expression in both the ileum and kidneys is increased in methionine deficient chickens (Fagundes et al., 2020).

Chapter 28

Food intake regulation

Mark A. Cline[1], Mike Denbow[1], Elizabeth Gilbert[1] and Sami Dridi[2]
[1]Department of Animal and Poultry Sciences, Virginia Tech, Blacksburg, VA, United States; [2]Center of Excellence for Poultry Science, University of Arkansas, Fayetteville, AR, United States

28.1 Introduction

Birds, like mammals, have complex mechanisms regulating food intake. Given a choice between more than one diet, turkeys, broilers, layers, and other avian species display the ability to self-select a diet adequate for growth or production (Denbow, 1999). Although compensation may not be complete, if exposed to severe feed restriction early in life, birds compensate by increasing their intake in order to support weight gain following the restriction. In contrast, force-feeding birds twice their ad libitum food intake causes Leghorns to stop eating for 7−10 days until their fat stores approach pre-force-feeding levels. Therefore, clearly, birds have the ability to regulate food intake.

Among the strongest evidence that food intake is regulated in birds is the temporal response to dietary amino acid imbalances. Broiler chicks decrease intake of a diet deficient in lysine, methionine, and tryptophan within 24 h posthatch (Picard et al., 1993). Preferences for certain diets are evident in as little as 7 h posthatch. The ability to discriminate among diets deficient in amino acids is dependent on the genetic background of the bird (Noble et al., 1993).

Intense genetic selection of poultry has resulted in strains optimized for either meat production or egg production. Genetic selection has resulted in broilers that are more than five times larger than layer-type chicks at 6 weeks of age (Zhao et al., 2004; Buzala and Janicki, 2016). This increased growth rate has resulted largely from increased food intake. Broiler breeders will essentially eat to gut capacity whereas layers will consume to meet an energetic need. There is evidence that broilers have more taste buds and display less contrafreeloading (choosing a food that requires more effort to select) than layer-type chickens (Buzala and Janicki, 2016).

Food intake regulation in birds has been reviewed (Kuenzel, 1994; Denbow, 2000; Furuse et al., 2007; Richards and Proszkowiec-Weglarz, 2007; Cline and Furuse, 2012; Tran et al., 2019) and involves sites both within and outside the central nervous system (CNS), and signals are integrated within the CNS. As in mammals, the CNS, and specifically the hypothalamus, has emerged as a key site in appetite control (Hussain and Bloom, 2013). Because the bulk of the research on avian food intake regulation has used poultry as a model, this chapter focuses mainly on domestic fowl species, in particular, the neonatal chick model. However, research with other avian species is reported in several tables.

28.2 Peripheral regulation of food intake

28.2.1 Gastrointestinal tract and ghrelin

Outside of the CNS, food intake is regulated by multiple organs, such as the gastrointestinal tract, liver (Denbow, 1994), and adipose tissue (Zhang et al., 2014). The crop does not appear to have a direct role in food intake regulation in that it does not appear to have receptors or release factors that modulate food intake. However, it may restrict intake physically when its capacity is reached and several studies referenced within this chapter describe appetite regulatory effects that are accompanied by changes in the rate of crop emptying. The gastrointestinal tract has osmoceptors that, when stimulated by hyperosmotic solutions, result in reduced food intake. Intraduodenal infusions of hyperosmotic solutions decrease food intake via a decrease in gastrointestinal motility (Denbow, 1994).

Ghrelin, originally identified as a growth hormone-releasing peptide, is released from the stomach of mammals. Intracerebroventricular (ICV) and intraperitoneal (IP) injections of ghrelin increase food intake in humans and rodents. In addition, its levels increase in plasma during fasting, and decrease upon refeeding. Ghrelin is also found in the proventriculus of birds. Plasma ghrelin levels increase during fasting in Japanese quail and six-day-old

Sturkie's Avian Physiology. https://doi.org/10.1016/B978-0-12-819770-7.00038-4

TABLE 28.1 Effects of compounds on food intake when infused into the hepatic portal system.[a]

Compound	Broilers	Leghorns
Glucose	→	↓
Amino acid preparation[b] FreAmineIII®	ND	→
Lysine	ND	↓
Leucine	ND	Delayed ↓
Ammonium chloride	ND	→
Epinephrine	ND	↓
Fatty acids[c] Liposyn®	→	↓

[a] *→, no effect; ↓, decrease in food intake;* ND, *not determined (Denbow, 1999).*
[b] *FreAmineIII® contains isoleucine, leucine, lysine, methionine, phenylalanine, threonine, tryptophan, valine, alanine, dl-, arginine, histidine, proline, serine, glycine, cysteine, sodium acetate, magnesium acetate, sodium chloride, potassium chloride, phosphoric acid, and potassium metabisulfite.*
[c] *Liposyn® is a commercial emulsified fat product.*

layers, but not in 3-week-old broilers (Richards and Proszkowiec-Weglarz, 2007; Richards and McMurtry, 2010). Ghrelin mRNA and peptide levels increase in the proventriculus during fasting and return to control levels after refeeding. However, brain ghrelin mRNA does not change during fasting or refeeding. While the changes in plasma ghrelin levels associated with fasting would suggest it may act as a peripheral orexigenic signal, in contrast to in rodents and humans, central administration of ghrelin decreases food intake in birds (Furuse et al., 2001). In Japanese quail, while IP injections of relatively low doses of ghrelin increase food intake, higher doses decrease food intake. Intravenous (IV) injections of ghrelin in chickens either weakly decreased food intake or had no effect.

In addition to ghrelin, cleavage of proghrelin yields a 23-amino acid amidated peptide called obestatin, which was first isolated and purified from the rat stomach. This peptide was reported to be the endogenous ligand of the GPR39 receptor (Wolfgang et al., 2006), although this has been questioned (Dong et al., 2009). The role of obestatin is unclear since it has been reported to decrease food intake and body weight, but other studies failed to show an effect on food intake in rats (Seoane et al., 2006). Xu et al. (2011a) reported that ICV injection of obestatin increased food intake in a dose-dependent manner in a high-weight selected line of chickens. However, Song et al. (2013) found that IV injection of obestatin had no effect on food intake in broilers or Leghorns. Further studies are needed to elucidate the role of obestatin in food intake in birds.

28.2.2 Liver

After absorption from the gastrointestinal tract, nutrients generally travel directly to the liver. Whereas in mammals, absorbed lipids are packaged into chylomicrons, enter the lymphatic system, and are transported to the subclavian vein; in birds, lipids are packaged into portomicrons that enter the hepatic portal vein and travel directly to the liver. Therefore, the liver is strategically located to monitor nutrient intake and control food intake in birds. Intrahepatic infusion of glucose, lysine, or lipids decreases food intake (Table 28.1), and these effects vary with the strain of bird. For example, intrahepatic infusion of glucose decreased food intake in Leghorns, but not broilers. Similarly, infusions of lipids decreased food intake in free feeding Leghorns, but not broilers. Although the liver appears able to alter food intake in response to changes in hepatic portal blood glucose concentration, there is little evidence that plasma or brain concentrations of glucose influence food intake. Savory (1987) reported no correlation between plasma glucose concentrations and food intake. Furthermore, injections of glucose, or its antimetabolites, into the lateral cerebroventricle have no effect on food intake (Denbow et al., 1982).

28.2.3 Dietary nutrients

While food intake is modified by direct injection of lipids into the liver, dietary lipids also alter food intake (Denbow, 1989). Feeding medium-chain triglycerides (glyceryl tricaprylate or glyceryl tricaprate) or corn oil-containing long-chain triglycerides to Leghorn chickens decreased food intake as soon as 30 min postfeeding. This agrees with studies showing that short- and medium-chain triacylglycerols were more effective in decreasing food intake than long-chain triacylglycerols when infused into the hepatic–portal system (Denbow, 1994). However, medium- and long-chain triacylglycerols were equally effective in decreasing food intake when administered intragastrically. Ketone bodies, acting both peripherally and centrally, also decrease food intake in chicks (Sashihara et al., 2001).

Dietary macronutrient (including lipid) composition not only influences food intake and dietary preference but also affects the food intake response to centrally injected neuropeptides. In turn, central administration of peptides may influence the preference for certain diets. Most studies that examined interactions of peptide injection and diet composition were conducted with rodent models, although within the past decade such studies have surfaced in chickens. One model was developed whereby isocaloric corn-soybean-meal-based broiler starter diets were formulated to differ in protein and fat content, resulting in a high-carbohydrate (HC), high-fat (HF), and high-protein (HP) formulation. In one study, the HF diet was formulated to have 60% of the metabolizable energy (ME) derived from lard and the HP diet to have 30% crude protein (CP) (Nelson et al., 2015). When broiler chicks were given free access to all diets and intracerebroventricularly (ICV; into the left lateral ventricle in the brain) injected with the hunger-stimulating peptide neuropeptide Y (NPY), they selected the HC or HP diets over the HF diet and chicks that were raised on the HF diet appeared to have a greater sensitivity to the orexigenic effects of centrally injected NPY (Nelson et al., 2015). In another study, prolactin-releasing peptide (PrRP), another orexigenic factor in birds, had slightly different associations with the diet; chicks that were raised on the HP diet were more sensitive to the orexigenic effects of ICV-injected PrRP and injection of the peptide in turn increased the preference of the chicks for the HP diet (Wang et al., 2015a). When dietary formulations were adjusted to reduce the amount of protein and fat in the HP (to 25% CP) and HF (15% and 30% ME from soybean oil instead of lard) diets, respectively, there were differences among diets that were magnified by fasting and refeeding, including reduced food intake in the chicks that consumed the HP and HF diets, and hypothalamic gene expression differences suggesting that corticotropin-releasing factor (CRF) and melanocortin signaling systems were involved (McConn et al., 2018c). Using these diets, the response to ICV NPY was tested in broiler chicks, and it was observed that chicks raised on the HC diet displayed the most robust NPY-induced increase in food intake while those on the HF diet had a lower threshold response to NPY (McConn et al., 2018a). Following ICV injection of NPY, chicks selected the HP and HC diet over the HF diet, with hypothalamic melanocortin receptor subtypes 4 (MC4R) and NPY receptor subtype 1 (NPYR1) mRNAs reduced in the chicks that consumed the HP and HC diets (McConn et al., 2018a). These results collectively suggest that nutrients from the diet can indirectly influence endogenous appetite regulatory systems via effects on major hypothalamic neuropeptide signaling systems, such as NPY.

28.2.4 Adipose tissue and leptin

An important physiological mechanism for regulating body weight involves bidirectional communication between the hypothalamus and adipose tissue (Zhang et al., 2014). The adipose tissue, at least in mammals, is richly vascularized and innervated by the sympathetic nervous system (SNS), the terminals of which co-store NPY and norepinephrine (NE) and project onto adipocytes. In addition to being a major stimulator of appetite, NPY stimulates adipogenesis and fat storage in adipocytes, both in mammals and in chickens (Zhang et al., 2015; Shipp et al., 2016). Thus, signals from the hypothalamus can be directed to the adipose tissue via endocrine or neurocrine mechanisms involving the SNS. The lipostatic theory of food intake proposed that the brain senses the state of fat depots and makes appropriate adjustments in food intake to maintain fat stores. In 1994, a protein coded by the Ob gene, named leptin, was cloned from the mouse (Zhang et al., 1994), and is believed to be part of a feedback system that indicates an animal's stores of white adipose tissue. As fat stores increase, circulating plasma leptin levels increase. This protein is lacking in ob/ob mice. Administering recombinant leptin to ob/ob mice reduces food intake, decreases body weight and lipid content, and increases thermogenesis. Thus, in mammals, leptin plays a critical role in maintaining energy homeostasis via signaling energy reserves to the brain and by suppressing appetite. After its discovery, attempts to identify the orthologous gene in birds yielded conflicting and controversial results.

In 1998, a group reported to have cloned the chicken leptin gene, with 97%, 96%, and 83% similarity to the mouse, rat, and human amino acid sequences, respectively (Taouis et al., 1998; Ashwell et al., 1999). The following year, another group reported that they were unable to amplify this putative chicken leptin sequence by PCR, concluding that the publication had reported a spurious sequence, likely the result of contamination with mammalian DNA (Friedman-Einat et al., 1999). During the time that the presence of leptin was still debated, the chicken leptin receptor was identified (Horev et al., 2000; Ohkubo et al., 2007). Central injection of human leptin into chickens was associated with a reduction in food intake, suggesting that receptor function is conserved in avians (Denbow et al., 2000). The existence of an endogenous and conserved receptor without a ligand seemed unlikely from an evolutionary standpoint and studies persisted until the Peregrine Falcon (*Falco peregrinus*) leptin sequence was reported (Prokop et al., 2014). Researchers attributed the difficulty in finding the falcon leptin gene to the high GC content (54.7%), and unusual tissue distribution which had led others to search for expression in tissues where it was

absent (Prokop et al., 2014). Shortly thereafter, leptin orthologues were identified for the zebra finch (*Taeniopygia guttata*) (Huang et al., 2014) and rock dove (*Columba livia*) (Friedman-Einat et al., 2014). For both species, there was little to no expression of leptin in the adipose tissue, which is in contrast to mammals where the transcript is most abundant in the adipose tissue, with a strong positive correlation between abundance and fat mass (Friedman and Halaas, 1998; Rosenbaum et al., 1996). Partial sequences from the Japanese quail (*Coturnix japonica*) (Friedman-Einat and Seroussi, 2014), and RNA-sequencing data were what led to the identification of the chicken leptin sequence (Seroussi et al., 2016). Similar to other avian species, chicken leptin bears a low homology to the mammalian sequence, and its mRNA is not highly expressed in the adipose tissue, and similarly to zebra finch, it is not expressed in the liver (Huang et al., 2014; Seroussi et al., 2016). These results imply that leptin does not function as an adipose tissue-derived signal to control energy balance in birds. With relatively low expression of leptin and its receptor in the hypothalamus, the major part of the brain thought to be responsible for modulating feeding behavior, it is unlikely that endogenous leptin plays a major role in appetite regulation in birds (Friedman-Einat et al., 2014; Huang et al., 2014). Consistent with this, ICV injections of a partial sequence corresponding to the chicken leptin identified by Seroussi et al. (2016) had no effect on food intake in broiler chicks (Sims et al., 2017).

Thus, there are some differences between birds and mammals in the roles of some hormone systems in regulating energy balance, in particular, ghrelin and leptin, which are major hunger- and satiety-associated factors in mammals, respectively, but appear to have different roles in avian species. Other hormonal systems including proteinaceous and nonproteinaceous hormones play an important role in regulating food intake and body fat mass. Many of the peptide hormones and systems will be described throughout this chapter, and it is important to bear in mind the relationship of feeding behavior to other physiological processes, such as reproduction, immune system activation, metabolic rate and growth, and stress responses, to name a few. A critical factor responsible for stress cascade activation is CRF. Release of CRF from the paraventricular nucleus (PVN) of the hypothalamus promotes the release of adrenocorticotropic hormone (ACTH) from the anterior pituitary, which then targets the adrenal cortex to stimulate the production of cortisol (Smith and Vale, 2006). Both CRF (Wang et al., 2019a, 2019c) and ACTH (Shipp et al., 2015b) are anorexigenic; ICV injection into chicks leads to reduced food intake. Central administration of ACTH was associated with activation of the lateral hypothalamic area (LHA), ventromedial hypothalamic nucleus (VMH), and infundibular nucleus (IN) the equivalent of the mammalian arcuate nucleus (ARC) and decreased hypothalamic CRF, urotensin 2 (UTS2), agouti-related peptide (AgRP), orexin, and melanocortin receptor 1 (MC1R) mRNA (Shipp et al., 2015b). While this chapter does not contain an exhaustive list of hormones and their effects on food intake in domestic fowl, it is important to note that many do indeed affect feeding behavior either directly or indirectly.

28.3 Central nervous system control of food intake

Food intake regulation is highly conserved across animals, and thus neural and endocrine networks controlling this behavior are similarly conserved. The hypothalamus has emerged as the major site of food intake regulation (Hussain and Bloom, 2013). The hypothalamus receives signals from the gut, pancreas, liver, and adipose tissue as well as other parts of the brain, and it integrates these inputs to modulate appetite and feeding behavior (Figure 28.1) (Richards and Proszkowiec-Weglarz, 2007). As in mammals, lesioning the medial hypothalamus of avian species increases food intake, whereas lesioning the LHA decreases food intake (Kuenzel et al., 1999). While these sites were traditionally considered the satiety and hunger centers, respectively, it is currently believed that they are considered to be parts of larger neural circuits involved in food intake regulation (Figure 28.2).

The neurochemical control of food intake is complex. Within the CNS, many neurochemicals have been shown to function in food intake control. As will be discussed in the "Classical Neurotransmitters" section, there are many classical neurotransmitters (Table 28.2) as well as peptides (Table 28.3) that act in the CNS to alter food intake. In general, these compounds act similarly between mammals and avian species. However, there are some notable exceptions. While peptide YY and pancreatic polypeptide decrease food intake in mammals, they stimulate food intake in birds. As discussed earlier, ghrelin is a potent orexigenic peptide in mammals but is anorexigenic in birds, and leptin acts as an important satiety factor that signals fat mass in mammals but does not appear to exert either of these functions in birds. Other peptides shown to be orexigenic in mammals, including melanin concentrating hormone (MCH), orexins (A and B) (Katayama et al., 2010a), and motilin, have no effect on food intake in chickens. Finally, PrRP stimulates food intake in chickens but inhibits it in mammals.

28.4 Classical neurotransmitters

Many classical neurotransmitters have a role in the CNS in the control of food intake in birds, and this effect can vary with the type of bird (Table 28.2). For example, ICV injection of epinephrine (E) increased food intake in broiler (meat-type) chickens (Denbow et al., 1981), but was

without effect in Leghorn (egg-type) chickens (Denbow et al., 1983), and reduced food intake in turkeys (Denbow, 1983). More recently, Katayama et al. (2010b) reported that high doses of NE injected ICV reduced food intake in broiler chicks, and this effect was not associated with changes in brain NPY or pro-opiomelanocortin (POMC) concentrations. However, Bungo et al. demonstrated a stimulatory effect of ICV NE on food intake in layer chicks. Dopamine, L -DOPA, and tyrosine did not affect feeding in layer chicks (Bungo et al., 2010). Serotonin (5-hydroxytryptamine; 5-HT) decreases food intake when injected into the brain of both Leghorns and broilers (Table 28.2). When serotonin was ICV injected into broiler chicks, there was activation of the VMH and IN, implicating these hypothalamic regions in mediating the food intake-reducing effects of 5-HT (Zhang et al., 2017). Adding fenfluramine, a drug that increases the action of serotonin, to the diet of layers and broilers decreased food intake (Hocking and Bernard, 1993), supporting that endogenous serotonin acts as an appetite suppressant in chickens.

In mammals, NE, when injected into specific brain sites, both increases and decreases food intake depending on the site of injection. Injections into the VMH or PVN stimulate feeding, while injections into lateral sites including the perifornical region decrease feeding. In Leghorns, NE stimulated food intake when injected into the VMH, PVN, and medial septal sites (Denbow and Sheppard, 1993). NE inhibited food intake when injected near the lateral septal organ and the anterior portion of both the nucleus reticularis superior, pars dorsalis, and the tractus occipitomesencephalicus. Furthermore, food intake was increased in layer-type chicks after ICV injections of clonidine, an α2-adrenergic agonist acting at presynaptic sites, and this effect was attenuated by yohimbine, an α2-adrenergic antagonist (Tachibana et al., 2009b). Whereas ICV injections of 0.1 and 0.2 nmol of clonidine stimulated food

intake in broilers (Bungo et al., 1999), 0.8 but not 0.4 nmol increased food intake in layer-type chicks. Therefore, it appears that selection for rapid growth rate in broilers results in increased sensitivity to α2-adrenergic stimulation. ICV injection of BRL37344, a β3-adrenergic receptor agonist, suppressed food intake (Tachibana et al., 2003a).

The major inhibitory neurotransmitter in the CNS is γ-aminobutyric acid (GABA). GABA increases food intake in both broilers and turkeys (see Table 28.2). This effect appears mediated by GABAA, but not GABAB (Jonaidi et al., 2002). Muscimol, a GABAA receptor agonist, was able to stimulate food intake in broilers, while baclofen, a GABAB receptors agonist, had no effect.

Histamine inhibits food intake when injected ICV into both broiler and Leghorn chicks (Meade and Denbow, 2001). Histamine can work at three receptor subtypes: H1, H2, and H3. The H3 receptor is an autoreceptor that inhibits the release of endogenous histamine from histaminergic

neurons. The anorexigenic effect of histamine was attenuated by the H1 receptor antagonist chlorpheniramine and the H2 receptor antagonist cimetidine. Taati et al. (2010) showed that injection of thioperaminde, an H3 antagonist that enhanced histamine release, decreased food intake in 3-week-old broilers. In contrast, R-α-methylhistamine, an H3 agonist, increased food intake. The H1 receptor antagonist chlorpheniramine attenuated the effect of thioperaminde, whereas famotidine, an H2 receptor antagonist, had no effect except at high doses, at which it decreased food intake. Therefore, while it appears that the H1 receptor is involved in mediating the effect of a histamine-induced decrease in food intake, the role of the H2 receptor is still unclear.

28.5 Peptides

The list of peptides known to alter food intake is large and growing (Cline and Furuse, 2012). Many of these peptides have orexigenic effects (Table 28.3), and most have anorexigenic effects (Table 28.4). In the discussions that follow note that the source of peptide is not indicated for most studies and whether an avian species-specific or mammalian sequence-specific peptide was used could influence the food intake and behavioral response to injection of the peptide, as could the route of administration. For most studies that focus on effects of central administration, peptides are injected ICV, with some involving cannulation into specific nuclei at older ages. Almost all of the studies cited herein (at least those that involve ICV injection) were conducted with chicks that were less than a week old. The reason is that the skull has not yet ossified, permitting a free-hand injection, which is also why cannulations are required at an older age.

During the last decade, there have been many reports of peptide-induced changes in feeding behavior that are accompanied by molecular studies, primarily a survey of gene expression changes at the whole hypothalamic and even nucleus-specific level. Because the understanding of appetite regulation in birds has lagged behind mammalian research, such studies have enhanced knowledge of appetite regulatory mechanisms by leaps and bounds although much remains to be elucidated, and such work is difficult due to the anatomical and functional complexities of the CNS. Punch-biopsy techniques for isolating brain nuclei and procedures facilitating the extraction of high-quality nucleic acids, as well as advents in sequencing technology have facilitated understanding the resolution of gene expression at the nucleus level. This is particularly important given the distinct functionalities of different hypothalamic nuclei. For most of the research described herein, assessments of molecular changes in response to ICV administration were carried out at 1-h postinjection, allowing for comparisons among studies. The 1-h time point is not arbitrary; it is the time at which expression of c-Fos, an indirect marker for neuronal activation, is expected to be most robust, and as such it is considered to be an optimal time to quantify it as a marker for brain nucleus activation.

28.5.1 Neuropeptide Y

First isolated from the pig brain in 1982 (Tatemoto et al., 1982), NPY is one of the most abundantly expressed peptides in the CNS. With a highly conserved sequence of 36 amino acids, the mammalian and avian amino acid sequences differ by a single residue (Blomqvist et al., 1992; Larhammar, 1996). In both mammals and avian species,

[c]*Treatment had an orexigenic effect.*

NPY is one of the most potent orexigenic regulators of food intake (Kuenzel and McMurtry, 1988). NPY stimulates food intake via NPY Y2 and Y5 receptors, but not the Y1 receptor. Whereas in mammals peptide YY and pancreatic polypeptide suppress appetite, in broiler and Leghorn chicks peptide YY increases food intake (Kuenzel et al., 1987; Denbow et al., 1988). Peptide YY was much more potent than NPY in stimulating food intake, which may

reflect a difference in the affinities of NPY and peptide YY to these NPY receptor subtypes.

In mammals, within the hypothalamus, the ARC is a major site for food intake regulation (Hussain and Bloom, 2013). This nucleus has a semipermeable blood−brain barrier allowing peripheral signals to reach the brain. There are first-order orexigenic neurons in the ARC containing NPY and co-expressing AgRP, and a second population of anorexigenic neurons containing POMC−CART (cocaine- and amphetamine-regulated transcript) neurons. These neurons then communicate with second-order neurons in other nuclei expressing such peptides as CRF, orexins, and MCH. Upon fasting, NPY mRNA levels increase in the ARC, and this coincides with an increase in NPY peptide content and release in the PVN.

The melanocortin 4 receptor (MC4R) is associated with inhibition of food intake. Release of AgRP, an endogenous MC4R antagonist, from the NPY−AgRP neurons in the ARC blocks the MC4R, causing increased food intake. In addition, α-melanocyte-stimulating hormone (α-MSH), which is cleaved from the POMC protein, is an agonist at the MC4R and causes decreased food intake. Therefore, fasting increases expression of AgRP mRNA and decreases expression of POMC mRNA.

In avian species, NPY-containing neurons are located in the IN, homologous to the ARC in mammals (Kuenzel, 1994; Wang et al., 2001), and these neurons co-express AgRP (Boswell et al., 2002). As in mammals, NPY gene expression increases in the hypothalamus in fasted and food-restricted avian species (Phillips-Singh et al., 2003; Song et al., 2012). Therefore, as in mammals, AgRP blocks the anorexigenic melanocortin pathway, while NPY mediates the orexigenic pathway.

ICV injections of NE do not alter brain NPY or POMC mRNA expression (Katayama et al., 2010b). However, the increase in food intake induced by ICV NPY is attenuated by yohimbine, an α 2-adrenergic receptor antagonist (Tachibana et al., 2009b). This suggests that NPY neurons possibly work via communication with adrenergic neurons that act at α2-adrenergic receptors. Furthermore, a GABAA antagonist is able to attenuate the response to NPY (Jonaidi and Noori, 2012). In young Japanese quail, ICV NPY was orexigenic, but only during the light cycle, and the IN was activated robustly, similar to other species (McConn et al., 2018b). Hypothalamic AgRP and NPYR1 and two mRNAs were all increased in NPY-injected quail, with increased NPYR2 mRNA also observed within the ARC (McConn et al., 2018b).

28.5.2 Melanocortins

Melanocortins are peptide hormones that are derived from POMC, including the melanocyte-stimulating hormones and ACTH, and in mammals most are released from neurons in the ARC. While these peptides can act at five different melanocortin receptor subtypes (MC1R through MC5R) distributed throughout the body, MC3R and MC4R are expressed in the mammalian brain. MC3R appears to regulate energy expenditure, while MC4R is involved with food intake. Agonists of the MC3R receptor decrease food intake.

ICV injection of α-MSH reduced food intake in fasted broiler chicks and attenuated NPY-induced food intake (Kawakami et al., 2000). Conversely, AgRP attenuated α-MSH-induced anorexia (Tachibana et al., 2001). CART, which is also found in the POMC neurons, also decreased food intake in broiler and layer chicks and attenuated NPY-induced feeding (Tachibana et al., 2003b). Broiler chicks ICV injected with α-MSH had more c-Fos expression in the IN, PVN, dorsomedial nucleus (DMN), and LHA (Delp et al., 2017). Moreover, in the IN, there was greater mRNA abundance of NPY, mesotocin (MT) receptor, and AgRP, and in the PVN reduced expression of NPYR1 and greater expression of c-Fos mRNA (Delp et al., 2017). In the DMN of α-MSH-injected chicks, there was also greater c-Fos mRNA and more L-amino acid decarboxylase (AADC) mRNA. These results collectively suggest that in broiler chicks, melanocortin signaling reduces NPY signaling in the PVN while activating NPY/AgRP neurons in the IN to reestablish basal levels of food intake. Anorexigenic effects were also observed in young Japanese quail, as well as activation of the VMH and PVN, which differed from activation patterns in broiler chicks (Lear et al., 2017). Hypothalamic (nucleus-specific samples were not collected) expression of AgRP and AADC was reduced while MC4R mRNA was increased in α-MSH-injected quail (Lear et al., 2017).

In mammals, β-MSH binds MC4R with higher affinity than α-MSH (Harrold et al., 2003), suggesting that it may be the main endogenous melanocortin receptor agonist. However, in chickens, α-MSH binds to MC4R with greater affinity than does β-MSH (Ling et al., 2004). In broiler chicks, β-MSH decreased food and water intake while increasing plasma corticosterone concentrations (Smith et al., 2008). Gamma-MSH, a selective MC3R agonist, also reduced food intake in broiler chicks, but required larger doses than α- or β-MSH (Smith et al., 2011). Hence, it appears that the melanocortin system is involved in anorexigenic pathways in birds, but the role and location of the various receptors still need further elucidation.

28.5.3 Corticotropin-releasing factor, urocortins, and urotensins

The CRF family of proteins includes CRF, sauvagine, urotensins, and urocortins in mammals. CRF acts within the brain to decrease food intake in both broilers and Leghorns (Furuse et al., 1997; Denbow et al., 1999). ICV injection of

the CRF homolog stresscopin reduced food and water intake in broiler and White Leghorn chicks (Cline et al., 2009d). This was associated with an increased number of c-Fos immunoreactive cells in the VMH, the parvicellular and magnocellular divisions of the PVN, and the posterior hypothalamic nucleus (PHN), indicating increased neuronal activity in these areas. This anorexigenic effect was mediated via CRF receptors. In broiler chicks, CRF injection was associated with activation of the IN, DMN, VMH, and PVN (Wang et al., 2019c). There was also decreased hypothalamic NPYR1 mRNA, more IN-specific CRF and CRFR2 mRNA, but less AgRP, NPY, and NPYR1 mRNA, and more CRFR2 and MT mRNA in the PVN and VMH, respectively. In the DMN, there was less NPYR1 mRNA in CRF-injected chicks (Wang et al., 2019c). Khan et al. (2008) showed that the anorexigenic effect of CRF was attenuated by blocking nitric oxide in broiler chicks. In layer chicks, CRF and urocortin-3 (UCN3) exerted similar anorexigenic effects post-ICV injection and also delayed crop emptying and increased cloacal temperatures (Ogino et al., 2014). In Japanese quail, the anorexigenic response to CRF was associated with activation of the LHA and PVN and increases in the hypothalamic mRNA abundance of POMC, MC4R, CRF, and CRFR2 (Wang et al., 2019a).

As discussed above, the site of action of ghrelin is the CNS. In mammals, ghrelin potently stimulates food intake mainly by stimulating NPY neurons located in the ARC. In contrast, an ICV injection of ghrelin inhibits food intake in broiler chicks, an effect opposite that in mammals (Furuse et al., 2007). In elucidating the mechanism of ghrelin in birds, Saito et al. (2005) showed that an ICV injection of ghrelin increased plasma corticosterone. Co-injection of the CRF receptor antagonist astressin attenuated the ghrelin-induced decrease in food intake and plasma corticosterone increase. Furthermore, co-injection of ghrelin with NPY inhibited the NPY-induced increase in food intake, and the ICV injection of ghrelin did not change NPY mRNA expression. In contrast to mammals, in which ghrelin induces the release of NPY from neurons in the ARC, in birds, ghrelin in the CNS inhibits food intake through the release of endogenous CRF. Taati et al. (2010) demonstrated that blockade of histamine H1 but not H2 receptors attenuated ghrelin's anorexigenic effect. Thus, in chicks, ghrelin, via the histaminergic system, likely causes CRF release, which is ultimately responsible for ghrelin-induced anorexia.

28.5.4 Mesotocin and arginine-vasotocin

Mesotocin (MT) and arginine-vasotocin (AVT) are both posterior pituitary-derived hormones that are homologous to mammalian oxytocin (OT) and vasopressin, respectively. ICV administration of MT to layer chicks decreased food intake, whereas IP injection had no effect (Masunari et al., 2013). Interestingly, both ICV-injected MT and AVT are anorexigenic and induce wing-flapping in chicks and effects are thought to be mediated through the vasopressin-4 receptor (Masunari et al., 2016). ICV-injected MT decreased food intake in broiler chicks and activated the PVN and LHA (McConn et al., 2019c). MT-injected chicks had greater expression of MT mRNA in the LHA and AADC in the PVN, and similar to OT, MT injection elevated cloacal temperatures (McConn et al., 2019c). Previous studies had alluded to involvement of α-adrenergic signaling in MT's effects, although ICV administration of yohimbine, an α_2-adrenergic receptor antagonist, had no effect on food intake, MT-mediated changes in food intake or hyperthermia (McConn et al., 2019c). ICV injection of OT also decreased feeding behavior in broiler chicks, which was accompanied by activation of the IN, DMN, LHA, PVN, and VMH, reduced hypothalamic CRF mRNA, and increased cloacal temperature (McConn et al., 2019a). It is interesting to note that OT and MT differ by only a single amino acid, yet they elicited slightly different effects in broiler chicks.

28.5.5 Opioids and kyotorphin

Opioids act as inhibitory neurotransmitters and are widely distributed throughout the CNS. Opioid receptors include μ, δ, or κ subtypes. The opioid antagonists naloxone and naltrexone decrease food intake in both broilers and layers (see Denbow, 1999). Met-enkephalin, also known as opioid growth factor, is an endogenous opioid peptide derived from proenkephalin that activates the opioid receptors. Opioids appear to alter food intake in birds by acting at the δ- and κ- opioid receptors (Bungo et al., 2004). Dodo et al. (2005) reported that antagonists of the μ-opioid receptor, especially the μ1-receptor, reduced NPY-induced feeding in neonatal chicks.

Nociceptin−orphanin FQ (N/OFQ) is structurally similar to opioids, and binds to the opioid-like G protein-coupled receptor 1, or nociceptin receptor (NOP). N/OFQ shows structural similarities to the classical opioid peptides, particularly dynorphin A, but N/OFQ does not interact with the dynorphin A−κ-opioid receptor system. N/OFQ stimulated food intake in rats (Polidori et al., 2000). Similar to other opioids, ICV injection of N/OFQ increased food intake and pecking frequency in broiler chicks (Abbasnejad et al., 2005). Similarly, ICV N/OFQ stimulated food intake in White Leghorn chicks, and this was associated with increased AgRP and decreased CART mRNA expression in the diencephalon (Bungo et al., 2009). N/OFQ-induced increase in food intake was blocked by α-MSH. There was no change in NPY or POMC mRNA.

Kyotorphin, (L-tyrosyl−L-arginine), a met-enkephalin-releasing dipeptide, is associated with analgesic and orexigenic effects, in association with opioid receptor signaling

(Webster et al., 2013). In broiler chicks, ICV injection of kyotorphin was orexigenic and effects were blocked when all opioid receptor subtypes were antagonized, suggesting that hunger-stimulating effects were mediated through opioid receptor signaling (Webster et al., 2013). These findings were consistent with earlier working showing that met-enkephalin administration increased food intake in chicks (McCormack and Denbow, 1989). Kyotorphin injection was also associated with increased c-Fos expression in the LHA, ARC, and nucleus of the solitary tract (NTS) in the brainstem, implicating these regions in mediating the central effects of kyotorphin (Webster et al., 2013).

28.5.6 FMRFamides

Since molluscan neuropeptide Phe−Met−Arg−Phe−NH2 (FMRFamide) was isolated from the ganglia of the clam, similar neuropeptides containing the RFamide sequence at their C-termini (RFamide peptides) have been characterized in various invertebrates. The chicken pentapeptide Leu−Pro−Leu−Arg−Phe−NH2 (LPLRFamide) cross-reacts with the FMRFamide antibody and was the first RFamide isolated from a vertebrate (Dockray et al., 1983). Several RFamides function as orexigenic factors in neonatal chicks, including PrRP and gonadotropin-inhibitory hormone (GnIH).

PrRP was originally proposed to be a stimulator of prolactin release in mammals, hence the name (Hinuma et al., 1998). PrRP in mammals consists of two versions, PrRP-20 (20 amino acids) and PrRP-31 (31 amino acids), with the shorter having the same sequence as the C-terminus of PrRP-31 (Tachibana and Sakamoto, 2014). A 31-amino acid PrRP known as PrRP2, and the C-terminal PrRP-20 were both identified in the brain of chickens, with the 31-amino acid version increasing food intake in chicks and decreasing prolactin concentrations after central administration (Tachibana et al., 2011b). Interestingly the effect on prolactin secretion in chicks differed depending on route of administration, where peripheral injection of the chicken PrRP2 (31 amino acids) increased prolactin secretion, and circulating growth hormone levels decreased in response to both central and peripheral injection (Tachibana et al., 2011b). In chickens, two PrRP receptors (cPrRPR1 and cPrRPR2) have been identified and detected in several brain regions, including the telencephalon, midbrain, cerebellum, hindbrain, and hypothalamus (Wang et al., 2012).

While central administration of PrRP decreased food intake in rats (Lawrence et al., 2000, 2002; Ellacott et al., 2002), ICV injection of PrRP increased food intake in layer chicks (Tachibana et al., 2004b), broiler chicks (Wang et al., 2015a, b), and young Japanese quail (McConn et al., 2020). In general, PrRP has a weaker orexigenic effect than NPY on an equimolar basis. The orexigenic effect of NPY was further enhanced with co-injection of PrRP, and hypothalamic NPY mRNA was increased in PrRP-injected chicks (Wang et al., 2015b). In Japanese quail, ICV PrRP was associated with activation of the DMN and ARC, with less and greater mRNA abundance of CRF in the DMN and ARC, respectively (McConn et al., 2020). Thus, PrRP and NPY may augment each other's orexigenic effects to stimulate feeding behavior in chickens.

Tsutsui et al. (2000) isolated a novel decapeptide containing the C-terminal LPLRFamide motif, SIKPSAYLPLRFamide, from the quail brain. This peptide inhibited gonadotropin-releasing factor, and it was termed GnIH. The GnIH precursor encodes one GnIH and two GnIH-related peptides (called GnIH-RP-1 and GnIH-RP-2). ICV injection of GnIH, GnIH-RP-1, and GnIH-RP-2 significantly stimulated food intake in layer chicks (Tachibana et al., 2005a). Tachibana et al. (2008) demonstrated that the effect of GnIH is likely mediated via the μ-, but not δ- or κ-opioid receptor in broiler chicks. GnIH also did not appear to work via nitric oxide since a nitric oxide synthesis inhibitor had no effect on GnIH-induced feeding. More recent studies provide insights on molecular mechanisms. McConn et al. (2014) demonstrated that increased feeding in layer chicks in response to ICV GnIH was associated with activation of the LHA and some changes in hypothalamic gene expression, including an increase in NPY and decrease in POMC mRNA in the whole hypothalamus and increase in MCH mRNA within the LHA (McConn et al., 2014).

Ukena et al. (2010) demonstrated that another RFamide, 26RFa, exists in the anterior hypothalamus of Japanese quail. Its receptor, GPR103, was detected in the cerebrum, diencephalon, mesencephalon, and cerebellum. Ukena et al. (2010) also demonstrated that central injection of 26RFa increased food intake of broiler but not layer-type chicks. Additionally, metastin, another RFamide first isolated from the placenta, increased food intake in broiler chicks, and its effects were mediated by μ-opioid receptors (Khan et al., 2009).

In contrast to PrRP, GnIH, and 26RFa, there are other members of this family associated with anorexia. Chicks that received ICV LPLRFamide ate less at 30 min postinjection, but this effect dissipated by 40 min postinjection (Cline et al., 2009c). Since LPLRFamide-treated chicks spent more time in deep rest while other behaviors were unaffected, the short-term anorexigenic effect of LPLRFamide is likely secondary to this behavior. Further evidence that LPLRFamide may not have a specific effect on food intake is a report of it having no effect on food intake in layer chicks Tachibana et al. (2005b).

Several members of the neuropeptide FF (NPFF) subfamily of the RFamide family decreased food intake in chicks (Cline and Furuse, 2012). For instance, ICV injections of NPFF dose-dependently reduced food intake in broilers (Cline et al., 2007a). The effect of NPFF is mediated through the μ and κ subtypes of opioid receptors, and NPFF attenuates NPY and β-endorphin (β-END)-induced food intake stimulation (Cline and Mathews, 2008).

28.5.7 Galanin

Galanin, a peptide found in both the CNS and intestine, is conserved across species. Tachibana et al. (2008) demonstrated that ICV galanin stimulated food but not water intake in both broiler and layer-type chicks. It appears to work via μ-opioid receptors, and α2 adrenoceptors likely mediate this response. In chicks from lines selected for low or high body weight, the IN is activated after ICV injection, suggesting that this nucleus is involved in the orexigenic effect of galanin (Hagen et al., 2013).

28.5.8 Visfatin

Visfatin, also known as pre-B cell colony-enhancing factor, is a peptide that was originally isolated from visceral fat of humans and mice, and mimics the actions of insulin (Fukuhara et al., 2005). Visfatin is associated with metabolic syndrome in humans (Filippatos et al., 2007). The effect of visfatin on food intake was first determined in broilers in which ICV injections nearly doubled food intake and pecking efficiency (Cline et al., 2008c). This was accompanied by an increase in the number of c-Fos immunoreactive cells in the LHA and a decrease in activity in the VMH. Brunetti et al. (2012) showed that in rats, visfatin injection into the ARC increased food intake and decreased CART and CRF mRNA levels, suggesting that visfatin has a similar effect in birds and mammals. More recently, another group confirmed that ICV injection of visfatin increased food intake in chicks and through transcriptomic analysis identified hypothalamic pathways that are likely involved, including POMC/CRF and NPY/AgRP (Li et al., 2018).

28.5.9 Somatostatin

Somatostatin, known for the inhibition of growth hormone release, also affects food intake. While it was shown to increase and decrease food intake in rats depending on their feeding state, ICV injections of somatostatin increased food intake in broilers and layer-type chicks (Tachibana et al., 2009a). Its effects were mediated by μ-opioid and adrenergic α2 receptors. Through ICV injections of somatostatin analogs, it was shown that somatostatin receptors SSTR2, SSTR3, and SSTR5, but not SSTR4, were associated with somatostatin-induced increased food intake (Tachibana et al., 2011a).

28.5.10 Glucagon superfamily

Glucagon-like peptide-1 (GLP1) is a member of the glucagon superfamily of peptides. Similar to mammals, ICV injection of GLP1 decreases food intake in broiler chicks (Bungo and Furuse, 2001). Growth hormone-releasing factor increases food intake in rats; however, it is a potent inhibitor of food intake in broiler chicks (Furuse et al., 2001). Similarly, other neuropeptides belonging to the glucagon superfamily, including vasoactive intestinal peptide (VIP) (Khan et al., 2013), gastric inhibitory peptide, and pituitary adenylate cyclase-activating polypeptide (PACAP), reduced food intake in layer chicks (Tachibana et al., 2004a). ICV injection of PACAP and VIP increases plasma corticosterone concentrations, and these effects are attenuated by co-injection with the CRF receptor antagonist astressin, suggesting that PACAP and VIP function through activation of CRF neurons (Tachibana et al., 2004a). Consistent with this hypothesis, ICV injection of VIP was associated with decreased diencephalic gene expression of CRF, UCN3, and CRFR2, suggesting involvement of CRF receptor signaling in mediating the anorexigenic effects of VIP (Khan et al., 2013). Similarly, glucagon (Honda et al., 2007a) and oxyntomodulin (Cline et al., 2008a) decreased food intake in chicks when injected ICV.

28.5.11 Cholecystokinin and gastrin

Cholecystokinin (CCK), originally isolated from the porcine small intestine, decreases food intake when injected peripherally or centrally into mammals. There are multiple bioactive forms of CCK, including CCK33, CCK (26−33; sulfated CCK8, CCK8S), and CCK (30−33; CCK4), with sulfated (tyrosine that is seventh amino acid from C-terminus) and unsulfated forms eliciting physiological effects. In chickens, CCK decreased food intake when centrally injected into broilers (Denbow and Myers, 1982). In layer chicks, both CCK8 and 8S reduced food intake following IP or ICV injection, however, via both routes effects of the sulfated form were of a greater magnitude than the nonsulfated form (Tachibana et al., 2012). That chicks displayed conditioned aversion with greater plasma corticosterone concentrations suggested that anorexigenic effects might be related to malaise, especially via the central route. In contrast, CCK4 had no effect on food intake via either injection route (Tachibana et al., 2012).

The structurally related peptide gastrin does not appear to decrease food intake in mammals. While the amino acid sequence of chicken CCK8 is identical to that of mammalian species, differences exist between chicken and mammalian gastrin. Furuse et al. (1999) demonstrated that ICV injection of chicken gastrin inhibits food intake and food passage in neonatal chicks. Moreover, the efficacy of these peptides depends on the length of their peptide sequence (Furuse et al., 2000).

28.5.12 Calcitonin family

Like the glucagon superfamily, members of the calcitonin gene peptide superfamily, including calcitonin, calcitonin

gene-related peptide (CGRP), adrenomedullin, and amylin, appear involved in food intake regulation. These peptides are derived via tissue-specific alternative splicing of the primary RNA transcripts of the calcitonin gene.

Amylin causes a dose-dependent decrease in food intake after ICV and IP injection in broilers (Cline et al., 2008d). This was associated with increased neuronal activity in the area postrema and the NTS, two nuclei in the brainstem. In addition, amylin caused increased alimentary canal transit time, plasma corticosterone concentration, and anxiety-related behaviors. Because amylin is co-secreted with insulin, it may be involved in terminating meals in chicks.

ICV injection of calcitonin also reduced food and water intake in broiler chicks (Layne et al., 2009). This was associated with increased activation of the ARC, DMN, and VMH, and the CRF system likely does not mediate this response. Similarly, broilers that received ICV and IP CGRP reduced both their food and water intake, but CGRP's effect on water intake appeared to be related to its effect on food intake (Cline et al., 2009a). CGRP-induced anorexia coincided with increased activation of the ARC, PVN, PHN, and VMH. Adrenomedullin, when ICV injected, produced anorexigenic effects in broiler chicks that appeared to be CRF-independent, and associated with activation of the PVN, VMH, and DMN (Wang et al., 2014a).

28.5.13 Insulin

Insulin decreases food intake when injected into the brain of mammals. Similarly, ICV injection of insulin decreased food intake in White Leghorn chicks (Honda et al., 2007b; Shiraishi et al., 2008a) while increasing expression of POMC, CART, and CRF, but not affecting NPY and AgRP mRNA in the hypothalamus (Honda et al., 2007b). Shiraishi et al. (2008a), however, reported a decrease in NPY expression after ICV insulin when including the brain stem. Blocking the melanocortin receptors prevented the anorexic effect of ICV insulin (Shiraishi et al., 2008a). Coinjection of β-END and insulin decreased central POMC expression more than insulin injection alone, while blocking μ-opioid receptors reduced the effect of insulin on food intake (Shiraishi et al., 2008b). Food intake was decreased in Leghorns by chicken and pig insulin, but not by human or bovine insulin (Shiraishi et al., 2009).

Several other appetite regulators related to insulin function have been identified. Beta-cell-tropin is derived from ACTH and is a beta-cell insulin secretagogue as the name implies. ICV injection into broiler chicks stimulated food intake, similar to rats, making it one of the relatively few endogenous factors that stimulates appetite (Shipp et al., 2015a). The drug, rosiglitazone (a thiazolidinedione and PPARγ agonist), is used to treat diabetes because of its insulin-sensitizing effects in peripheral tissues and one of the documented side effects is increased eating, which was also observed after ICV injection into broiler chicks (Matias et al., 2017).

28.5.14 Bombesin

Bombesin, a tetradecapeptide identified in amphibian skin, inhibits food intake in mammalian species. Denbow (1989) reported that both ICV and IV injection of bombesin decreased food and water intake in turkeys. ICV injection of bombesin inhibits food intake in broilers, and co-injection with NPY suppressed the orexigenic effect of NPY (Bungo et al., 2000). ICV and IP injections of bombesin analogs alytesin and litorin also decreased food intake in broiler chicks (Cline et al., 2008b, 2010a). Similar to its analogs, bombesin, when administered IP, was anorexigenic in layer chicks, and also delayed crop emptying (Tachibana et al., 2010c).

28.5.15 Neuromedin family

There are at least seven neuropeptides in the neuromedin family, including the bombesin-like peptides (B and C), tachykinin-like (K and L), neurotensin-like (N), and neuromedin U-like (U and S), most of which have been demonstrated to inhibit appetite in chicks. Several bombesin-like peptides, including gastrin-releasing peptide (GRP) and neuromedins B and C (NMB and NMC, respectively) (Tachibana et al., 2010b), as well as NMS (Tachibana et al., 2010a), exerted potent anorexigenic effects following ICV injection into layer chicks, with no effect on drinking behavior. Via the ICV route, GRP reduced food intake in broiler chicks but had no effect on alimentary canal transit rate (Bohler et al., 2019). In GRP-injected chicks, there was increased activation of the LHA, PVN, ARC, as well as the NTS (Bohler et al., 2019).

Neuromedins B and C were also anorexigenic when administered via the IP route, and reduced crop-emptying rate irrespective of route of administration, although effects were weaker than for bombesin (Tachibana et al., 2010c).

Substance P, a member of the tachykinin family, reduced food intake after ICV injection into broiler chicks (Mace et al., 2014). The PVN of substance P-injected chicks was activated, and this coincided with increased UTS2 mRNA within the PVN, suggestive of a potential hypothalamic molecular mechanism involving CRF receptor signaling. In Japanese quail, similar effects were observed after ICV injection, with activation of the PVN and LHA, and upregulation of UTS2 and CRF mRNA in the PVN (Pauliukonis et al., 2020).

Neuropeptide K (NPK), another tachykinin peptide, reduced food intake of chicks and Japanese quail after ICV

injection, and these effects in quail were associated with activation of the ARC, LHA, and PVN (Wang et al., 2019b), and in chicks only the ARC and PVN (Prall and Cline, 2008). In the ARC of NPK-injected quail, there was less NPYR1, NPY, and AgRP mRNA but more POMC, CART, and neurokinin receptor 1 mRNA. In the PVN, NPK injection was associated with increases in CRF, CRFR2, MC3R, MC4R, and UCN3 mRNA (Wang et al., 2019b). These results suggested that effects of NPK are mediated via the PVN, and indeed, when NPK was microinjected into the PVN of broilers, there was a reduction in food intake (McConn et al., 2019b). ICV injection of NPK into broiler chicks was also associated with reduced PVN-specific CRF mRNA and ARC-specific AgRP mRNA (McConn et al., 2019b).

28.6 Selection for single growth-related traits alters food intake control mechanisms

As already discussed, while broilers have been genetically selected for rapid body weight gain and feed conversion, Leghorn chickens have been selected for egg production and, thus, a smaller body mass, and differences have been identified in their feeding responses to centrally and peripherally administered neurotransmitters and peptides. Much of the work exploring how selection for growth rate has altered the mechanisms controlling food intake has been conducted using unique lines of birds divergently selected for either low (LWS) or high (HWS) body weight at 8 weeks of age (Siegel, 1962; Rubin et al., 2010; Marquez et al., 2010; Jambui et ala., 2017). Selected for more than 60 generations, these lines at selection age (56 days) have more than a 12-fold difference in body weight with correlated differences in food intake and body composition, and they are composed of anorexic and obese individuals. The LWS line exhibits natural anorexia (Zelenka et al., 1988), and delayed (Dunnington and Siegel, 1996) or prevented sexual maturity (Dunnington et al., 1983, 1984). The HWS line contains compulsive eaters (Dunnington and Siegel, 1984). Burkhart et al. (1983) reported that lesioning the VMH of LWS chickens resulted in nonhyperphagic obesity, whereas similar lesions in HWS chickens had no effect. The VMH is thought to be involved in satiety, and selection for body weight may have altered its function.

As was suggested by Bray (1991) for mammals, Denbow (1999) suggested that differences in body weight in lines of chickens may have resulted from changes in the balance between the parasympathetic nervous system and SNS. Selection for increased body weight may have augmented the actions of the parasympathetic branch of the autonomic nervous system. Support for this hypothesis was provided when it was shown that LWS birds appear to have greater SNS activity compared to the HWS line (Kuo et al., 2001). For many of the anorexigenic neuropeptides, including α-MSH, CRF, insulin (Smith et al., 2011), amylin, and neuropeptide AF, the LWS birds respond to a lower dose than the HWS birds (Cline et al., 2010b). For example, CRF decreases food intake in both the LWS and HWS lines, but the LWS line responded to a lower dose than did the HWS line (Cline et al., 2009b). However, for OT (McConn et al., 2019a), neuropeptide S, calcitonin (Cline et al., 2010c), and CGRP (Cline et al., 2010c), the HWS respond to a lower dose than the LWS. MT, which differs by OT by only a single amino acid, produced anorexigenic effects in both lines, with the HWS responding at a higher dose threshold but having a longer duration of response (McConn et al., 2019b). The HWS and LWS respond similarly to GnIH (McConn et al., 2016), ghrelin, and galanin (Hagen et al., 2013). For several peptides, one line is nonresponsive; the LWS does not respond to NPY (Newmyer et al., 2013) or AgRP, while the HWS line does not reduce food intake when administered human recombinant leptin.

The lack of response in the LWS line to NPY was of particular interest because it is such a potent orexigenic factor with effects highly conserved among species, and hypothalamic nucleus activation was similar between lines after ICV injection; the LHA and PVN displayed increases in c-Fos expression in both lines. It was later discovered that the reduced sensitivity to NPY in the LWS chicks was stress-dependent; when LWS but not HWS chicks were exposed to a combination of nutritional and thermal stressor on the day of hatch, they became resistant to food intake-stimulating effects of ICV NPY 5 days later (Yi et al., 2016). It was then confirmed that stress-induced magnification of anorexia in the LWS was CRF-signaling dependent (Wang et al., 2017). ICV injection of astressin prior to stressor exposure abolished the refractoriness to NPY in LWS chicks, and in stressed LWS chicks there was increased mRNA abundance of CRF and its receptors in the PVN and NPY in the ARC (Wang et al., 2017). This stress-induced upregulation of hypothalamic CRF involved epigenetic changes in the CRF gene. In stressed LWS chicks, there was reduced methylation of DNA at a single site in the promoter region that disrupted binding of a transcriptional repressor, methyl-domain binding-protein 2 (Xiao et al., 2020). These results coupled to the observation that LWS chicks have greater SNS tone and concentrations of circulating corticosterone than HWS chicks, suggest that this line is more sensitive to chronic activation of the stress cascade, which is accompanied by increased anorexigenic tone due to heightened hypothalamic CRF signaling.

Several other avian genetic lines have been developed and used to determine the molecular mechanisms involved in the regulation of feed intake. Clark and co-workers determined the feed intake pattern of ISA brown layer

hens selected for high or low feed conversion ratio and showed that there is an impact of daytime on energy intake (Clark et al., 2019). Specifically, they found that both groups increased their feeding rate from 0300 to 1700h. Average feed intake was greater in low-feed efficient compared to the high-feed efficient birds (Clark et al., 2019).

Two Rhode Island Red chicken lines, divergently selected (Bordas and Merat, 1981) for high (R^+) or low (R^-) residual feed consumption exhibit a significant difference in energy intake where the R^+ line consumes (~70%) more feed compared to their R^- counterparts (Sintubin et al., 2014). Several orexigenic hypothalamic neuropeptides such as NPY and AgRP were more highly expressed at the mRNA level in R^+ compared to R^- chickens, which may explain the hyperphagic phenotype of the R^+ line (Sintubin et al., 2014). The hypothalamic adiponectin system, ghrelin system, and suppressor of cytokine signaling 3 (SOCS3) were differentially expressed between R^+ and R^- chicken lines (Sintubin et al., 2014). Although there is still a paucity of information in chickens, adiponectin has been shown to maintain energy homeostasis via stimulating appetite and feed intake in mammals (Kubota et al., 2007). Interestingly, serum and cerebrospinal fluid levels of adiponectin increased during fasting and were reduced after refeeding in rodents and adiponectin-deficient mice fed a high-fat diet exhibited reduced feed intake (Kubota et al., 2007). SOCS3 mRNA is localized throughout the brain and overexpression of SOCS3 in POMC neurons caused leptin resistance and obesity in mice (Reed et al., 2010). In addition, rats with SOCS3 knockdown in the mediobasal hypothalamus showed dysregulation of NPY expression in the ARC and alterations in their meal patterns: average meal size in the light period was increased and was accompanied by a compensatory decrease in meal frequency in the dark phase (De Backer et al., 2010). However, it is still unknown if other brain areas are involved in the effects of SOCS 3 on appetite and feed intake.

The expression profiles of (an)orexigenic hypothalamic neuropeptides were also determined in quail lines divergently selected for feed efficiency. The feed efficiency phenotype was achieved by reduced feed intake in females and increased body weight gain in males, suggesting that the mechanisms involved in the feed efficiency are gender-dependent. Molecular analyses showed that the relative expression of classical hypothalamic neuropeptides such as NPY, POMC, CART, CRF, melanocortin receptors (MC1R, MC2R, MC4R, and MC5R), and orexin was decreased in the high-feed efficient compared to low-feed efficient male quail (Blankenship et al., 2016). In female quail, the above-mentioned genes did not differ between groups, however adiponectin gene expression was lower in high-feed efficient compared to low-feed efficient female quails (Blankenship et al., 2016).

In summary, several lines of chicken and quail have been developed through selection for body weight or feed intake and serve as valuable models for understanding the physiological pathways involved in regulating appetite and whole-body energy homeostasis.

28.7 Other pathways involved in central appetite regulation

28.7.1 Cannabinoids

The active ingredient in marijuana is Δ9-tetrahydrocannabinol (Δ9-THC), and it can bind to the cannabinoid receptors CB1 and CB2 found in the brain. The endogenous ligands for the cannabinoid receptors are 2-arachidonoylglycerol and anandamide, and endogenous antagonists include O-2050 and AM4113. Endogenous cannabinoids are synthesized from phospholipid precursors in the cell membrane, and are typically released post-synaptically and act in a retrograde manner at presynaptic terminals. The CB1 receptor is present in the brain, as well as peripherally, in both birds and mammals, while the CB2 receptor is found on immune and blood cells (Pagotto et al., 2006). While the effects of Δ9-THC on food intake have been mixed, it is generally believed that it causes increased food intake and that decreased food intake is a secondary effect due to sedation (Pagotto et al., 2006). Abel et al. (1972) first showed an increase in food intake in chicks in response to Δ9-THC. Giving an inverse agonist either via the feed or by IV injection attenuated food intake in broiler chicks (Novoseletsky et al., 2011), supporting an orexigenic role for cannabinoids in birds.

28.7.2 AMP-activated protein kinase

AMP-activated protein kinase (AMPK) is a heterotrimeric enzyme complex composed of one catalytic (alpha) subunit and two regulatory (beta and gamma) subunits. AMPK is activated by allosteric regulation of AMP and by phosphorylation of threonine (thr 172) on the alpha subunit by upstream kinases, including liver kinase B1, calcium/calmodulin-dependent protein kinase kinase, and TGF-beta-activated kinase-1. AMPK acts as an energy sensor. Glucose, leptin, and insulin inhibit hypothalamic AMPK activity and decrease food intake in mice, while ghrelin and adiponectin stimulate hypothalamic AMPK activity and increase food intake in rats (Xu et al., 2011a). ICV injection of ghrelin inhibited hypothalamic AMPK gene expression and phosphorylation of the alpha subunit of AMPK. Furthermore, ghrelin was more efficacious in decreasing food intake in low-weight selected birds than in high-weight selected birds, supporting the hypothesis that selection for lower body weight resulted in increased sensitivity to ghrelin and the AMPK system (Xu et al., 2011a). When an AMPK stimulator AICAR and inhibitor Compound C were ICV injected into chicks, AICAR decreased food intake in the low-weight but not high-weight chicks, whereas Compound C increased food

intake in high-weight but not low-weight chicks (Xu et al., 2011b). Further evidence that endogenous AMPK regulates appetite is that dietary supplementation of alpha-lipoic acid, an AMPK inhibitor, decreased food intake in broiler chicks, an effect that was associated with reductions in the activated form of AMPK in the hypothalamus and was not due to taste aversion (Wang et al., 2014b).

28.7.3 Mechanistic target of rapamycin

In addition to its critical role in early brain development, synaptic plasticity, learning, and memory (Hentges et al., 2001; Tang et al., 2002; Ehninger et al., 2008), the highly conserved serine/threonine kinase mechanistic target of rapamycin (mTOR; Brown et al., 1994; Sabatini et al., 1994), plays a crucial and complex role in feed intake control. In 2006, Seeley's group demonstrated that mTOR and its downstream mediators such as the P70 ribosomal S6 protein kinase 1 (S6K1) are co-localized with AgRP- and POMC-expressing neurons in the rat ARC (Cota et al., 2006). Administration of leucine or leptin activated mTOR signaling and reduced feed intake and body weight, and inhibition of mTOR blockaded leptin's anorectic effects (Cota et al., 2006). Leptin was found to increase hypothalamic mTOR activity via the signal transducer and activator of transcription 3 (Buettner et al., 2006), and STATs have been reported to regulate the expression of (an)orexigenic neuropeptides which promote changes in feeding behavior (Münzberg et al., 2003; Ladyman and Grattan, 2013). Deletion of the tumor suppressor TSC1, the major upstream inhibitory regulator of mTOR, in POMC neurons resulted in hyperphagia and an obesity phenotype in mice (Mori et al., 2009). In quail, hypothalamic mTOR mRNA was lower, but STAT1, 5, and 6 were higher in high compared to low-feed efficient males (Blankenship et al., 2016). Lee and Aggrey found that mTOR gene expression was upregulated in the duodenum of chickens divergently selected for low-residual feed intake compared to their high-residual feed intake counterparts (Lee and Aggrey, 2016). Although mechanistic and functional studies are needed, the differential expression of central and peripheral mTOR between high- and low-feed efficient avian (quails and chickens) species suggests that mTOR may play a key role in energy homeostasis regulation.

28.7.4 Autophagy

Autophagy, a cellular self-eating or self-degradative process, was first characterized by Christian De Duve in 1967 (Deter and De Duve, 1967). Originally, autophagy was generally thought of as a programmed cell death called autophagic cell death (Yu et al., 2004, 2006). In more recent years, autophagy was identified as a survival mechanism. It plays a housekeeping role in removing misfolded and aggregated proteins, eliminating intracellular pathogens, and clearing damaged organelles such as endoplasmic reticulum (reticulophagy) and mitochondria (mitophagy) (Lee et al., 2012; Kroemer et al., 2008; Youle and Narendra, 2011). Evidence has emerged to support the role of autophagy in the regulation of energy homeostasis. Firstly, autophagy is activated not only by cellular damage, but also by starvation (Lin et al., 2012). When nutrients are scarce, autophagy allows cells to reutilize their own constituents for energy. More recently, Meng and Cai showed, by using site-specific deletion of autophagy related gene (Atg7) in the mediobasal hypothalamus, that inhibition of central autophagy increased feed intake and reduced energy expenditure (Meng and Cai, 2011) and demonstrated that this effect was mediated through the NF-κB pathway. Kaushik et al. (2011) demonstrated that starvation increased hypothalamic uptake of free fatty acids (FFAs) to make triglycerides within neuronal lipid droplets. This, in turn, leads to induction of neuronal autophagy that degrades lipid droplets (lipophagy) and generates neuron-intrinsic FFA, which induce the hypothalamic expression of AgRP and promote feed intake (Kaushik et al., 2011). Blocking lipophagy in AgRP-expressing neurons upregulated the hypothalamic levels of POMC and its cleavage product α-MSH leading to decreased feed intake in response to feed deprivation (Kaushik et al., 2011). Quan et al. (2012), on the other hand, generated a mouse model with site-specific deletion of Atg7 in hypothalamic POMC neurons and identified a key role in feeding behavior and leptin signaling. In chickens, Piekarski-Welsher et al. (2018) reported that autophagy machinery was enhanced in high-feed efficient compared to low-feed efficient pedigree male broilers. ICV administration of human recombinant leptin reduced feed intake, induced autophagic machinery, and modulated the hypothalamic expression of feeding-related neuropeptides in chickens (Piekarski et al., 2018). Together these studies indicate that autophagy may regulate feeding behavior in chickens which merits further in-depth mechanistic and functional studies.

Chapter 29

Overviews of avian neuropeptides and peptides

Yajun Wang

Key Laboratory of Bio-resources and Eco-environment of Ministry of Education, College of Life Sciences, Sichuan University, Chengdu, Sichuan, PR China

29.1 Introduction

Peptides are short stretches of amino acids (aas) linked by peptide bonds. They play important roles in nearly all physiological processes such as growth and development, reproduction, stress, metabolism, calcium homeostasis, immunity, cardiovascular functions, and central nervous system (CNS) functions (e.g., food intake, memory, behavior and analgesia). Inside the cells, peptide precursors (prepropeptides) generally require proteolytic cleavage and sometimes posttranslational modification(s) (such as amidation and disulfide formation) to become the bioactive mature peptides. Most peptides act either as hormones or neurotransmitters/neuromodulators to exert their actions via membrane-spanning receptors, such as G protein-coupled receptor (GPCR) with seven transmembrane domains. Some peptides also display antimicrobial activities. According to their sources and functions, peptides can be further classified as neuropeptides, endocrine peptides (hormones), gut peptides and host defense peptides (HDPs), etc. Among these, neuropeptides are the peptides released by neurons to influence the physiological activity in the body.

Due to the availability of sequenced genomes of many birds, such as chickens, turkeys, and zebra finches, nearly all avian peptides and their receptors can be predicted through bioinformatic approach (Delfino et al., 2010; Xie et al., 2010). The recent advancement in sequencing technology also accelerates the studies on the structures and functions of avian peptides and their receptors, which will not only help to uncover the roles of these peptides in avian physiological processes, such as growth, reproduction, metabolism, and energy balance, but also facilitate our better understanding of their contributions to the unique phenotypical traits of birds (e.g., flight and migration) and domestication of avian species (e.g., chickens and ducks).

Based on the literatures and sequenced avian genomes, in this chapter, we will present an overview of the structures, expression, and major actions of 134 peptides (Table 29.1) belonging to different peptide families in birds (e.g., chickens, quails, and finches) and their differences to mammalian peptides. In addition, the cognate/predicted receptors for avian peptides are also mentioned briefly.

29.1.1 Galanin/spexin peptide family

Galanin is a neuromodulator in the brain and peripheral nervous system (PNS) of vertebrates. Several structurally related peptides, including galanin-like peptide (GALP, 60 aas) (Ohtaki et al., 1999), Spexin (SPX), and Kisspeptins (KISS 1, KISS2, KISS3, and KISS4), have later been identified, all of which are proposed to be originated from a common ancestral gene and belong to the same peptide family (Kim et al., 2014).

Galanin was isolated from the chicken intestine (Norberg et al., 1991) and quail oviduct (Li et al., 1996). It is a 29-residue peptide which contains an amidated threonine at its C-terminus, which is proteolytically cleaved from a large precursor. Interestingly, *GALP* gene is likely lost in the avian lineage (Ho et al., 2012).

SPX is a 14-residue peptide encoded by the *C12ORF30* gene (Mirabeau et al., 2007; Sonmez et al., 2009) in mammals. In chickens, two ortholog peptides of 14 aas (named SPX1 and SPX2) encoded by separate genes have been identified. Both peptides share high sequence similarity with each other and a comparatively low identity with chicken galanin (Fig. 29.1) (Kim et al., 2014; Lim et al., 2019).

Note: Only the major chicken peptides/neuropeptides are listed here; "-NH2" means C-terminal amidation of peptide may be required for its biological activity; other modifications (e.g., disulfide bond, sulfonation, acylation, and N-terminal glutamate cyclization) of peptides are described in the main text, and not described here.

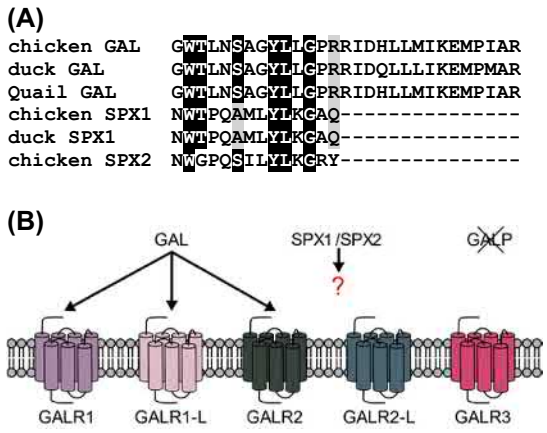

FIGURE 29.1 (A) Alignment of galanin family peptides, Galanin (GAL) and Spexin (SPX1, SPX2) in chickens, ducks, and quails. Two other galanin family members found in mammals, GALP and KISS, are likely lost in avian lineage. (B) Five receptors [GALR1 (EU647890), GALR1-like (GALR1-L, EU530818), GALR2 (EU525170), GALR2-like (GALR2-L, EU725863), and GALR3 (NP_001124057)] have been identified in birds. Among them, GALR1-L and GALR2-L exist in birds and have not been identified in mammals. GALR1, GALR1-L, and GALR2 can function as receptors for GAL. It is unknown whether they can act as receptor(s) for SPX1 and SPX2 in birds.

KISS1 has been proposed to be a key regulator of reproduction by activating gonadotropin-releasing hormone (GnRH) neurons, which can initiate the onset of puberty in mammals (Pinilla et al., 2012). However, KISS1 is possibly lost in avian genomes (Um et al., 2010). Interestingly, a KISS2-like gene was identified in ducks (HG328246), zebra finches, and rock pigeons (Pasquier et al., 2014). Nevertheless, avian KISS2 seems to be degenerated considerably in avian lineage, questioning its roles in birds.

In mammals, three GPCRs for GAL, GALP, and SPX, named GALR1, GALR2, and GALR3, have been identified. GALR1 is a high-affinity receptor for GAL. GALR2 and GALR3 are high-affinity receptors for GALP. GALR3 can function as a high-affinity receptor for SPX. In contrast, 5 GPCRs, named GALR1, GALR1-like (GALR1-L), GALR2, GALR2-like, and GALR3, have been identified in birds. GALR1, GALR1-L, and GALR2 can function as the three receptors for chicken GAL, and their activation inhibits cAMP/PKA signaling and stimulates the MAPK/ERK cascade (Ho et al., 2011, 2012). However, it is unknown whether SPX1 and SPX2 can activate the five receptors (Kim et al., 2014).

GPR54 can function as a receptor for KISS1 peptide in mammals. However, *GPR54* is likely lost in birds. The failure in identifying *KISS1* and *GPR54* does not support the role of KISS−GPR54 signaling in avian reproduction (Pasquier et al., 2014).

Galanin peptide is widely expressed in avian CNS, PNS, and other tissues, such as the intestine and oviduct (Norberg et al., 1991). In chickens, galanin is distributed in the CNS including the hypothalamus and brainstem (Jozsa and Mess, 1993; Klein et al., 2006) and is important in its regulation, such as stimulating food intake of layer and broiler chicks (Tachibana et al., 2008). In quail oviduct, galanin is expressed in the lumbosacral sympathetic ganglion neurons innervating the avian uterine muscle and thus can induce oviposition in quails (Li et al., 1996; Sakamoto et al., 2000; Ubuka et al., 2001). To date, the roles of SPXs in birds remain unclear.

29.1.2 Tachykinin peptide family

The tachykinin family neuropeptides are 10−12 aas in length and characterized by the presence of a C-terminal pentapeptide "Phe-X-Gly-Leu-Met-NH2", where X is either an aromatic aa (Phe/Tyr) or an aliphatic aa (Val or Ile) (Severini et al., 2002). Two tachykinin genes, TAC1 and TAC3, likely exist in chicken and other birds. After posttranslational processing, chicken TAC1 precursor can give rise to three bioactive peptides, substance P (SP, 11 aa), neurokinin A (NKA, 10 aa) and, neuropeptide ɣ (21 aa, an N-terminally extended form of NKA), among which SP and NKA were first purified from chicken small intestine (Conlon et al., 1988). TAC3 precursor can produce a neurokinin B (NKB, 10 aa).

In mammals, three GPCRs, named TACR1, TACR2, and TACR3, can selectively bind to SP, NKA, and NKB, respectively. Likewise, TACR1, TACR2, and TACR3 are predicted to exist in avian genomes. The pharmacological property, signaling property, and ligand selectivity of three receptors are largely unknown in birds.

In birds, SP immunoreactivity is widely distributed in neuronal cells or nerve fibers of the spinal cord (Du et al., 1987; Du and Dubois, 1988; Sakamoto and Atsumi, 1989), retina (Millar and Chubb, 1984a,b; Tahara et al., 1986), different brain regions (Reubi and Jessell, 1978) [e.g., hippocampus (Gould et al., 2001), hypothalamus (Erichsen et al., 1982), and median eminence [ME] (Ho and DePalatis, 1980)], epidermis and dermis (Sann et al., 1996), parathyroid gland (Egawa and Kameda, 1995), gut (Fontaine-Perus et al., 1981; McGregor et al., 1982; Saffrey et al., 1982; Epstein et al., 1983), and oviduct (De Saedeleer et al., 1989). In contrast to SP, the information regarding the distribution of NKA/NKB is limited. Radioisotope-binding assays or qPCR assays indicate the existence and expression of tachykinin (SP, NKA, and NKB) receptors in chicken brain (Too and Hanley, 1988), intestinal muscle (Liu and Burcher, 2001), and hypothalamic nuclei (Wang et al., 2019).

The expression of tachykinins (SP or NPK) and their receptors in the CNS and PNS suggests that as in mammals, tachykinins mainly function as neurotransmitters or neuromodulators associated with many physiological processes, such as pain transmission, inhibition of food intake

in chickens (Prall and Cline, 2008; Tachibana et al., 2010a; Mace et al., 2014; McConn et al., 2019) and quails (Wang et al., 2019; Pauliukonis et al., 2020), water intake in ducks and pigeons (de Caro et al., 1980a, 1980b; Massi et al., 1987), antidromic vasodilation (Sann et al., 1996), nasal salt gland secretion in ducks (Wilson, 1987), contraction of intestinal smooth muscle in chickens (Brodin et al., 1981), and oviductal and duodenal motility (De Saedeleer et al., 1989).

29.1.3 Calcitonin peptide family

Calcitonin (CT) peptide family includes CT, calcitonin gene-related peptide (CGRP), amylin (IAPP), and adrenomedullin (ADM) (Poyner et al., 2002). In chickens, these peptides were also found and encoded by four genes, *CACLA, IAPP, ADM*, and *ADM2*. Two *CACLA* transcripts generated by tissue-specific alternative splicing were identified: one coding for a bioactive CT peptide (32 aa) (Homma et al., 1986) and the other for a CGRP neuropeptide (37 aa) (Minvielle et al., 1986, 1987). *IAPP* encodes a bioactive IAPP of 37 aa, which shares ~80% sequence identity to human IAPP (Fan et al., 1994). *ADM* encodes a mature ADM peptide of 54 aa, which shares ~72% sequence identity to the human ortholog (Zudaire et al., 2005); *ADM2* is predicted to encode a mature ADM2 peptide of 53 aa (also named intermedin). These peptides show low aa sequence identity with each other; however, their secondary structures are conserved, including an intramolecular disulfide bond close to the N-terminus, a region of the amphipathic α-helix, and an amidated C terminus (Fig. 29.2A) (Poyner et al., 2002).

In mammals, two receptors for CT family peptides, calcitonin receptor (CTR) and calcitonin receptor-like receptor (CLR), have been identified. CTR alone can function as a CTR (Poyner et al., 2002), while CTR or CLR must heterodimerize with one of the three receptor activity–modifying proteins (RAMP1, RAMP2, and RAMP3) and give rise to the receptor(s) for CGRP (CLR–RAMP1 complex), ADM (CLR–RAMP2 complex), ADM2 (CLR–RAMP3 complex), and IAPP (three receptors, CTR–RAMP1, CTR-RAMP2, and CTR–RAMP3) (Poyner et al., 2002; Hay et al., 2018). Although the two receptors for CT family peptides (CTR and CLR) and three RAMPs have been identified in birds, the functionality of these avian receptors/receptor complexes is still unknown.

In birds (e.g., chicken), CT peptide is expressed predominantly in the C cells of ultimobranchial glands (Kameda, 1991), but also found in other tissues, such as ovarian follicles and the anterior pituitary (Krzysik-Walker et al., 2007; Maddineni et al., 2007). CGRP-ir, sometimes colocalized with SP, is widely distributed in neurons or neuronal fibers of the CNS and peripheral tissues (Lanuza et al., 2000). *IAPP* appears to be predominantly expressed

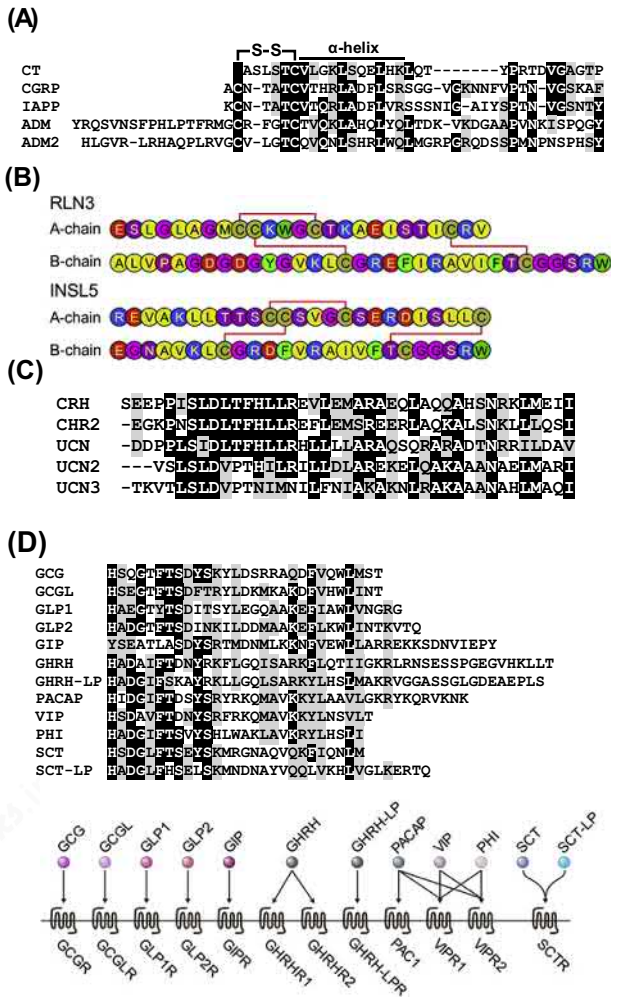

FIGURE 29.2 (A–D) Sequences of chicken calcitonin (CT) family peptides (A), relaxin family peptides (RLN3, INSL5) (B), CRH family peptides (C), and glucagon (GCG) superfamily peptides (D). *Note*: in (A), each CT family peptide contains one disulfide bond and an α-helix structure. In (D), the receptor(s) for each GCG superfamily peptide are shown at the bottom. GHRH has two GHRH receptors (GHRHR1 and GHRHR2); GCGL has a specific receptor (GCGLR); PHI and VIP share the two receptors (VIPR1, VIPR2), while PACAP has three receptors (PAC1, VIPR1, and VIPR2); SCT and SCT-LP share a common receptor (SCTR).

in the extrapancreatic tissues including the brain and intestine endocrine cells, contrasting to the abundant coexpression of IAPP with insulin in rodent islet β-cells (Fan et al., 1994; Mulder et al., 1997). Both *ADM* mRNA and ADM–ir have been detected in a variety of chicken tissues including the lung, adrenal gland, colon, small intestine, pancreas, kidneys, and pituitary, but nondetectable in the brain, suggesting that it cannot function as a neurotransmitter or neuromodulator in chicken brain, as reported in mammals (Lopez et al., 1999; Cuesta et al., 2005).

In birds, CT was originally proposed to control calcium homeostasis (Copp et al., 1967); however, its

calcium-lowering effect has yet been confirmed (Chan et al., 1969; Baimbridge and Taylor, 1980; Anderson et al., 1982; Sommerville and Fox, 1987; Hurwitz, 1996). CT also plays roles in the pituitary, hypothalamus, adrenal gland, and ovary, such as inhibition of food and water intake and stimulation of adrenocorticotropic hormone (ACTH)-induced corticosterone production in chickens (Krzysik-Walker et al., 2007; Maddineni et al., 2007; Nakagawa-Mizuyachi et al., 2009; Cline et al., 2010b). As a neuropeptide, CGRP plays a variety of roles in the CNS and peripheral tissues, such as vasodilation, intestinal smooth muscle relaxation, food and water intake, and calcium metabolism (Ancill et al., 1990; Cline et al., 2010b). IAPP has been reported to affect feeding and alimentary canal transit in chickens after central and peripheral administration (Cline et al., 2008b; Cline et al., 2010a). Interestingly, long-term subcutaneous (sc) injection of IAPP can lower the plasma calcium level and increase the thickness of eggshell (Guzel et al., 2009). Despite the diverse roles of ADM and ADM2 reported in mammals, such as vasodilation, regulation of hormone secretion, promotion of angiogenesis, cardiovascular homeostasis, and antimicrobial activity (Hinson et al., 2000; Hong et al., 2012), however, the roles of avian ADM/ADM2 remain largely unknown, except for the potential roles of ADM in food intake and pulmonary hypertension in chickens (Gomez et al., 2007; Wang et al., 2014).

29.1.4 Parathyroid hormone family

In vertebrates, the parathyroid hormone (PTH) family consists of four structurally related peptides, including PTH, parathyroid hormone−related protein (PTHrP), tuberoinfundibular peptide of 39 residues (TIP39, also known as PTH2), and PTH-like peptide (PTH-L). In birds, only PTH, PTHrP, and PTH-L have been identified, while TIP39 is likely lost in the avian lineage (Pinheiro et al., 2010). In chickens, *PTH* encodes a mature PTH hormone of 88 aa (Khosla et al., 1988; Russell and Sherwood, 1989). *PTHrP* can generate multiple spliced transcripts and thus give rise to two forms of PTHrP differing in their C-terminal tails ($PTHrP_{1\text{-}139}$, 139 aa and $PTHrP_{1\text{-}141}$, 141 aa) (Thiede and Rutledge, 1990; Pinheiro et al., 2010). In chickens and turkeys, *PTH-L* produces a mature peptide of 131 or 130 aa. Despite the length of these three hormones, the N-terminal region (34 aa) of $PTH_{1\text{-}34}$, $PTHrP_{1\text{-}34}$, and $PTH\text{-}L_{1\text{-}34}$ is highly conserved and crucial for their biological activity, while their C-terminal region is less conserved (Pinheiro et al., 2012).

Two GPCRs, named PTH1R and PTH3R, for the three hormones have been identified in chickens. Both receptors share ~52% aa identity with each other and belong to the GPCR B1 subfamily. Intriguingly, PTH1R expressed in HEK293 cells can be potently activated by $PTHrP_{1\text{-}34}$ and $PTH\text{-}L_{1\text{-}34}$ (not by $PTH_{1\text{-}34}$) and its activation increases the intracellular cAMP level and calcium concentration, whereas PTH3R can be effectively activated by $PTHrP_{1\text{-}34}$ and $PTH_{1\text{-}34}$ (not by $PTH\text{-}L_{1\text{-}34}$) and its activation stimulates cAMP accumulation (Pinheiro et al., 2012). The considerably low potency of chicken $PTH_{1\text{-}34}$ in activating PTH1R suggests that PTH1R may require accessory protein(s) (e.g., RAMPs) to fulfill its function in vivo, or PTH1R could be potently activated only by the full-length PTH peptide.

PTH2R and *TIP39* genes are lost in avian genomes, suggesting that the functions of TIP39−PTH2R may be replaced by other PTH family member(s) in birds.

In chickens, *PTH* mRNA is nearly exclusively expressed in the parathyroid gland, while *PTHrP* and *PTH-L* have similarly wide tissue expression, including the cartilage, muscle, kidney, midbrain, hindbrain, pituitary, bone, thyroid, and parathyroid gland (Pinheiro et al., 2010). In egg-laying hens, *PTHrP* is expressed in the isthmus and shell gland of oviduct, which likely acts a local modulator of vascular smooth muscle tension and shell gland motility in birds (Thiede et al., 1991; Francis et al., 2003). *PTH1R* is widely expressed in embryos and adult chicken tissues, including parathyroid gland, lung, kidneys, liver, bone, and cartilage, while *PTH3R* is weakly expressed in adult chicken tissues and embryos (Pinheiro et al., 2012; Dale et al., 2015).

In birds, PTH is released by parathyroid chief cells in response to low serum calcium levels. It acts as an endocrine hormone to control serum calcium and phosphate levels via PTH receptor expressed in the bone, kidneys, and intestine, and thus plays important roles in calcium homeostasis, endochondral bone formation, bone remodeling, and eggshell calcification (Dacke, 1976; van de Velde et al., 1984; Singh et al., 1986; Wideman, 1987; Hurwitz, 1996). Although PTHrP and PTH have similar biological actions on target tissues, it is more likely that PTHrP acts as a paracrine/autocrine regulator in avian tissues, such as controlling the pace of growth plate chondrocyte proliferation and differentiation (O'Keefe et al., 1997; Medill et al., 2001). In addition to their effects on calcium homeostasis, PTH/PTHrP have been reported to enhance the basal or ACTH-stimulated aldosterone/corticosterone secretion in chicken adrenocortical cells (Rosenberg et al., 1986, 1988, 1989; Kawashima et al., 2005), control ovarian follicle selection by stimulating proliferation, and steroidogenic capacity of follicular cells (Guo et al., 2019) and inhibit blood vessel constriction (Pang et al., 1984).

PTH-L is a novel hormone identified in birds; it is unknown whether it plays roles similar to PTHrP/PTH in birds. It was reported that as in mammals (Strewler, 2000), PTHrP precursor can produce another bioactive peptide, osteostatin ($PTH_{107\text{-}139/141}$); however, its roles remain to be clarified in birds.

29.1.5 Relaxin peptide family

Relaxin (RLN)/insulin-like peptide (INSL) family contains seven members, including three RLN-like peptides (RLN1, RLN2, and RLN3) and four INSL peptides (INSL3, INSL4, INSL5, and INSL6) in humans. These peptides are encoded by separate genes, which were predicted to be originated from a common ancestral gene (Yegorov and Good, 2012). Each bioactive peptide is composed of A-chain and B-chain linked by two intermolecular disulfide bonds. In addition, an intramolecular disulfide bond is present on the A-chain (Bathgate et al., 2013). In chickens, only *RLN3* (a paralog of human *RLN3*) and *INSL5* genes have been found in the genome (Lovell et al., 2014). Chicken RLN3 peptide is a putative heterodimer consisting of A-chain (25 aa) and B-chain (33 aa), while INSL5 is likely a heterodimer consisting of A-chain of 25aa and B-chain of 25 aa (Fig. 29.2B).

Three GPCRs (named RXFP1, RXFP2-like, and RXFP3) for RLN3 and INSL5 are predicted to exist in avian genomes (Yegorov and Good, 2012). Our preliminary data show that chicken RXFP1 and RXFP3 can function as receptors for RLN3 and their activation stimulates Gs-cAMP and Gi-cAMP signaling pathways, respectively, while RXFP2L can act as a receptor for INSL5 and its activation stimulates Gs-cAMP/PKA signaling pathway (Lv and Wang, Unpublished data).

In birds, only a few studies reported the expression of *RLN3* in the ovary, pituitary, and hypothalamus (Higgins et al., 2010). In chickens, RLN-like immunoreactive signals are localized in granulosa cells of postovulatory follicles and likely act as an ovarian hormone to inhibit uterine muscle contraction (Brackett et al., 1997). The latest findings from our laboratory show that chicken *RLN3* is abundantly expressed in the hypothalamus, pituitary gonadotrophs, and granulosa cells of developing ovarian follicles, and *INSL5* is predominantly expressed in the rectum and cecum. These findings suggest that avian RLN3 is likely a peptide hormone/neuropeptide to regulate many physiological processes, such as feeding and reproduction, as reported in mammals (Bathgate et al., 2013), while avian INSL5 is likely a novel gut hormone derived from the lower part of the gastrointestinal (GI) tract in birds.

29.1.6 Ghrelin/motilin peptide family

Ghrelin (GHRL) and motilin (MLN) peptides are two structurally related gut hormones (Asakawa et al., 2001; Peeters, 2005), which belong to the same peptide family (Hara et al., 2018). GHRL is a 26-aa peptide purified from chicken proventriculus. It is derived from a precursor of 116 aa (Kaiya et al., 2002; Richards et al., 2006). Acylation of either *n*-octanoic or n-decanoic acid at Ser-3 of this peptide is essential for ligand bioactivity and binding affinity. MLN was first isolated from acid extracts of chicken small intestine mucosa. It is a 22-aa peptide found in chickens, quails, and pheasants. It shows six residue differences when compared to the human ortholog (De Clercq et al., 1996; Huang et al., 1999; Apu et al., 2016; Zhang et al., 2020).

The specific receptor for GHRL and MLN has been cloned from chickens. GHRL receptor (GHSR1) has two isoforms (GHSR1a and GHSR1c) generated by alternative splicing. GHSR1a is a full-length receptor containing seven transmembrane domains (TM1−7), while GHSR1c lacks TM6 (Geelissen et al., 2003; Tanaka et al., 2003). Motilin receptor (MLNR) is a GPCR of 349 aa (Yamamoto et al., 2008). GHSR1a and MLNR share ∼53% aa sequence identity with each other, and their activation can increase the intracellular calcium concentration (Yamamoto et al., 2008; Kitazawa et al., 2009).

GHRL is predominantly expressed in the proventriculus and weakly in other tissues (e.g., brain and intestine) of chickens (Kaiya et al., 2002; Neglia et al., 2004; Richards et al., 2006), while GHSR is widely expressed with high expression level noted in the anterior pituitary and hypothalamus and low expression in the GI tract (Tanaka et al., 2003; Richards et al., 2006). MLN-ir is localized in the mucosal layer of small intestine (duodenum, jejunum, and ileum) in quails and chickens (Apu et al., 2016). MLNR is also widely distributed in chicken tissues, with the abundant expression in the proventriculus, duodenum, and oviduct (Yamamoto et al., 2008).

In birds, MLN and GHRL induce contraction of the GI tract in a region-dependent manner (Kitazawa and Kaiya, 2019). MLN stimulates the smooth muscle contraction of small intestine and proventriculus in quails, pheasants, and chickens (Kitazawa et al., 1995; Apu et al., 2016; Zhang et al., 2020), whereas GHRL appears to mainly regulate contractions of the upper (crop) and lower (colon) GI tract in chickens and quails (Kitazawa et al., 2007, 2009). Moreover, GHRL was reported to be associated with other physiological processes, such as regulation of feeding, growth hormone (GH) secretion, and HPA axis activity. For instance, intravenous injection of GHRL can increase plasma GH and corticosterone levels (Ahmed and Harvey, 2002; Kaiya et al., 2002); intracerebroventricular (*icv*) injection of GHRL inhibits food intake in chicks, contrary to the orexigenic action of GHRL in mammals (Furuse et al., 2001; Saito et al., 2002, 2005).

29.1.7 NMU/NMS peptide family

Neuromedin U (NMU) is a neuropeptide conserved across vertebrates (Brighton et al., 2004). In chickens, two NMU forms, named NMU-9 (9 aa) and NMU-25 (25 aa), have been purified from the intestine (O'Harte et al., 1991; Domin et al., 1992). NMU-25 is an N-terminally extended

form of NMU-9. Both NMU-25 and NMU-9 have an amidated C-terminus and are derived from the same precursor encoded by *NMU* gene, which also encodes an NMU precursor−related peptide of 33 aa (Wan et al., 2018).

In rodents, neuromedin S (NMS) is a neuropeptide of 36 aa encoded by *NMS* gene (Mori et al., 2008; Mitchell et al., 2009). In chickens, *NMS* gene encodes an NMS peptide of 9 aa with an amidated C-terminus (NMS-9) (Wan et al., 2018). The question whether the longer form of NMS exists in birds remains. Interestingly, chicken NMU-9 and NMS-9 share high structural similarity with only 2 aa difference noted at positions 1 and 4 (Wan et al., 2018).

Two receptors for NMU and NMS have been identified in chickens and named NMUR1 and NMUR2, respectively (Mitchell et al., 2009; Yamamoto et al., 2011). Both receptors are primarily coupled to Gq protein and their activation triggers intracellular calcium mobilization and enhances ERK phosphorylation (Yamamoto et al., 2011; Wan et al., 2018). Chicken NMUR1 is a receptor common for NMU-25, NMU-9, and NMS-9, while chicken NMUR2 is likely an NMS-preferring receptor (Wan et al., 2018).

In chickens, *NMU* and *NMUR1* are widely expressed in a variety of tissues with abundant expression noted in the GI tract, whereas *NMUR2* expression is mainly restricted to the brain (e.g., hypothalamus) and anterior pituitary, and *NMS* is widely expressed in many tissues including the pituitary, hypothalamus, and adrenal gland (Yamamoto et al., 2011; Wan et al., 2018).

In birds, central injection of NMU or NMS can inhibit food intake and increase locomotor activity and wing-flapping behavior in chicks (Kamisoyama et al., 2007; Tachibana et al., 2010b,c) or quails (Shousha et al., 2005, 2006). However, it is unknown whether they are involved in the regulation of smooth muscle contraction, pain, pituitary hormone secretion, blood pressure, and circadian rhythm in birds, as reported in mammals (Mori et al., 2008; Mitchell et al., 2009).

29.1.8 Neuropeptide S

In mammals, neuropeptide S (NPS) and its receptor (NPSR) have been reported to play important physiological/pathophysiological roles in the CNS, such as locomotor activity, wakefulness, panic disorder, anxiolytic behavior, sleeping disorders, food intake, memory, asthma, and drug addiction (Guerrini et al., 2010; Valsalan and Manoj, 2014). *NPS* and *NPSR* also exist in avian genome. In chickens, *NPS* is predicted to produce a bioactive peptide of 20 aa. NPSR is a seven-transmembrane GPCR of 373 aa (KX595273).

In chickens, *icv* injection of rat NPS inhibits food intake, reduces plasma corticosterone concentration, decreases exploratory pecking, jumping, and locomotion and increases time spent in deep rest (Cline et al., 2007; Cline et al., 2008c). Moreover, HWS chicken is more sensitive to NPS injection than LWS chickens (Cline et al., 2008c).

29.1.9 Neurotensin and neuromedin N

Neurotensin (NTS) is a peptide of 13 aa expressed in the CNS and GI tract in mammals and plays diverse roles in many physiological/pathological processes, such as regulation of analgesia, feeding, blood pressure, and sleep in the CNS and control of gastric acid secretin (SCT) and colonic motility in the GI tract (Mustain et al., 2011). Besides NTS, neuromedin N (NN, 6 aa) is also encoded by *NTS* gene. In chickens, both NTS (13 aa) and NN (6 aa, also called LANT6) peptides have been purified from the small intestine (Carraway and Bhatnagar, 1980; Carraway and Ferris, 1983). It is clear that both NTS and NN share structural and functional similarity, which are derived from the same NTS precursor (Carraway et al., 1993; Tanaka et al., 2013). In addition, a large LANT6 form of ~15 kDa also exists in chicken intestine. It may display the biological activity similar to NN, as in mammals (Carraway et al., 1993). The biological actions of chicken NTS and NN are likely mediated by an NTSR1, which is a member of GPCR family and its activation can increase calcium concentration (Numao et al., 2011).

In chickens, NN and NTS peptides were detected to exist in a molar ratio of ~1.2−1.7 in HCl extracts of chicken tissues, including the small intestine, cecum, colon, brain, thymus, and pancreas. Among these tissues, NTS and NN have the greatest abundance in the intestine (Carraway et al., 1993), where NTS-ir is mainly distributed in the endocrine N cells of GI epithelium layer in chickens, Japanese quails, and pigeons (Sundler et al., 1977; Atoji et al., 1994). Recently, Nishimura et al. (2017) reported the colocalization of NTS with glucagon-like peptide 1 (GLP1) in some enteroendocrine cells of distal ileum crypts (Nishimura et al., 2017). Beside the GI tract, NTS-ir is distributed in thymus endocrine cells (Atoji et al., 1996b). Moreover, NN/NTS-ir neurons/fibers are widely distributed in the CNS, including the retina (Eldred et al., 1987), various brain regions (e.g., hypothalamus and nucleus accumbens) (Atoji et al., 1996a; Masuda et al., 2014; Balint et al., 2016), and spinal cord (Atoji et al., 1996a). Like NTS, NTSR1 is also expressed in the GI tract, liver, thymus epithelial cells, and CNS (Numao et al., 2011; Tanaka et al., 2013). These findings suggest that NTS/NN may act as a circulating gut hormone, local paracrine factor, and neurotransmitter in avian CNS, GI tract, thymus, and liver.

So far, NTS has been reported to elevate the hepatic bile acid output (Gui et al., 2000), inhibit pepsin output from the proventriculus (Degolier et al., 1997), and induce motility

of the ileum and cecum (Rawson et al., 1990) in birds. The other physiological roles of avian NTS/NN in the CNS and peripheral tissues remain to be clarified.

29.1.10 RF-amide peptide family

In birds, RF-amide peptide family includes eight structurally related peptides: neuropeptide AF (NPAF), gonadotropin-inhibitory peptide (GnIH), GnIH-related peptide 1 (GnIH-RP1), GnIH-related peptide 2 (GnIH-RP2), prolactin-releasing peptide (PrRP), prolactin-releasing peptide 2 (PrRP2, also named C-RFa), and 26RFa (also called QRFP) (Osugi et al., 2006; Wang et al., 2012c; Tachibana and Sakamoto, 2014). All these peptides are characterized by the presence of a C-terminal Arg-Phe-NH2 (RF-amide) motif, which is essential for their biological activity and receptor binding. Moreover, all peptides are proteolytically cleaved from their precursors encoded by *NPFF*, *NPVF*, *PrRP*, *PrRP2*, and *QRFP* genes, respectively.

In birds, NPFF precursor can produce a single bioactive NPAF peptide of 20 aa, which can potently activate NPFF receptor 2 (NPFFR2) and inhibit cAMP/PKA signaling pathway (Chen et al., 2020). NPVF precursor is likely to generate three structurally related peptides, GnIH (12 aa), GnRH-RP1 (37 aa), and GnIH-RP2 (13 aa) (Satake et al., 2001; Ikemoto and Park, 2005; Tobari et al., 2010), all of which can bind to the same NPFF receptor 1 (NPFFR1, also called GnIH-R) with high affinity (Yin et al., 2005). Like NPFFR2, NPFFR1 activation also inhibits cAMP/PKA and activates MAPK/ERK1/2 signaling pathways in chickens (Shimizu and Bedecarrats, 2010).

PrRP precursor can produce a mature PrRP peptide of 20 aa (Wang et al., 2012c), while PrRP2 precursor generates two forms of PrRP2 peptide with an identical C-terminus: $PrRP2_{20}$ ($C\text{-}RFa_{20}$, 20 aa) and $PrRP2_{31}$ ($C\text{-}RFa_{31}$, 31 aa). $PrRP2_{31}$ is an N-terminally extended form of $PrRP2_{20}$ (Tachibana et al., 2011b; Wang et al., 2012c). Three GPCRs for PrRP and PrRP2 have been identified and named as PrRPR1, PrRPR2, and PrRP2-R (also called C-RFaR). PrRPR1 and PrRPR2 can act as the receptors common for both PrRP and PrRP2, whereas PrRP2-R can function as a PrRP2-specific receptor (Wang et al., 2012c). Three receptors are primarily coupled to Gq protein and their activation triggers intracellular calcium mobilization (Wang et al., 2012c).

QRFP precursor produces a mature 26RFa peptide of 27 aa, which can activate its receptor GPR103 (QRFPR) potently and trigger postreceptor calcium mobilization (Ukena et al., 2010).

In chickens, *NPFF* mRNA is highly expressed in the CNS, including the hypothalamus and weakly in other tissues, while its receptor *NPFFR1* is highly expressed in the anterior pituitary and hypothalamus and weakly in other tissues (Ikemoto and Park, 2005; Chen et al., 2020). *icv* injection of rat NPAF inhibits food and water intake and decreases plasma glucose concentration in chicks (Cline et al., 2009a).

In quails and zebra finches, GnIH-ir is mainly localized in the hypothalamic paraventricular nuclei (PVN) and some GnIH-ir fibers project into the external layer of ME (Tsutsui et al., 2000). A later study revealed that GnIH-ir is also localized at the dorsomedial nucleus of the hypothalamus, and GnIH-ir fibers are widely distributed in multiple brain regions, including the preoptic area (POA) rich in GnRH-I neurons in finch brain (Tobari et al., 2010). GnIH receptor (NPFFR1) is expressed in several brain regions and the anterior pituitary (Ikemoto and Park, 2005; Yin et al., 2005). In quails, GnIH can inhibit basal luteinizing hormone (LH) secretion of the anterior pituitary (Tsutsui et al., 2000). Similarly, GnIH can inhibit basal pituitary follicle-stimulating hormone (FSH) and LH release and *FSHβ* and *CGA* expression in chickens (Ciccone et al., 2004). Moreover, *icv* injection of GnIH stimulates food intake and upregulates orexigenic factor (melanin-concentrating hormone [MCH] and neuropeptide Y [NPY]) expression and downregulates proopiomelanocortin (POMC) expression (McConn et al., 2014). These findings indicate that NPAF and GnIH (or GnIH-RPs) can act as a neuromodulator or neuroendocrine hormone in birds.

In chickens, *PrRP* and *PrRP2* are widely expressed in adult tissues, including the hypothalamus, anterior pituitary, and gonads detected by RT-PCR assay, while the three receptors for PrRP and PrRP2 are widely expressed in most tissues including the anterior pituitary, hypothalamus, and gonads (Wang et al., 2012c). *icv* injection of chicken $PrRP2_{31}$ increases food intake, contrary to the anorexic action of PrRP observed in rats and goldfish (Tachibana et al., 2011b; Tachibana and Tsutsui, 2016). Moreover, central and peripheral administration of PrRP2 decreases plasma GH levels, while peripheral administration of PrRP2 can increase plasma prolactin (PRL) level, and *icv* injection of PrRP2 decrease PRL levels.

In chickens, *QRFP* (26RFa) is expressed in the anterior hypothalamus nucleus (AM) (Ukena et al., 2010). In zebra finches, QRFP is also expressed in the AM and other hypothalamus nuclei (e.g., ventromedial nucleus of hypothalamus and lateral hypothalamus) associated with feeding, while QRFPR (GPR103) is distributed throughout the brain expressed including the hypothalamus (Tobari et al., 2011). In zebra finches and broiler (not layer) chickens, *icv* injection of RF26a can increase food intake (Ukena et al., 2010; Tobari et al., 2011). This finding indicates the involvement of 26RFa in the regulation of feeding and energy balance.

29.1.11 Cholecystokinin and gastrin peptide family

Cholecystokinin (CCK) and gastrin (GAST) are two peptides encoded by separate genes and sharing the conserved C-terminal "Trp-Met-Asp-Phe-NH2" motif, which is crucial for their biological activity. In chickens, CCK precursor can produce multiple CCKs of different lengths, namely CCK70, CCK8, and CCK7, in the intestine after posttranslational processing, all of which have the identical C-terminus, but vary in the length of their N-termini (Jonson et al., 2000). As in mammals, avian CCK peptide exists in nonsulfated and sulfated forms, in which the latter has a sulfated tyrosine at position 7 counted from the C-terminus. Chicken GAST precursor can produce four forms of peptides at different lengths with an identical C-terminus: gastrin-53, gastrin-30, gastrin-21, and gastrin-7, among which gastrin-53 is the predominant form existed in antrum mucosa (Bjornskov et al., 1992; Wu et al., 1995; Jensen et al., 2001). Chicken GAST mainly exists in the sulfated form with a sulfated tyrosine at position 7 countered from the C-terminus (Bjornskov et al., 1992).

Two GPCRs, named CCK1R (CCKAR) and CCK2R (CCKBR) for CCK/GAST have been cloned from chickens (Nilsson et al., 2003). Chicken CCK2R displays high affinity for sulfated CCK8 and gastrin-17 and a lower affinity for CCK4 in vitro, thus acting as a common receptor for GAST and CCK (Nilsson et al., 2003). Nevertheless, the signaling property of avian CCK1R and CCK2R is unknown.

In chickens, GAST mRNA or peptide is exclusively expressed in gastric antrum region revealed by qPCR assay (Reid and Dunn, 2018) and immunostaining (Martinez et al., 1993), whereas CCK is highly expressed in the basal hypothalamus, moderately in the small intestine (e.g., in ileum endocrine cells), and weakly in other remaining parts of the GI tract (Reid and Dunn, 2018). Both CCK1R and CCK2R are widely, but differentially, expressed in chicken tissues. For instance, CCK2R is preferentially expressed in the brain and proventriculus (Ohkubo et al., 2007).

In birds, CCK and GAST act as the neurotransmitter or gut hormone to regulate brain and gut functions. In the GI tract, CCK increases bile outflow and pancreatic enzyme secretion and inhibits crop emptying (Furuse, 1999). In addition, central/peripheral injection of CCK reduces food intake (Savory and Gentle, 1980; Denbow and Myers, 1982; Rodriguez-Sinovas et al., 1997; Dunn et al., 2013); thus, CCK can act as a satiety signal involved in the control of feeding and growth in poultry (Rikimaru et al., 2012; Dunn et al., 2013; Reid and Dunn, 2018; Yi et al., 2018). Recently, CCK−CCK2R signaling in the nucleus intercollicularis of midbrain has been reported to be associated with chicken crowing (Shimmura et al., 2019). Unlike CCK, GAST secreted from gastric antrum can stimulate gastric acid secretion, but has no effect on pancreatic secretion and gall bladder contraction in chickens (Dimaline and Lee, 1990; Furuse, 1999).

29.1.12 Orexin peptide family

In chickens, two orexin peptides, orexin-A and orexin-B (also called hypocretins), have been identified, both of which share ~50% sequence identity and are produced by the same precursor. Chicken orexin-A is a neuropeptide of 33 aa with two intramolecular disulfide bonds (Cys6−Cys12 and Cys7−Cys14) and an amidated C-terminus, while orexin-B is a 28 aa and C-terminally amidated neuropeptide (Ohkubo et al., 2002). Only a single GPCR for orexins A and B named OX2R has been identified in chickens, which contrasts the findings in mammals, where two orexin receptors (OX1R, OX2R) have been identified (Sakurai et al., 1998; Ohkubo et al., 2003). The pharmacological and signaling property of OX2R remains unclear in birds.

In birds, orexin is predominantly expressed in the hypothalamus (Ohkubo et al., 2002). Within the hypothalamus, orexin neurons are reported to be distributed in the periventricular nucleus and lateral hypothalamic area in chickens (Ohkubo et al., 2002) and quails (Phillips-Singh et al., 2003) in earlier studies. However, recent studies show that orexin neurons are localized in the PVN in chickens and house finches (Singletary et al., 2006; Miranda et al., 2013). *OX2R* is abundantly expressed in the hypothalamus, cerebrum, and optic tectum and weakly in the pituitary gland, adrenal gland, and testis. It is clear that orexin can act as a neuropeptide functioning in chicken brain; however, more studies are required to clarify the roles of orexin in avian CNS (Furuse et al., 1999; Katayama et al., 2010; Song et al., 2012; Miranda et al., 2013).

29.1.13 Melanin-concentrating hormone peptide

MCH is a 17-aa cyclic peptide, which was originally identified in chum salmon pituitaries as a hormone that induces aggregation of melanin granules within melanophores in fish scales (Kawauchi et al., 1983). Recently, *MCH* cDNA was cloned from chicken hypothalamus (Sun et al., 2013). The mature chicken MCH is a 19-aa cyclic peptide and shares high structural similarity to fish MCH (Cui et al., 2017). Moreover, an MCH receptor (named *MCHR4*) has also been identified in chickens and ducks. Avian MCHR4 is coupled to Gq protein and its activation triggers calcium mobilization and enhances ERK phosphorylation (Cui et al., 2017).

In chickens, *MCH* mRNA is predominantly expressed in the hypothalamus (Cui et al., 2017), and MCH-ir perikarya are localized in the periventricular hypothalamic

nucleus near the paraventricular organ and in the lateral hypothalamic areas (Cardot et al., 1999). The distribution pattern of MCH in the hypothalamus suggests that MCH may play roles in avian CNS, such as regulation of feeding, similar to those described in rats (Cardot et al., 1999). qPCR assay revealed that *MCHR4* is widely expressed in chicken hypothalamus and other brain regions, further supporting the central actions of MCH in birds. Interestingly, *MCHR4* is also highly expressed in the testis (Cui et al., 2017); however, its physiological role therein is unknown.

29.1.14 Prokineticin peptide family

In mammals, prokineticin (PROK) family comprises two structurally related peptides, named PROK1 and PROK2. As in mammals, both *PROK1* and *PROK2* genes exist in chickens, quails, and other birds. Chicken *PROK1* is predicted to encode a peptide of 86 aa, while *PROK2* produces a peptide of 88 aa. Both peptides possess five intramolecular disulfide bonds and a conserved "AVITGA" motif at the N-termini essential for their biological activity (Negri et al., 2007). Interestingly, only a single PROK receptor exists in chicken genome and is designated as PKR1 (FJ61954), contrasting to the findings in mammals, where two receptors (PKR1 and PKR2) for PROK1 and PROK2 have been identified (Negri and Ferrara, 2018). Therefore, further studies are required 1) to examine the functionality of PROK1/2-PKR2 system in birds and 2) to elucidate whether as in mammals, PROK/PKR2 is involved in the regulation of GI tract motility, circadian rhythm, neurogenesis, angiogenesis, hematopoiesis, reproduction, and nociception (Negri and Ferrara, 2018).

29.1.15 Corticotropin-releasing hormone peptide family

In birds, corticotropin-releasing hormone (CRH) family consists of five peptides: CRH, urocortin (UCN), urocortin II (UCN2), urocortin III (UCN3), and corticotropin-releasing hormone 2 (CRH2) (Vandenborne et al., 2005a; Grommen et al., 2017; Bu et al., 2019). These peptides share ~23−63% aa sequence identity with each other and all are C-terminally amidated. Five peptides are derived from their respective precursors encoded by separate genes, which were originated from a common ancestral gene. In chickens, CRH is a 41-aa peptide and CRH2 is a 40-aa peptide. Both peptides share ~63% aa identity (Vandenborne et al., 2005a; Bu et al., 2019). The UCN, UCN2, and UCN3 peptides have 40, 38, and 40 aa, respectively, and share a relatively low identity with CRH/CRH2 (Fig. 29.2C). The biological actions of CRHs/UCNs are mediated by two structurally related GPCRs, named CRH receptor 1 (CRHR1) and CRH receptor 2 (CRHR2) (Yu et al., 1996; de Groef et al., 2004). Both receptors have been proven to couple to Gs-AC/cAMP signaling pathways (Mo et al., 2015). Chicken CRHR1 can be potently activated by CRH and UCN, thus acting as a receptor common for both peptides. CRHR2 can be potently activated by CRH, CRH2, UCN, UCN2, and UCN3 and is a receptor common for the five peptides (Mo et al., 2015; Bu et al., 2019) (Wan et al., unpublished data).

In birds, CRH is expressed in the hypothalamus (paraventricular, preoptic, and mammillary nuclei [MM] of the hypothalamus) and other brain regions (e.g., nuclei dorsomedialis and dorsolateralis thalami, nucleus accumbens, etc.) (Jozsa et al., 1984, 1986; Yamada and Mikami, 1985). CRH can directly stimulate pituitary ACTH and TSH secretion via CRHR1 and CRHR2, respectively (De Groef et al., 2005). In addition, central CRH also regulates other physiological processes, such as decreased food intake, retarded crop-emptying rate, and increased body temperature, voluntary activity, and numbers of vocalization (Ogino et al., 2014).

Unlike *CRH*, *CRH2* is widely expressed in chicken tissues including the CNS, GI tract, and pituitary. *In vitro* experiments show that CRH2 can stimulate pituitary *TSHβ* expression and ACTH secretion. These findings suggest that CRH2 plays roles similar, but nonidentical, to those of CRH (Bu et al., 2019).

Using in situ hybridization, *UCN3* mRNA was found to be expressed predominantly in the hypothalamus, pons, and medulla of posthatch chick brains. This finding implies the involvement of UCN3 in the regulation of feeding and the autonomic motor control of the GI tract system (Cline et al., 2009b; Ogino et al., 2014; Grommen et al., 2017). To date, information regarding the physiological roles of CRHs/UCNs remains rather limited in birds.

29.1.16 Neuropeptide W and neuropeptide B

Neuropeptide W (NPW) and neuropeptide B (NPB) are two structurally related peptides in mammals. Both peptides are reported to be involved in the central regulation of neuroendocrine axes, feeding behavior, energy homeostasis, circadian rhythm, pain sensation, and emotions (Chottova Dvorakova, 2018). In chickens, NPW, NPB, and their receptors have recently been characterized. Chicken *NPW* encodes a mature NPW peptide of 23 and 30 aa (NPW23 and NPW30), while *NPB* gene encodes a NPB peptide of 28 aa (NPB28). NPW30 and NPB28 share 57% aa sequence identity. Two GPCRs for NPW and NPB (NPBWR1 and NPBWR2) have been identified in birds. NPBWR2 is likely an NPW-specific receptor, which can also be activated by NPB at high concentrations (>100 nM). Interestingly, NPBWR1 seems nonfunctional

in chickens (Bu et al., 2016; Scanes, 2016). However, high concentration of NPW was reported to activate this receptor in geese.

In adult chickens, *NPW* is highly expressed in the hypothalamus and weakly expressed in other tissues including the anterior pituitary and other brain regions, while NPW receptor (*NPBWR2*) is predominantly expressed in the anterior pituitary. This finding suggests that NPW–NPBWR2 signaling is involved in the regulation of pituitary functions, such as inhibition of GH and PRL secretion (Bu et al., 2016). *NPB* is widely expressed in a variety of chicken tissues including the hypothalamus, and *NPBWR1* is highly expressed in the hypothalamus, telencephalon, hindbrain, and midbrain. However, the physiological relevance of *NPB*/*NPBWR1* expression is unknown in birds (Bu et al., 2016).

29.1.17 Opioid peptide family

In mammals, opioid peptide family includes several structurally related neuropeptides, including Met-enkephalin, Leu-enkephalin, β-endorphin, Met-enkephalin-Arg-Phe, dynorphin-A and dynorphin-B, neo-endorphin, Met-enkephalin-Arg-Gly-Leu, metorphamide, and nociceptin. All these peptides differ in length, but possess an identical core motif (Y/FGGF) at their N-termini. In birds, these opioid peptides are derived from four distinct precursors, i.e., proenkephalin (PENK), POMC, prodynorphin (PDYN), and pronociceptin (PNOC), which are encoded by four separate genes, namely *PENK*, *POMC*, *PDYN*, and *PNOC* (Scanes and Pierzchala-Koziec, 2018). In chickens, PENK precursor may produce four copies of Met-enkephalin (YGGFM), one Leu-enkephalin (YGGFL), one Met-enkephalin-Arg-Phe (YGGFMRF), and one octopeptide (Met-enkephalin-Arg-Ser-Val). PDYN precursor is predicted to generate dynorphin-A, dynorphin-B, and one Met-enkephalin, which is absent in other vertebrate groups. However, chicken PDYN precursor cannot produce "neo-endorphin." Chicken PNOC and POMC precursors can produce mature nociceptin (17aa) and β-endorphin (31aa), respectively (Bu et al., 2020).

Four functional receptors for opioid peptides, named DOR, MOR, KOR, and ORL1, have been characterized in chickens. DOR acts as a common receptor for Met-enkephalin and Leu-enkephalin, while KOR is a receptor common for dynorphin-A, dynorphin-B, and nociceptin. In contrast, ORL1 can only be specifically activated by nociceptin and thus is a nociceptin-specific receptor. Unlike DOR, KOR, and ORL1, MOR is moderately/weakly activated by enkephalins and other opioid peptides, including β-endorphin (Bu et al., 2020). Activation of these receptors can decrease intracellular cAMP levels and stimulate MAPK/ERK signaling pathway (Bu et al., 2020).

In chickens, *PENK* mRNA is highly expressed in the brain (including the hypothalamus, midbrain, hindbrain, and telencephalon), spinal cord and testes, and moderately in the anterior pituitary and skin. *cPOMC* mRNA is expressed predominantly in the anterior pituitary, moderately in the hypothalamus, and weakly in the spinal cord, skin, ovary, testes, and muscle. Interestingly, *cPDYN* mRNA is abundantly expressed in the hypothalamus, heart, and muscle, and weakly in other tissues including spinal cord, lung, and anterior pituitary. *cPNOC* is highly expressed in the brain (e.g., hypothalamus, hindbrain, midbrain, cerebellum, and telencephalon), spinal cord and heart, and weakly expressed in the muscle. Like the four opioid precursors, the four opioid receptors (*OPRD1, OPRM1, OPRK1,* and *OPRL1*) expression is mainly restricted to various brain regions (including the hypothalamus) and spinal cord. Only a moderate/weak expression of opioid receptor(s) was noted in several peripheral tissues, including the lung (*OPRM1*), testis (*OPRM1*), anterior pituitary (*OPRK1, OPRL1,* and *OPRM1*), and ovary (*OPRK1*) (Bu et al., 2020).

The predominant expression of opioid peptides and their receptors in chicken brain and spinal cord suggests that opioid peptides play crucial roles in avian CNS, such as addiction, analgesic action, antinociception, memory formation, reproduction, and food intake (Bungo et al., 2004, 2009; Dodo et al., 2005). The expression of β-endorphin in the pituitary, enkephalins in the pituitary and testis, nociceptin in the heart, and dynorphins in the heart and muscle hints that these opioid peptides play paracrine/autocrine or endocrine roles in avian peripheral tissues (Bu et al., 2020).

29.1.18 Somatostatin/cortistatin peptide family

In birds and mammals, SST and CST are two structurally and functionally related cyclic peptides and encoded by two separate genes, *SST* and *CST* (Gunther et al., 2018). In chickens, after proteolytic processing, SST precursor can produce a mature SST peptide of 14 aa (SST14) or 28 aa (SST28). SST28 is an N-terminally extended form of SST14. CST precursor can produce a mature CST peptide of 14 aa (CST14) or 24 aa (CST24) with an identical C-terminus (Trabucchi et al., 2003). Interestingly, SST14 shows remarkable structural conservation with CST14 with only one aa difference noted at position 2 (Gly in SST14 and Pro in CST14) (Meng et al., 2014).

Five GPCRs for SST and CST, namely SSTR1, SSTR2, SSTR3, SSTR4, and SSTR5, have been characterized in chickens (Meng et al., 2014). SSTR1 to 4 are the four receptors common for SST14, SST28, and CST14 peptides, while SSTR5 is a SST28-specific receptor. Activation of the five receptors can decrease intracellular cAMP levels (Meng et al., 2014).

In chickens, *SST* mRNA is abundantly expressed in the brain, spinal cord, and pancreas detected by Northern blot, while *CST* mRNA expression is mainly restricted to brain and spinal cord (Trabucchi et al., 2003). RT-PCR assay revealed that *SST* and *CST* are also expressed in the intestine and gonads (Meng et al., 2014). Within the brain, *SST* mRNA is distributed in the hippocampus, hyperstriatum, POA, ventricular hypothalamic nuclei, optic tectum, and several nuclei of the mesencephalon and rhombencephalon, while C*ST* is expressed in the paraolfactory lobe, the paleostriatum, and some nuclei of the mesencephalon and rhombencephalon. In addition to the above-mentioned tissues, SST-ir cells were also detected in the retina (Buckerfield et al., 1981), thyroid gland, gut, carotid body (Kameda, 1989), and pancreatic D-cells (Weir et al., 1976; Hazelwood, 1984). Like SST/CST, SSTR1-5 are widely, but differentially, expressed in chicken tissues including various brain regions, indicating that the diverse actions of SST/CST are likely mediated by the distinct SSTR(s) expressed in tissue-/cell-specific manner.

In chickens, SST and its receptors have been reported to inhibit pituitary hormone (e.g., GH and TSH) secretion (Harvey et al., 1978; Perez et al., 1987; Donoghue and Scanes, 1991; De Groef et al., 2003, 2007; Anderson and Scanes, 2012; Meng et al., 2014), pancreatic hormone (e.g., glucagon, insulin, and PP) secretion (Honey et al., 1980, 1981; Hazelwood, 1984), lipolysis (Strosser et al., 1983), thyroid function, as well as stimulate food intake (Tachibana et al., 2009; Tachibana et al., 2011a; Yousefvand et al., 2019). However, the information regarding the roles of CST is largely unknown in birds (Meng et al., 2014).

29.1.19 Urotensin II/urotensin II–related peptide family

Urotensin 2 (UTS2) and URP are cyclic peptides, which function as neuropeptides to regulate multiple physiological processes, such as sleep, food intake, cardiovascular function, locomotion, and anxiety (Vaudry et al., 2015). Both peptides share high structural similarity and contain a conserved cyclic motif (CFWKYC) crucial for their biological activity (Leprince et al., 2008; Vaudry et al., 2015). In chickens, *UTS* gene likely encodes a mature UTS2 of 12 or 17 aa (UTS2-12. UTS2-17), while *URP* encodes a URP peptide of 8 aa (Tostivint et al., 2006). Four GPCRs for UTS2/URP, namely *UTS2R1*, *UTS2R2*, *UTS2R3,* and *UTS2R5,* exist in chicken genome (Tostivint et al., 2014; Vaudry et al., 2015). However, our knowledge regarding the expression, functionality, and roles of UTS2, URP and their four receptors in birds is currently limited.

29.1.20 Glucagon peptide superfamily

In birds, glucagon (GCG) superfamily consists of 12 structurally related peptides, including GCG (29 aa), GLP1 (30 aa), glucagon-like peptide 2 (GLP2, 33 aa), glucose-dependent insulinotropic polypeptide (GIP, 41 aa), glucagon-like peptide (GCGL, 29 aa), SCT (27 aa), secretin-like peptide (SCT-LP, 34 aa), growth hormone–releasing hormone (GHRH, 27aa/47aa), GHRH-related peptide (GHRH-LP, 46 aa), pituitary adenylate cyclase–activating polypeptide (PACAP: 27 aa/38 aa), vasoactive intestinal polypeptide (VIP, 28 aa), and peptide histidine–isoleucine (PHI, 27 aa) (Fig. 29.2D). Among them, GCGL, GHRH-LP, and SCT-LP peptides are lost in mammals. These peptides are encoded by seven genes, namely *GCG*, *GIP, GCGL, GHRH, SCT, PACAP* (*ADCYAP1*), and *VIP*, which are generated by genome duplication during early vertebrate evolution (Sherwood et al., 2000; Wang et al., 2012b). In chickens, *GCG* gene encodes three bioactive peptides, i.e., GCG, GLP1, and GLP2 (Hasegawa et al., 1990; Irwin and Wong, 1995; Richards and McMurtry, 2008); *GIP*, *GCGL*, and *GHRH* genes code for GIP, GCGL, and GHRH peptides, respectively (Irwin and Zhang, 2006; Wang et al., 2007; Wang et al., 2012b); *SCT* encodes for SCT-LP and SCT peptides (Wang et al., 2012a); *PACAP* encodes two bioactive peptides, i.e., GHRH-LP and PACAP (McRory et al., 1997; Wang et al., 2006); and *VIP* codes for bioactive VIP and PHI peptides (Talbot et al., 1995).

Nearly, all the receptors for GCG family peptides (except GIP) have been functionally characterized in chickens (Fig. 29.2D). These receptors are coupled to Gs-cAMP/PKA signaling pathway. GCG, GLP1, GLP2, GCGL, GHRH, and GHRH-LP possess their specific receptor(s), named GCG receptor (GCGR) (Wang et al., 2008), GLP1 receptor (GLP1R) (Huang et al., 2012), GLP2 receptor (GLP2R) (Mo et al., 2014), GCGL receptor (GCGLR) (Wang et al., 2012), GHRH receptors (GHRHR1 and GHRHR2) (Wang et al., 2010), and GHRH-LP receptor (GHRH-LPR) (Wang et al., 2010). Interestingly, PACAP, VIP, and PHI share two common receptors, named VIPR1 and VIPR2, and PACAP also has a PACAP-specific receptor (PAC1) (Wang et al., 2010). SCT and SCT-LP share a common receptor, SCT receptor (SCTR) (Wang et al., 2012a). The functionality of GIP receptor still remains unknown in birds.

In vertebrates, GCG superfamily peptides can function as gut hormones, neuroendocrine hormones, and neurotransmitters/neuromodulators (Sherwood et al., 2000).

Specifically, in birds, *GHRH* mRNA is mainly expressed in the hypothalamus (Wang et al., 2007; Martinez-Moreno et al., 2014) and can potently stimulate pituitary GH secretion in vitro, thus being an authentic GH-releasing factor. In addition, *icv* injection of GHRH inhibits food intake in the hypothalamus (Harvey et al., 2014; Meng et al., 2014; Tachibana et al., 2015).

GCG is highly expressed in chicken pancreas and proventriculus and moderately/weakly in other tissues including the duodenum, liver, brain, heart, lung, muscle,

fat, kidney, and spleen (Richards and McMurtry, 2008). In the pancreas, GCG peptide is abundantly expressed in the islet A cells. Three receptors (GCGR, GLP1R, and GLP2R) for GCG, GLP1, and GLP2 have also been reported to be widely, but differentially, expressed in chicken tissues. The predominant expression of GCGR in liver and fat indicates that GCG can stimulate glucose output and inhibit lipogenesis in liver and promote lipolysis in adipocytes (Langslow and Hales, 1969; Langslow, 1973; Goodridge et al., 1974; Krug et al., 1976; Campbell and Scanes, 1987; Richards and McMurtry, 2008; Wang et al., 2008). The wide expression of GLP1R and GLP2R in chicken tissues including the hypothalamus and pancreas (Richards and McMurtry, 2008; Huang et al., 2012; Mo et al., 2014) suggests their possible involvement in the regulation of feeding, pancreatic functions, GI tract motility, and intestinal growth in birds (Furuse et al., 1997; Richards and McMurtry, 2008; Huang et al., 2012; Mo et al., 2014; Honda et al., 2015).

GCGL is highly expressed in the hypothalamus and *GCGLR* is predominantly expressed in the anterior pituitary thyrotropes and hypothalamus (Wang et al., 2012c; Huang et al., 2014a). Further studies revealed that GCGL can stimulate pituitary TSH expression and secretion specifically and inhibit food intake in the hypothalamus (Honda et al., 2014; Huang et al., 2014a).

SCT is predominantly expressed in the duodenum, jejunum, and ileum, while SCTR is highly expressed along the GI tract (including proventriculus, gizzard, duodenum, jejunum, ileum, and colon), liver, and testis. This finding indicates that SCT and SCT-LP peptides are mainly produced by small intestine and play important roles in GI tract activity (gastric acid and pepsin secretion) and hepatic functions (Burhol, 1974; Wang et al., 2012a).

VIP gene produces two alternative spliced transcripts: the long transcript encoding PHI and VIP peptides, while the short one encodes VIP only and is the predominant form expressed in chicken tissues (Talbot et al., 1995). VIP mRNA/peptide is abundantly expressed in the hypothalamus and has been proved to be the major PRL-releasing factor in birds (Sharp et al., 1989; Talbot et al., 1995). In addition, *VIP* mRNA is also expressed in other brain regions (cerebellum and forebrain), liver, kidneys, gut, pancreas, and pituitary. This finding, together with the wide expression of two VIP receptors in all chicken tissues, including various brain regions, GI tract, liver, pancreas, ovary, and testis, suggests that VIP can act as a neurotransmitter or local factor to regulate many physiological processes, such as pancreatic bicarbonate secretion, vasodilation, intestinal smooth muscle relaxation, and ovarian granulosa cell differentiation and steroidogenesis (Dimaline and Dockray, 1979; Johnson and Tilly, 1988; Johnson et al., 1994; Kim and Johnson, 2016). Since PHI-coding transcript is weakly expressed in avian tissues, it implies a limited role of PHI in birds.

PACAP mRNA/ir is found in the brain (e.g., hypothalamus), small intestine, testis, ovary, and heart (Sundler et al., 1992; McRory et al., 1997; Peeters et al., 1998; Wang et al., 2006; Prisco et al., 2019). These findings, together with the expression of the specific receptor for GHRH-LP (GHRH-LPR)/PACAP (PAC1) in these tissues (Wang et al., 2010), suggest that GHRH-LP and PACAP can function as a neuromodulator/neurotransmitter and play important roles in avian CNS, such as inhibition of food intake (Tachibana et al., 2015) or function as a local regulatory factor in the heart, intestine, and gonads.

To date, the expression, functionality, and role of GIP—GIPR are largely unknown in birds.

29.1.21 Apelin and elabela peptides

In mammals and teleosts, Apelin (APLN), and Elabela (ELA, also named Apela) are two peptides sharing little structural similarity; however, both peptides use the same Apelin receptor (APLNR) to exert their regulatory roles in vivo, such as the regulation of cardiovascular development and function, blood pressure, fluid homeostasis, angiogenesis, neuroendocrine activity, heart development, food intake, drinking behavior, pituitary hormone secretion, metabolism, and neuroprotection (Pitkin et al., 2010). In chickens, *APLN* gene is predicted to generate a mature APLN peptide of different lengths, such as 36 aa (APLN-36), 16 aa (APLN-16), and 13 aa (APLN-13), while *ELA* gene is predicted to generate a mature ELA peptide of different lengths, including 32 aa (ELA-32), 22 aa (ELA-22), or 11 aa (ELA-11). The shortest forms of APLN/ELA peptides (APLN-13/ELA-11) correspond to the C-terminal portion of APLN-36/ELA-32 and seem to be less bioactive than their longest forms (Zhang et al., 2018b).

Three GPCRs for APLN and ELA, namely APLNR1, APLNR2, and GPR25, have been identified in chickens. APLNR1 can be potently activated by APLN-36 ($EC_{50:}$ 0.18 nM) and ELA-32 ($EC_{50:}$ 0.87 nM) and thus is a receptor common for APLN and ELA. In contrast, APLNR2 could only be weakly activated by APLN-36/ELA-32 at a high concentration far beyond the physiological range, implying a less significant role of APLNR2 in chickens (Zhang et al., 2018b). Interestingly, GPR25, which is an orphan receptor in mammals, can be activated by chicken APLN and ELA-32, indicating that GPR25 is a novel functional receptor for APLN and ELA (Zhang et al., 2018a). Activation of APLNR1, APLNR2, and GPR25 has been shown to decrease intracellular cAMP levels (Zhang et al., 2018a, 2018b).

In chickens, *APLN* and *ELA* are widely, but differentially, expressed in various tissues. *APLN* is highly expressed in the brain, heart, and lung and moderately/weakly expressed in other tissues, while ELA is highly expressed in the kidney, liver, spleen, and pancreas and

moderately/weakly expressed other remaining tissues. This finding, together with the expression of *APLNR1/GPR25* in these tissues, suggests that APLN/ELA plays important roles in avian tissues, which requires further investigation (Zhang et al., 2018a, 2018b).

29.1.22 Neuropeptide Y family

Neuropeptide Y (NPY) family includes three structurally and functionally related peptides, NPY, peptide YY (PYY), and pancreatic polypeptide (PP) in vertebrates. These peptides are composed of 36 (or 37) aa and characterized by the presence of a PP-fold and an amidated C-terminus (Cerda-Reverter and Larhammar, 2000). In chickens, NPY, PYY, and PP peptides have 36, 37, and 36 aa (named NPY_{1-36}, PYY_{1-37}, and PP_{1-36}), respectively, all of which are cleaved from their corresponding large precursors (NPY-, PYY-, and PP-precursor) (Kimmel et al., 1975; Blomqvist et al., 1992; Conlon and O'Harte, 1992; Aoki et al., 2017; Gao et al., 2017; Reid et al., 2017). Among them, NPY_{1-36} and PYY_{1-37} show remarkable conservation between birds and mammals, whereas PP_{1-36} is less conserved.

In chickens, six GPCRs for NPY_{1-36}/PYY_{1-37}/PP_{1-36} (named Y1, Y2, Y4, Y5, Y6, and Y7) have been identified (Salaneck et al., 2000; Holmberg et al., 2002; Bromee et al., 2006b). Y2 and Y7 can function as the receptors common for NPY_{1-36} and PYY_{1-37}; Y1 can function as a common receptor for NPY_{1-36} and PYY_{1-37} with a slight selectivity toward NPY_{1-36}; Y5 is a receptor common for the three peptides with a slight selectivity toward NPY_{1-36} and PYY_{1-37}; Y4 is a PP-preferring receptor, which can also be activated by PYY_{1-37} with a low potency; and Y6 shows little response to NPY family peptides, causing one to question whether avian Y6 is functional (He et al., 2016; Gao et al., 2017).

In chickens, *NPY* mRNA is highly expressed in the hypothalamus, telencephalon, midbrain, hindbrain, and anterior pituitary and weakly in other tissues detected by qPCR assay (Gao et al., 2017). *PYY* is highly expressed in the pancreas, moderately in various brain regions (e.g., hypothalamus), and small intestine (duodenum, jejunum, and ileum) (Aoki et al., 2017; Gao et al., 2017; Reid et al., 2017). In contrast, *PP* is nearly exclusively expressed in the pancreas (Gao et al., 2017; Reid et al., 2017).

NPY family peptides are suggested to be involved in the regulation of food intake, adipogenesis, gastric acid secretion and contraction, and pancreatic functions in birds (Leclercq, 1984; Duke et al., 1985; Kuenzel et al., 1987; Denbow et al., 1988; Kuenzel, 1994; Zhang et al., 2015).

29.1.23 Natriuretic peptide family

In vertebrates, natriuretic peptide (NP) family consists of seven structurally related members, including atrial natriuretic peptide (ANP), brain natriuretic peptide (BNP), ventricular natriuretic peptide, and four C-type natriuretic peptides (CNP1, CNP2, CNP3, and CNP4) (Takei et al., 2011). These peptides are involved in the control of sodium and water balance, cardiovascular homeostasis, and skeletal development (Potter et al., 2009). All the peptides are characterized by the presence of a 17-aa cyclic ring and cleaved from their corresponding preprohormones encoded by separate genes. In chickens, the genes encoding the four natriuretic peptides (BNP, ANP-like peptide, CNP1, and CNP3) have been cloned (Akizuki et al., 1991; Trajanovska et al., 2007). The mature BNP, ANP-like peptide (also called RNP), CNP1, and CNP3 have 29, 34, 22, and 22 aa, respectively (Miyata et al., 1988; Arimura et al., 1991; Trajanovska et al., 2007). Interestingly, a novel gene orthologous to human *CNP* also exists in chicken genome (XM_015291500), which encodes a CNP peptide of 22 aa (Fig. 29.3A).

The actions of the five avian NPs are likely mediated by four NP receptors: NPR1 (XM_015298478), NPR2 (XM_003642919.4), a novel NPR1-like receptor (NPR1L, XM_025145121), and NPR3 (XM_004937172.3). The first three receptors may bind to the five NPs and increase intracellular cGMP levels, while NPR3 may

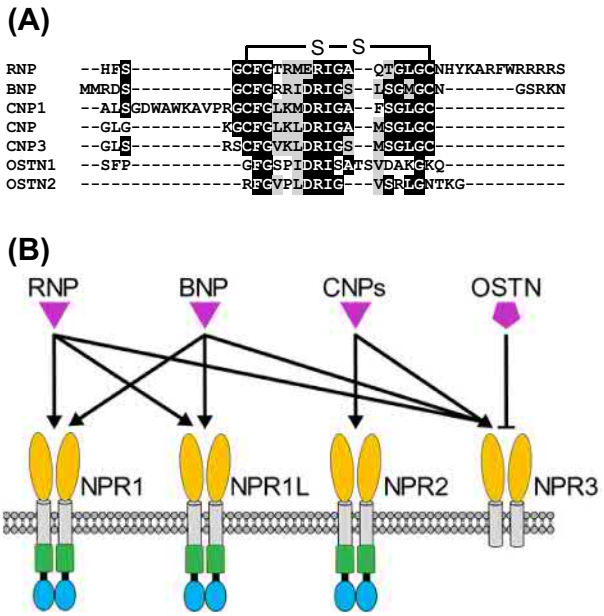

FIGURE 29.3 (A) Sequence alignment of five chicken natriuretic peptides (RNP, BNP, CNP, CNP1, and CNP3) with the two regions of OSTN peptide ($OSTN_1$/$OSTN_2$) homologous to NPs; (B) Hypothetical interaction of the five avian NPs and OSTN with the four NP receptors (NPR1, NPR1L, NPR2, and NPR3), which requires experimental validation. NPR1, NPR1L, and NPR2 may bind the five NPs and increase cGMP levels, while NPR3 may act as a clearance receptor for the five NPs. OSTN may bind to NPR3 and thus modulates the availability and action of the NPs.

function as a clearance receptor for the five NPs in birds. The ligand–receptor interaction proposed here needs further verification (Fig. 29.3B).

In chickens, *BNP* mRNA is abundantly expressed in both atria and ventricles (Toshimori et al., 1990; Trajanovska et al., 2007), but not in other tissues. ANP-like gene (*RNP*) is highly expressed in the kidney and weakly in the heart. *CNP1* is expressed in the brain, intestine, liver, and adrenal gland. *CNP3* is expressed in the brain, heart, and kidney. Moreover, four *NP* mRNAs are also expressed in chicken embryos (Houweling et al., 2005; Trajanovska et al., 2007). To date, the expression of novel *CNP* remains unknown.

In birds, NPs are likely to be involved in avian cardiovascular functions and fluid regulation and sodium excretion (Toop and Donald, 2004; Bie, 2018). In addition, NPs also regulate other physiological processes in birds. For instance, CNP3–NPR2 signaling is involved in the synthesis of glycosaminoglycans of the chondrogenic matrix and hypertrophy of differentiated chondrocytes (Kocamaz et al., 2012), while BNP–NPR1 signaling can stimulate proliferation and differentiation of preadipocytes in chicken (Huang et al., 2015).

29.1.24 Osteocrin peptide

In mammals, osteocrin (OSTN) peptide was identified as a novel bone-secreted factor modulating osteoblast phenotype, or as a muscle-derived factor (named Musclin) linked to glucose metabolism (Thomas et al., 2003; Nishizawa et al., 2004). OSTN peptide contains two regions homologous to NP, but lacks the two cysteine residues for ring structure formation of NPs (Fig. 29.3A) (Moffatt and Thomas, 2009). OSTN can bind to the clearance receptor NPR3 for NPs with high affinity (Moffatt et al., 2007; Kita et al., 2009) and thus modulate the action/availability of NPs in vivo. In chickens, *OSTN* is predicted to encode a peptide of 109 aa or a short peptide of 51 aa after proteolytic cleavage at the putative KKKR site (Thomas et al., 2003). However, the biological activity and physiological roles of OSTN are unknown in birds.

29.1.25 Neurosecretory protein GL and neurosecretory protein GM family

Neurosecretory protein GL (NPGL) and neurosecretory protein GM (NPGM) are two secretory peptides recently identified in chickens and mammals. In chickens, NPGL is a 83-aa peptide encoded by *NPGL* (*FAM237A*) gene, while NPGM is a 83-aa peptide encoded by *NPGM* (*FAM237B*) gene. Both peptides share ~54% aa identity and contain a putative intramolecular disulfide bond and an amidated C-terminus (Ukena et al., 2014; Shikano et al., 2018a). To date, the receptors for the two peptides have yet been identified in any vertebrate species.

NPGL is expressed in the infundibular nuclei (IN) and medial MM of the mediobasal hypothalamus. sc and icv infusions of NPGL can increase body mass gain and feeding in chicks (Shikano et al., 2018b; Ukena, 2018). *NPGM* is also expressed in the MM and IN. In particular, NPGM and NPGL show a degree of colocalization, especially in the MM. *icv* injection of NPGM decreases food intake, while chronic *sc* infusion of NPGM increases body mass gain in chicks (Shikano et al., 2018c).

29.1.26 Ornitho-kinin peptide

Kinin is implicated in the regulation of pain, inflammation, vasodilation, vascular permeability, and natriuresis in mammals (Marceau and Regoli, 2004). It is a 9-aa peptide, which is released from the kininogen precursor under the processing of kallikrein enzymes (Conlon, 1999). In chickens, kinin peptide contains 9 aa (Arg-Pro-Pro-Gly-Phe-Thr-Leu-Arg), which has two aa difference when compared to human kinin, thus is named as "ornitho-kinin" (Kimura et al., 1987).

Two GPCRs orthologous to human bradykinin B1 (*BDKRB1*) and B2 (*BDKRB2*) receptors exist in chicken genome (Bromee et al., 2006a). BDKRB2 can be activated by ornitho-kinin potently and stimulates intracellular Gq-phospholipase C (Gq-PLC) signaling pathway (Schroeder et al., 1997); however, the pharmacological property of avian BDKRB1 remains unclear.

The information regarding the roles and expression of ornitho-kinin and its receptors is limited in birds. In chickens, the kininogen gene (*KNG1*) encoding ornitho-kinin is reported to be expressed in the liver, while *BDKRB1* and *BDKRB2* are expressed in the liver and lung. In chickens, ornitho-kinin can induce the contraction of oviduct smooth muscle and has a strong hypotensive effect after injection via the wing vein (Kimura et al., 1987). A recent study reported that ornitho-kinin and their receptors participate in the inflammatory response of chickens (Guabiraba et al., 2017).

29.1.27 Angiotensin II peptide

In vertebrates, angiotensinogen encoded by *AGT* gene is processed by renin to produce a decapeptide angiotensin I. Angiotensin I is further cleaved by an angiotensin-converting enzyme to produce the bioactive octapeptide Angiotensin II (Ang II), which causes vasoconstriction, increased blood pressure, and stimulates adrenal aldosterone secretion in most vertebrate groups (Karnik et al., 2015). In chickens, Ang II is also an 8-aa peptide, which shows two aa difference at positions 1 (Asp^1) and 5 (Val^5) to human Ang II (Nakayama et al., 1973).

Two GPCRs for Ang II, named AT1 and AT2, exist in avian genomes. In chickens and turkeys, Ang II can activate AT1 and stimulate intracellular IP production and

calcium mobilization (Carsia et al., 1993; Murphy et al., 1993; Kempf et al., 1996); however, the signaling property of AT2 remains unclear in birds.

In chickens, *AT1* is expressed in the adrenal gland, heart, kidney, and endothelial cells (Kempf et al., 1996). Ang II can not only regulate cardiovascular development (Baker and Aceto, 1990) and arterial pressure (Crossley et al., 2010) at embryonic stage but also control cardiovascular functions and blood pressure of chickens (Nishimura et al., 1982, 2003). However, in contrast to its exclusive vasopressor action in mammals, Ang II has a dual action when administered to chickens (Nishimura et al., 1982; Kempf and Corvol, 2001). Chicken Ang II [(Asp^1, Val^5) Ang II] can produce an endothelium-dependent vasorelaxation, followed by a vasopressor action that is induced by an Ang II-dependent catecholamine release (Kempf and Corvol, 2001). The dual action of Ang II observed in birds is likely associated with the unique spatio-temporal expression patterns of AT1 and/or AT2 in target tissues (Kempf and Corvol, 2001; Nishimura et al., 2003), which requires further investigation.

29.1.28 Endothelin peptide family

In birds, three endothelin (EDN) peptides, named endothelin-1 (EDN1), endothelin-2 (EDN2), and endothelin-3 (EDN3), have been identified. Each EDN peptide is derived from a precursor of ~200 aa (named prepro-EDN) (Liu et al., 2019). This large precursor is first processed by furin endopeptidase to yield an intermediate product of 39–42 aa (known as Big-EDN, which is biologically inactive), which is further cleaved by endothelin-converting enzymes to give bioactive mature EDN peptides (Liu et al., 2019). These mature bioactive EDNs are peptides of 21 aa and characterized by the presence of two intrachain disulfide bonds at Cys3-Cys11 and Cys1-Cys15 (Davenport et al., 2016; Liu et al., 2019).

Three GPCRs for EDN1/EDN2/EDN3, named EDNRA, EDNRB, and EDNRB2, have been characterized in chickens (Liu et al., 2019). Among them, EDNRA is a receptor common for EDN1 and EDN2, while EDNRB and EDNRB2 are the two receptors common for EDN1, EDN2, and EDN3. Activation of the three receptors by EDNs stimulates intracellular Gq-PLC and Gs-AC/cAMP/PKA signaling pathways.

qPCR assays revealed that *EDNs* and *EDNRs* are widely, but differentially, expressed in chicken tissues (Liu et al., 2019). In birds, EDN–EDNR signaling has been reported to play critical roles in many physiological/pathological processes, such as cardiovascular development (Gourdie et al., 1998; Groenendijk et al., 2008), angiogenesis (Cruz et al., 2001), pulmonary arterial hypertension (Gomez et al., 2007), morphogenesis of the face and heart (Kempf et al., 1998; Nataf et al., 1998), and the proliferation, migration, and differentiation of trunk neural crest cells into the enteric nervous system (Nagy and Goldstein, 2006) or the melanocytes (Lahav et al., 1996; Pla and Larue, 2003; Harris et al., 2008) which influence skin pigmentation and plumage patterning in quails and chickens (Dorshorst et al., 2011; Shinomiya et al., 2012; Han et al., 2014; Kinoshita et al., 2014).

29.1.29 Bombesin peptide family

Gastrin-releasing peptide (GRP) and neuromedin B (NMB) are two structurally related peptides, which belong to bombesin peptide family. In chickens, two active forms of GRP with an identical C terminus, GRP_{27} (27 aas) and GRP_{10} (10 aas) (McDonald et al., 1980; Campbell et al., 1990), have been isolated from the proventriculus. Both GRP forms are released by cleavage from the same precursor encoded by *GRP* gene. NMB is a 10-aa peptide encoded by *NMB* gene and shares high aa sequence identity (60%) with GRP_{10} (Mo et al., 2017).

Three GPCRs for GRP and NMB, namely GRPR, NMBR, and Bombesin receptor subtype 3 (BRS3), have been characterized in chickens (Iwabuchi et al., 2003; Mo et al., 2017). GRPR and NMBR are GRP-specific and NMB-specific receptors, respectively. Interestingly, BRS3 can function as a common receptor for both peptides in chickens (Mo et al., 2017), contrary to mammalian finding, in which BRS3 is reported to be an orphan receptor. Activation of the three chicken receptors can stimulate calcium mobilization and enhance ERK phosphorylation.

qPCR assay revealed that GRP has the highest expression level in the anterior pituitary and a comparatively low expression level in other tissues, such as the proventriculus, hypothalamus, telencephalon, spinal cord, gizzard, ovary, and testes. Immunostaining studies showed that GRP is localized in gonadotrophs (LH cells) and endocrine cells in the proventriculus (Vaillant et al., 1979; Buffa et al., 1982; Mo et al., 2017). These findings, together with the wide expression of GRPR in chicken tissues including the hypothalamus, proventriculus, ovary and pancreas, indicate that GRP may act as an endocrine hormone or a local factor to regulate many physiological processes of birds, such as feeding, gall bladder motility, crop-emptying rate, pancreatic fluid secretion, gastric acid secretion, and reproduction (Linari et al., 1975; Linari and Linari, 1975; Tachibana et al., 2010b,c). Unlike *GRP*, *NMB* is highly expressed in the testes and moderately/weakly expressed in other tissues (including the CNS and ovary), except the kidneys, liver, lung, and muscle (Mo et al., 2017). This finding indicates that NMB is more likely a local paracrine/autocrine factor (e.g., as a neuromodulator in the CNS) to regulate avian physiological processes, such as food intake and testis development/functions (Tachibana et al., 2010b,c; Tachibana et al., 2010d; Mo et al., 2017). The predominant

expression of BRS3 in chicken telencephalon suggests a role of BRS3 signaling in avian brain (Ohki-Hamazaki et al., 2005; Mo et al., 2017), which warrants further investigation.

29.1.30 Melanocortin system peptides

In birds, melanocortin system consists of melanocortin peptides, Agouti-related peptide (AgRP), Agouti signaling protein (ASIP), melanocortin receptors, and two melanocortin receptor 2 accessory proteins (MRAP and MRAP2). In chickens, melanocortin peptides include α-melanocyte-stimulating hormone (α-MSH, 13 aa), β-MSH (18 aa), ɣ-MSH (11 aa), and adrenocorticotropin (ACTH, 39 aa) (Takeuchi et al., 1999), all of which contain a conserved "HFRW" motif essential for melanocortin receptor activation. It is clear that all melanocortin peptides are produced from the same POMC precursor after tissue-specific processing by two prohormone convertases (PC2 and PC1/3) (Dores et al., 2016; Zhang et al., 2017). Chicken AgRP and ASIP are two structurally related peptides of 137 aa and 108 aa, respectively, and both peptides contain multiple (say four−five) intramolecular disulfide bonds.

Five GPCRs, named MC1R, MC2R, MC3R, MC4R, and MC5R, have been cloned and identified as the receptors for melanocortins, AgRP, and ASIP (Fig. 29.4A) (Takeuchi et al., 1998; Takeuchi and Takahashi, 1998, 1999; Ling et al., 2003, 2004). α-MSH and ACTH can

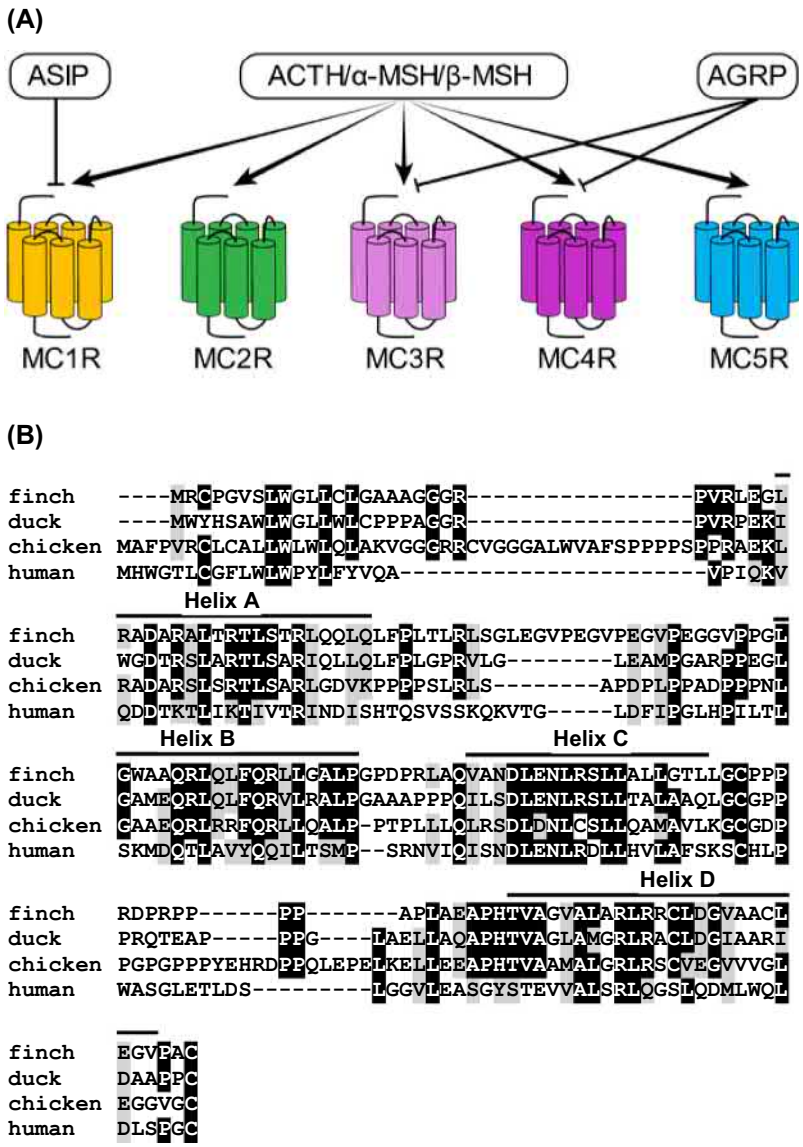

FIGURE 29.4 (A) melanocortin peptides (e.g., ACTH, α-MSH, and β-MSH) can activate the five melanocortin receptors (MC1R, MC2R, MC3R, MC4R, and MC5R) and increase cAMP levels, while AgRP or ASIP can act as either an endogenous antagonist or an inverse agonist to modulate receptor signaling. (B) Sequence alignment of zebra finch, duck, chicken, and human leptin (LEP). Only ~30% amino acid identity is observed between avian and human/mouse leptin (LEP); however, four α-helix structures also exist in avian LEP. These are marked in the figure.

function as the endogenous agonists for MC1R, while ASIP likely acts as an endogenous antagonist or reverse agonist of MC1R to modulate its signaling (Ling et al., 2003). MC2R can interact with MRAP to enhance its surface expression and ligand binding, thus enabling it to become a functional ACTH-specific receptor (Barlock et al., 2014; Zhang et al., 2017). MC3R and MC4R can act as the two receptors common for $ACTH_{1\text{-}39}$, α-MSH, β-MSH, and ɣ-MSH, in the absence of MRAP2. However, in the presence of MRAP2, both MC3R and MC4R become ACTH-preferring receptors (Zhang et al., 2017). Interestingly, AgRP has dual functions. It acts either as an endogenous antagonist or reverse agonist of MC3R and MC4R to modulate their signaling (Zhang et al., 2017). MC5R can function as a receptor for ACTH, α-MSH, and β-MSH (Ling et al., 2004). When coexpressed with MRAP, MC5R displays an increased sensitivity to ACTH (Thomas et al., 2018).

In chickens, *POMC* mRNA is expressed predominantly in the anterior pituitary, moderately in the hypothalamus, and weakly in other tissues including the skin, kidneys, adrenal gland, fat, and gonads (Takeuchi et al., 1999; Zhang et al., 2017). *AgRP* mRNA is widely expressed in chicken tissues with a high expression level noted in the hypothalamus (Takeuchi et al., 2000; Zhang et al., 2017). Interestingly, three types of *ASIP* transcripts likely driven by alternative promoter usage are reported to allow their differential expression in chicken tissues including the skin (feather follicles), hypothalamus, pituitary, heart, lung, spleen, adrenal gland, ovary, and testes (Yoshihara et al., 2012).

Five melanocortin receptors are also found to be differentially expressed in chicken tissues including the hypothalamus, adrenal gland, and skin (Takeuchi et al., 2000; Zhang et al., 2017; Thomas et al., 2018). This finding supports that the five receptors may mediate the diverse actions of melanocortins, AgRP, and ASIP in birds, such as MC1R-mediated skin melanin synthesis and plumage color formation (Kerje et al., 2003; Ling et al., 2003), MC2R-mediated adrenal steroidogenesis (Barlock et al., 2014), and MC3R/MC4R-mediated feeding, energy balance, growth, and body weight control (Boswell et al., 2002; Cline et al., 2008a; Smith et al., 2008; Shipp et al., 2015; Zhang et al., 2017). To date, the role of MC5R signaling is unknown in birds.

29.1.31 Arginine vasotocin/mesotocin peptides

In birds, arginine vasotocin (AVT) and mesotocin (MT) are two structurally related peptides and orthologous to mammalian arginine vasopressin (AVP) and oxytocin (OXT) peptides, respectively. They are also the two endocrine hormones secreted by avian posterior pituitary. Both peptides contain 9 aa and share structural conservation across vertebrates, including the presence of an intramolecular disulfide bond and an amidated C-terminus.

Four GPCRs for AVT and MT have been characterized in chickens and named AVPR1A (also called VT4, or V1a) (Selvam et al., 2013), AVPR1B (VT2 or V1b) (Cornett et al., 2003), MTR (VT3, or OXTR) (Gubrij et al., 2005), and AVPR2b (VT1) (Tan et al., 2000), respectively (Wu et al., 2019). Among them, *AVPR1A*, *AVPR1B*, and *MTR* are orthologous to human *AVPR1A*, *AVPR1B*, and *OXTR*, respectively, whereas *AVPR2b* exists in birds, but is lost in mammals (e.g., humans) (Wu et al., 2019). Avian AVPR1A, AVPR1B, AVPR2b, and MTR are the four functional receptors for AVT, while MTR functions as the sole receptor for MT. Since AVT is ∼four to eightfold more potent than MT in activating AVPR2b, thus avian AVPR2b can be viewed as an AVT-preferring receptor. All receptors are coupled to Gq (/Gs) protein and their activation triggers calcium mobilization and stimulates MAPK/ERK and cAMP/PKA signaling pathways (Wu et al., 2019).

The physiological roles of avian AVT and MT have been described in other chapters of this book, and thus not included here.

29.1.32 Cocaine- and amphetamine-regulated transcript peptides

Cocaine- and amphetamine-regulated transcript (CART) peptide is a neuropeptide of 41 or 48 aa abundantly expressed in the hypothalamic arcuate nucleus (ARC) and reported to play important roles in regulating feeding and energy balance in mammals (Rogge et al., 2008). In chickens, two *CART* genes, named *CART1* (KC249966) and *CART2* (KC249967), were identified. Chicken *CART1* is orthologous to mammalian *CART*, while *CART2* is likely lost in mammals but exists in birds and other lower vertebrates. Chicken *CART1* (also called *CART*) encodes a mature CART peptide of 41 aa ($CART_{48\text{-}89}$) or 48 aa ($CART_{42\text{-}89}$), which shows 96−98% aa identity to human CART and shares the three characteristic putative intramolecular disulfide bonds. Chicken *CART2* is predicted to produce a mature peptide of 41 aa ($CART2_{51\text{-}91}$), which shows only 59% sequence identity to human CART (Cai et al., 2015). To date, the receptor for CART peptide remains unknown in vertebrates.

In chickens, CART peptide (encoded by *CART1*) is predominantly expressed in the anterior pituitary and its expression and secretion is regulated by hypothalamic gonadotropin-releasing hormone 1(GnRH1) (Cai et al., 2015; Mo et al., 2019). This finding indicates that CART peptide is a novel pituitary hormone in chickens, which is likely associated with avian reproduction (Mo et al., 2019). Moreover, fasting downregulates and CRH upregulates pituitary *CART1* mRNA expression (Cai et al., 2015;

Mo et al., 2015). Besides the pituitary, *CART* is also expressed in the hypothalamus and fasting downregulates *CART1* expression. In zebra finches, CART-ir cells were observed in the bed nucleus of the stria terminalis, hypothalamic paraventricular, supraoptic, dorsomedial, IN, lateral hypothalamic, Edinger–Westphal, and parabrachial nuclei. Moreover, fasting reduces, and refeeding increases CART-ir fibers in the IN, where CART-ir fibers contact and interact with NPY neurons. These findings indicate that CART also plays roles in the CNS, such as the regulation of food intake and energy homeostasis in birds (Tachibana et al., 2003; Singh et al., 2016).

Unlike *CART1*, *CART2* has an extremely low expression level in chickens (Cai et al., 2015), implying a less significant role under normal physiological conditions.

29.1.33 Leptin

In mammals, leptin (LEP), an adipose-derived peptide, plays pivotal roles in the regulation of food intake, energy balance, obesity, and reproduction. Recently, an authentic LEP of ~16 kDa has been identified in avian species, including zebra finches (Huang et al., 2014b; Prokop et al., 2014), budgerigars (Huang et al., 2014b), peregrine falcons (Prokop et al., 2014), rock doves (Friedman-Einat et al., 2014), chickens, ducks (Seroussi et al., 2016), and Japanese quails (Wang et al., 2016). The full-length avian LEP only shows ~30% sequence identity to mammalian ortholog, but it contains a pair of cysteine residues and four-helix bundle structure, resembling the tertiary structure of mouse/human LEP (Fig. 29.4B) (Huang et al., 2014b; Friedman-Einat and Seroussi, 2019).

Functional assay shows that recombinant finch LEP can potently activate finch/chicken LEP receptor (LEPR) and stimulate the intracellular JAK2-STAT3 signaling pathway (Huang et al., 2014b), indicating that LEPR is a functional receptor for avian LEP.

qPCR and RNA-seq analysis reveal that *LEP* mRNA is highly expressed in the brain (e.g., cerebellum and telencephalon) and pituitary and weakly in other tissues of zebra finches and chickens, while *LEPR* is abundantly expressed in the anterior pituitary, moderately in the brain (including cerebellum), gonads, and weakly in other tissues examined (Huang et al., 2014b; Seroussi et al., 2016). The little or no expression of *LEP* in the adipose tissue and liver indicates that LEP can neither act as an adipocyte-derived signal nor as a liver-derived signal to control energy balance and food intake in birds. Meanwhile, these findings suggest that LEP acts more likely as an autocrine/paracrine factor, instead of an adipocyte-derived circulating hormone, in avian tissues, such as in the brain and anterior pituitary (Huang et al., 2014b; Seroussi et al., 2016; Friedman-Einat and Seroussi, 2019). The "nonadipokine" nature of avian LEP also urges us to find other hidden "adipostat signal(s)," which can function as the long-term peripheral metabolic signal to control avian energy balance.

29.1.34 Thyrotropin-releasing hormone

Thyrotropin-releasing hormone (TRH) is a 3-aa neuropeptide hormone secreted by the hypothalamus of vertebrates. In chickens, bioactive TRH (pyro-Glu-His-Pro-NH2) is cleaved from the TRH precursor, which contains four copies of "Gln-His-Pro-Gly" motifs flanked by the dibasic residues (Vandenborne et al., 2005b).

Two structurally related TRH receptors (TRHRs) have been characterized in chickens and named TRHR1 and TRHR3, respectively (Li et al., 2020). TRHR1 and TRHR3 are likely coupled to Gq protein, and their activation can trigger calcium mobilization and MAPK/ERK signaling cascade (Sun et al., 1998; Li et al., 2020).

In birds (e.g., chickens and ducks), TRH is predominantly expressed in the hypothalamus (e.g., in the parvocellular portion of the PVN and lateral hypothalamic area) revealed by qPCR (Li et al., 2020), in situ hybridization (Vandenborne et al., 2005b), and immunostaining (Jozsa et al., 1988). *TRHR1* is predominantly expressed in chicken anterior pituitary and weakly in other tissues including the hypothalamus (Sun et al., 1998), while *TRHR3* is widely expressed in chicken tissues (Li et al., 2020). In testes, TRH has a moderate expression level. These findings indicate that TRH can regulate the functions of the pituitary (e.g., TSH, PRL, and GH secretion) and extrapituitary tissue.

29.1.35 Esophageal cancer–related gene 4–derived peptides

Esophageal cancer–related gene 4 (*ECRG4*), also called *C2ORF40* gene, is predicted to encode a hormone-like peptide involved in the regulation of many processes, such as tumor suppression, stress, and inflammatory response in mammals (Gonzalez et al., 2011). In chickens, *ECRG4* is predicted to encode a mature augurin peptide of 124 aa ($ECRG4_{29\text{-}152}$). This augurin peptide could be further processed by furin or thrombin. Furin processing at site 71–74 may produce two fragments, $ECRG_{29\text{-}70}$ (ecilin) and $ECRG4_{75\text{-}152}$ (argilin). Thrombin processing at site 132–136 may produce $ECRG4_{29\text{-}131}$ (CΔ16-augurin), $ECRG4_{75\text{-}131}$ (CΔ16-argilin), and $ECRG4_{137\text{-}152}$ (CΔ16).

Recently, in mammals, several scavenger receptors (e.g., LOX1) were identified as the receptors for ECRG-derived peptide, CΔ16-argilin (Moriguchi et al., 2018). In addition, CΔ16 (the C-terminal ECRG4 fragment of 16 aa) was also reported to interact with toll-like receptor 4–CD14–MD2 complex (Podvin et al., 2015). However, little is known about the receptors and roles of ECRG4-derived peptides in birds.

29.1.36 Chemerin

Chemerin is a chemoattractant protein and adipokine encoded by the retinoic acid receptor responder 2 (*RARRES2*) gene, which has been reported to regulate many physiological/pathological processes in mammals, such as inflammation, adipogenesis, obesity, cardiovascular disease, reproduction, and host defense (e.g., inhibition of bacterial growth) (Kulig et al., 2011; Banas et al., 2013; Kennedy and Davenport, 2018). In chickens, *RARRES2* encodes a precursor protein of 162 aa, which contains an N-terminal signaling peptide of 17 aa and a C-terminal prochemerin (18−162 aa) containing three disulfide bonds. The circulating prochemerin has low biological activity and thus needs the removal of its short C-terminus to produce the most active chemerin of 140 aa (named chemerin$_{18\text{-}147}$).

Two putative GPCRs, named chemokine-like receptor 1 (CMKLR1) and G-protein−coupled receptor 1 (GPR1), for chemerin$_{18\text{-}147}$ exist in chicken and other birds; however, their functionality is unknown.

In turkeys, *RARRES2* was reported to be mainly expressed in the liver, while *CMKLR1* and *GPR1* ubiquitously expressed in various tissues, including ovarian follicular cells (Diot et al., 2015). In chickens, food restriction can increase plasma chemerin levels during laying periods, which is proposed to be associated with increased fertility in broiler breeder hens (Mellouk et al., 2018). These pioneering studies suggest that chemerin may regulate avian reproduction. Despite the high concentration of chemerin (∼200 ng/mL in broiler chickens) detected in avian plasma (Mellouk et al., 2018), little is known about the ratio of active versus inactive chemerin forms in vivo and the other physiological roles of chemerin in birds, such as its roles in inflammation, lipid metabolism, and host defense etc.

29.1.37 Granin-derived peptides

Chromogranin A (CgA), chromogranin B (CgB), and secretogranin II (SgII) are three members in granin family, which are expressed in the neurons and endocrine tissues. These acidic secretory proteins are not only involved in the regulation of sorting and packaging hormones inside secretory granules and secretory granule formation but also can be proteolytically processed into many biologically active peptides in mammals (Troger et al., 2017). CgA, CgB, and SgII proteins also exist in birds and are expressed in endocrine tissues (e.g., pituitary and adrenal gland) and neurons (Salvi et al., 1996; Kameda et al., 1998; Gomi et al., 2015). Although the overall aa sequence identity (∼37−57%) between avian (e.g., chicken) and human CgA, CgB, and SgII is not high (Proudman et al., 2003), avian CgA protein can produce two peptides, vasostatin I (CgA$_{1\text{-}76}$, 76 aa) and serpinin peptide (26 aa) in ostrich pituitaries (Lazure et al., 1990; Tota et al., 2012; Troger et al., 2017). Chicken CgB may produce cCgB$_{1\text{-}41}$ (41 aa) and secretolytin (cCgB$_{641\text{-}653}$; 13 aa) (Montero-Hadjadje et al., 2008), and SgII can produce secretoneurin (SN, 33 aa, SgII$_{159\text{-}191}$) (Leitner et al., 1998) and a potential "EM66 peptide" (cSgII$_{194\text{-}260}$: 67 aa). In chickens, CgB$_{1\text{-}41}$, secretolytin, SN, and EM66 peptides show high sequence identity with their corresponding mammalian counterparts (Leitner et al., 1998). In contrast, other granin-derived peptides previously reported (e.g., pancreastatin and catastatin) (Troger et al., 2017) show little or low sequence identity between birds and mammals.

Granin-derived peptides play multiple functional roles in mammals (Troger et al., 2017). For instance, vasotatin I displays antimicrobial activity and regulates cardiovascular function; Serpinins (three forms: serpinin, serpinin-RRG, and pyro-Glu-serpinin) derived from the C-terminus of CgA can modulate cardiovascular function; CgB$_{1\text{-}41}$ inhibits parathormone release and secretolytin displays antimicrobial activity; SN is involved in the regulation of neurogenesis, neuroprotection, angiogenesis, chemoattraction, and hormone secretion, while EM66 is involved in the hypothalamic regulation of feeding behavior (Trebak et al., 2017). Despite the presence of these granin-derived peptides in birds, however, their roles are unknown. Moreover, the identity of cognate receptors for these avian peptides is an open question.

Besides CgA, CgB, and SgII, four additional proteins, namely secretogranin 3 (SgIII), secretogranin 5 (SgV), VGF (SgVII), and proSAAS, belong to the granin family (Bartolomucci et al., 2011). Since SgIII, SgV, and VGF exist in chickens (/zebra finches), this supports the existence of additional granin-derived peptides in birds, which require further studies.

It was reported that in mammals (e.g., humans), proSAAS can be processed into two active peptides, named PEN (AADHDVGSELPPEGVLGALLRV) and big-LEN (LETPAPQVPARRLLPP), which can function as the endogenous ligands for GPR83 and GPR171, respectively (Gomes et al., 2013, 2016). However, *proSAAS* gene is lost in avian lineage, clearly indicating that PEN and big-LEN peptides are not the endogenous ligands for avian GPR83, GPR83-like receptor, and GPR171.

29.1.38 Antimicrobial host defense peptides

HDPs are small and cationic peptides of <50 aa, which function as an essential part of innate host defense against pathogens in vertebrates. In birds, HDPs consist of β-defensins, ovo-defensins, cathelicidins (CATH), liver-expressed antimicrobial peptide-2 (LEAP-2), NK-lysin (NK3), hepcidin, etc.

Over 25 β-defensin peptides/genes have been identified in birds (Cuperus et al., 2013). In chickens, 14 defensin

genes clustered on chromosome 3 have been identified and named *AvBD1-14*, respectively (Xiao et al., 2004; Lynn et al., 2007). In zebra finches, 22 defensin genes have been identified, and 10 of them are orthologous to chicken defensin genes (Hellgren and Ekblom, 2010). The variation in the copy number of defensin genes in birds is caused by rapid local gene duplication or gene loss during speciation. In chickens, each defensin gene encodes a precursor, which generally contains a signal peptide and C-terminal mature defensin peptide. The predicted mature defensin peptides, except AvBD11, are ~40 aa long and characterized by the presence of three disulfide bridges and the formation of three β-sheets and α-helix structure at their N termini. AvBD11 is an 82-aa peptide and contains two defensin domains, N- and C-terminal domains (Guyot et al., 2020). The N-terminal domain mediates antibacterial, antiparasitic, and antiinvasive activities, while the C-terminal domain potentiates the latter two activities. The antiviral activity in infected chicken cells, accompanied by marked cytotoxicity, requires the full-length AvBD11 peptide (Guyot et al., 2020). In addition, posttranslational modifications have been identified in some chicken AvBDs, such as the C-terminal amidation of mature AvBD1 and the N-terminal glutaminyl cyclization (pyroglutamic acid at position 1) of mature AvBD7 (Derache et al., 2009) and AvBD6.

Ovo-defensins were originally identified in avian oviducts, where they are secreted and stored in the egg white and display antibacterial activity (Gong et al., 2010). In chickens and zebra finches, five ovo-defensins, named OvoDA1, OvoDA2, OvoDA3, OvoDB1, and OvoDBb, have been identified and all of them share structural similarity to β-defensin, such as the presence of three disulfide bonds and formation of three antiparallel β-sheets (Whenham et al., 2015; Zhang et al., 2019).

Avian CATH prepropeptide contains an N-terminal signal peptide, a cathelin-like domain, and a C-terminal mature CATH peptide of 26–40 aa. In chickens, four *CATH* genes clustered on chromosome 2 have been identified, named *CATH1*, *CATH2*, *CATH3*, and *CATHB1*, respectively (Xiao et al., 2006; Goitsuka et al., 2007; van Dijk et al., 2011). They are α-helical cationic peptides and have an amphipathic structure to interact with negatively charged molecules on bacterial surface, like lipopolysaccharide or lipoteichoic acid (Bommineni et al., 2007; Cuperus et al., 2013). Thus, all four CATH peptides display potent antiantimicrobial activity. In addition, two C-terminal amidated forms of CATH2 (26 aa/31 aa) may also exist in chickens, as in mammals (van Dijk et al., 2011).

LEAP-2 peptide is a 54 aa, cationic peptide with two disulfide bridges, and is highly expressed in chicken liver and small intestine and its expression is upregulated by *Salmonella* infection (Lynn et al., 2003, 2004). *In vitro*, LEAP2 peptide shows antibacterial activity against *Salmonella typhimurium* by permeabilizing bacterial outer membrane (Townes et al., 2004, 2009).

In chickens, NK−lysin gene encodes a mature cysteine-rich NK−lysin peptide of 78 aa with five α-helical regions, which display an antibacterial activity (Hong et al., 2006; Lee et al., 2014). Interestingly, aa substitution at the position 29 (Asn^{29} to Asp^{29}) of NK−lysin in chicken strains (White leghorn vs. Cornish) affects its antimicrobial activity and anticancer activity (Lee et al., 2012).

In mammals, hepcidin was initially identified as a cationic antibacterial/fungal peptide of 20/25 aa with four disulfide bonds, which is predominantly expressed in the liver (Krause et al., 2000; Park et al., 2001). Later studies show that hepcidin is likely a hepatic peptide hormone involved in the maintenance of iron homeostasis, such as the regulation of iron storage in macrophages, and intestinal iron absorption (Pigeon et al., 2001; Wunderer et al., 2020). Interestingly, hepcidin gene likely exists in some avian species, such as Swainson's thrush (XM_033084442) (Fig. 29.5). Moreover, avian hepcidin gene can encode a mature hepcidin peptide of 25 aa, which contains four intramolecular disulfide bonds crucial for stabilizing their β-sheet structures, implying a conserved role of hepcidin in birds. However, the antimicrobial activity of hepcidin has yet been tested in avian species.

Taken together, the presence of cationicity and amphipathicity characterized in HDPs is essential for their biological activities, such as antibacterial activity, antiviral activity, antifungal activity, antiparasitic activity, immunomodulatory actions, wound healing, and induction of adaptive immunity (Mookherjee et al., 2020). Future studies on their inter-/intraspecies copy number variation, tissue-specific expression, pathogen-/hormone-regulated expression, posttranslational modifications, and unique biological activities will help to uncover the roles of avian HDPs and promote their applications in poultry industry.

FIGURE 29.5 Sequence comparison of hepcidin peptide predicted in 14 avian species, including *Catharus ustulatus* (Swainson's thrush).

29.1.39 Other peptides

In addition to the peptides mentioned above, many other peptides such as GnRH1, GnRH2, insulin, pituitary hormones [GH, PRL, FSH, LH, and thyrotropin (TSH)], cytokines, chemokines, and peptide growth factors (e.g., EGF, IGF, VEGF, and TGFβ families/superfamily), have been described in other chapters (or elsewhere), and thus, are not described here.

29.2 Summary

In this chapter, we briefly described the structure, functions, expression, and major actions of 134 peptides/neuropeptides involved in the regulation of avian growth, stress, food intake, energy balance, lipid and glucose metabolism, reproduction, water homeostasis, calcium homeostasis, cardiovascular functions, blood pressure, host defense, etc. These peptides are encoded by 111 genes. Most of these avian peptides (97) have their corresponding mammalian orthologs, and some of them play physiological roles similar to those in mammals, such as hypothalamic GHRH and SST, stimulate, and inhibit pituitary GH secretion, respectively (Meng et al., 2014). However, notable differences are present between these two animal groups:

Firstly, more than 20 unique peptides exist in birds. Most of these peptides are derived from gene duplication and are the expanded peptide family members, which are likely lost or absent in mammals. For instance, avian GCG superfamily has 12 members including GCGL, SCT-LP, GHRH-LP peptides, while mammalian GCG superfamily only has 9 bioactive members and GCGL, SCT-LP, and GHRH-LP are lost in the lineage. Similarly, unique members were also identified in the avian CRH family (CRH2), PTH family (PTH-L), RF-amide peptide family contains (PrRP2), NP family (CNP1, CNP3), and host defensin peptides (five ovo-defensins birds).

Secondly, some peptide families have fewer members in birds when compared to mammals. For example, only two members of RLN family (RLN3-like and INSL5) were identified in chickens, while seven members are present in human RLN family (RLN1, RLN2, RLN3, INSL3, INSL4, INSL5, and INSL6). Likewise, a few member(s) in the galanin peptide superfamily (GALP and KISS) and opioid peptide family (Neo-endorphin) were probably lost in avian lineage.

Thirdly, the number of receptors for most peptide families differs between birds and mammals. For instance, chicken GHRH has two GHRHRs (GHRHR1 and GHRHR2), while mammals only have one GHRH receptor (Wang et al., 2010). Similarly, PrRP has three receptors (PrRPR1, PrRPR2, and PrRP2R); in comparison, there is one PrRP receptor in mammals (Wang et al., 2012c). Mammals got an AVT receptor (AVPR2a) and a PTH receptor (PTH2R), which are likely lost in chickens (Wu et al., 2019). The difference in the repertoires of avian peptides and their receptors indicate that further studies are required to examine how avian peptide–receptor interaction differs from that of mammals.

Finally, although the names of some peptides are used across different species, it is of important to note that it should not be taken for granted that they exert the same actions as their names imply in avian species. In particular, some avian peptides may have actions and expression patterns distinct from their mammalian counterparts. For instance, avian SCT does not exert characteristic regulation on pancreatic fluid secretion (Wang et al., 2012a), and avian LEP (*ob*) is not expressed in avian adipose tissue and cannot display an "adipostat activity" to control energy balance as in mammals (Friedman-Einat and Seroussi, 2019). Thus, caution should be taken to elucidate the physiological roles of these avian peptides.

Taken together, the number, structures, function, expression, and major actions of avian peptides and their receptors likely differ from those in mammals, so we cannot simply transfer our knowledge on mammalian peptides onto avian models. Clearly, it is essential to perform further extensive in-depth studies on the functions and roles of avian peptides and their receptors. This will not only help to reveal their unique roles in avian biology, such as body composition, feathering and plumage patterning, metabolism, brooding, singing, and energy storage and utilization before and during flight, migration and seasonal breeding, etc., but also aid to uncover the "hidden" conserved roles of peptide–receptor pairs across vertebrates from the perspective of comparative endocrinology.[1]

30.1 Introduction

The pituitary gland (hypophysis) is intimately connected to the hypothalamus in both an anatomically and functionally close relationship. The structure of the hypothalamo-hypophyseal complex is shown in Figure 30.1. The pituitary gland consists of two distinct structures as summarized in Table 30.1:

- The anterior pituitary gland or pars distalis, which sits in a depression in the bone—sella turcica
- The posterior pituitary gland or pars nervosa, which is connected to the base of the brain by the infundibulum

30.2 Embryonic development of the pituitary gland

The pituitary gland has a complex structure and an interesting embryonic development. The anterior and posterior pituitary glands have distinctly differences in anatomy, physiology, and embryonic developments. Pituitary tissue can be classified as either adenohypophysis or neurohypophysis each with a distinct embryonic origin (see Figure 30.2). The adenohypophysis is derived from Rathke's pouch and this, in turn, derived from the medial stomodeal ectoderm (i.e., from the roof of the mouth) at the rostral border of the neural plate (chicken: Sánchez-Arrones et al., 2015). A distinct Rathke's pouch is developed during Hamburger and Hamilton stage 12 (Romanoff, 1960). It expresses transcription factor 4 (Tcf4), the paired like homodomain transcription factor (Pitx2) and sonic

[a]*Frequently considered only as part of hypothalamus.*

hedgehog signally molecule (Shh) (Sánchez-Arrones et al., 2015). The lens protein, δ-crystallin, is transiently expressed in cells of the Rathke's pouch (chicken embryo: Inoue et al., 2012). Subsequently by Hamburger and Hamilton stage 18, the adenohypophysis primordium is fully formed and is moving to close by and underlying the hypothalamus (Sánchez-Arrones et al., 2015). The neurohypophysis is derived from the infundibulum (an outgrowth of the brain). In birds, the adenohypophysis goes on to form the pars distalis with some adenohypophyseal cells migrating to form the pars tuberalis below the median eminence.

AH—adenohypophysis, NH—neurohypophysis, och—optic chiasm. *Based on Sánchez-Arrones, L., Ferrán, J.L., Hidalgo-Sanchez, M., Puelles, L., 2015. Origin and early development of the chicken adenohypophysis. Front. Neuroanat. 9, 7.*

30.3 Anatomy of the pituitary gland

30.3.1 Anatomy of the anterior pituitary gland (pars distalis)

The avian pars distalis consists of two distinct lobes: the cephalic and caudal lobes. The anterior pituitary gland is composed of secretory cells, folliculo-stellate cells, extracellular colloid, and connective tissues composed of fibrous materials (Mohanty, 2006) together possibly with microglial cells (discussed below).

30.3.1.1 Secretory cells

The anterior pituitary gland (pars distalis) has the full complement of secretory cells: corticotropes producing adrenocorticotropic hormone (ACTH), gonadotropes producing either luteinizing hormone (LH) or follicle-stimulating hormone (FSH), lactotropes producing prolactin (PRL), somatotropes producing growth hormone (GH), and thyrotropes producing thyrotropin/thyroid-stimulating hormone (TSH) (Table 30.2). Gastrin-releasing peptide (GRP) is expressed in LH-producing gonadotropes (Mo et al., 2017). In addition, there are somatolactotropes producing both GH and PRL (turkey: Ramesh et al., 1998, 2001) and cells that co-express pro-opiomelanocortin (POMC) and α-sub-unit of the glycoprotein hormones LH, FSH, and TSH (chickens: Pals et al., 2006).

There are changes in secretory cells with physiological state with specific secretory cells undergoing proliferation or apoptosis. For instance, there are marked changes after cessation of lay due to forced molt (chicken: Yoshimura et al., 1997; Chowdhury and Yoshimura, 2002).

The pars distalis is richly supplied with blood vessels including the hypophyseal portal vessels. These provide a route from the neurosecretory nerve terminals in the median eminence to the anterior pituitary gland (Figure 30.1). Indeed, it is by way of these portal blood vessels that the anterior pituitary gland is controlled by releasing hormones (or hypothalamic hypophysiotropic factors) (Figure 30.1; Table 30.3).

In some avian species, pituitary tumors have been identified with multiple somatotropes (budgerigar: Langohr et al., 2012).

30.3.1.2 Folliculo-stellate cells

In addition to secretory cells, there are nonendocrine cells, the folliculo-stellate cells in both the cephalic and caudal lobes of the anterior pituitary gland. Avian folliculo-stellate cells are of extrapituitary origin. These mesenchyme cells invade the anterior pituitary gland between days 15 and 18 of embryonic development in the chicken (Horiguchi et al., 2016). These cells express markers including immune-reactive S-100 proteins (quail: Harrison et al., 1982; Van

TABLE 30.2 Summary of the chemistry of the hormones of the pituitary gland.

Pituitary hormone	Alternate name (IUPAC/IUB)	Chemistry
Hormones of anterior pituitary gland		
Adrenocorticotropic hormone (ACTH)	Corticotropin	Synthesized as protein (pro-opiomelanocortin or POMC) then proteolytically cleaved to 39 amino acid residue polypeptide
Follicle-stimulating hormone (FSH)	Follitropin	Two glycoprotein subunits: * α-subunit common to FSH, LH, and TSH * β-subunit—specific to FSH
Luteinizing hormone (LH)	Lutropin	Two glycoprotein subunits: * α-subunit common to FSH, LH, and TSH * β-subunit—specific to LH
Growth hormone (GH)	Somatotropin	Protein + glycosylated variants
Prolactin (PRL)	Lactotropin	Protein + glycosylated variants
Thyroid-stimulating hormone (TSH)	Thyrotropin	Two glycoprotein subunits: * α-subunit common to FSH, LH, and TSH * β-subunit—specific to TSH
Hormones of posterior pituitary gland		
	Other names	
Arginine vasotocin (AVT)	8-arginine oxytocin	Synthesized as a protein, then proteolytically cleaved yielding peptide with 9 amino acid residues
Mesotocin (MT)	8-isoleucine oxytocin	Synthesized as a protein, then proteolytically cleaved yielding peptide with 9 amino acid residues
Putative pituitary hormones		
Melanocyte-stimulating hormone (MSH)	Melanotropin	Three distinct peptides—α-, β-, and γ-MSH
β-endorphin		Polypeptide
Lipotropic hormone	Lipotropin	Polypeptide

TABLE 30.3 Summary of stimulatory and inhibitory releasing hormones in birds.

Anterior pituitary hormone	Stimulatory-releasing hormone	Inhibitory-releasing hormone
Adrenocorticotropic hormone (ACTH)	* Corticotropin-releasing hormone (CRH) (via CRH type 1 receptor) * Arginine vasotocin (AVT)	—
Follicle-stimulating hormone (FSH)	* Gonadotropin-releasing hormone I (GnRH 1) * GnRH II * Activin	* Gonadotropin-inhibitory hormone (GnIH) * Inhibin
Luteinizing hormone (LH)	* Gonadotropin-releasing hormone I (GnRH 1) * GnRH II	* Gonadotropin-inhibitory hormone (GnIH)
Growth hormone (GH)	* Growth hormone—releasing hormone (GHRH) * Thyrotropin-releasing hormone (TRH) * Glucagon-like peptide (GCGL) * Ghrelin * Neuropeptide W * PACAP, leptin, GnRH	Somatostatin (SS or SRIF)
Prolactin (PRL)	* Vasoactive intestinal peptide (VIP) * Prolactin-releasing peptide (PrRp) * Neuropeptide W * TRH, AVT, peptide histidine isoleucine (PHI)	Dopamine
Thyroid-stimulating hormone (TSH)	* TRH * CRH (via CRH type 2 receptor)	SS

Nassauw et al., 1987; Harrison, 1989; chicken: Allaerts et al., 1999) and cytokeratin (chicken: Nishimura et al., 2017). Folliculo-stellate cells are agranular and do not express anterior pituitary hormones (chicken: Nishimura et al., 2017). Possible roles for the folliculo-stellate cells may include aiding structural integrity of the follicles and/or autocrine-paracrine regulation of adjacent secretory cells and/or immune-endocrine interaction. There is evidence that folliculo-stellate cells influence thyrotropes (quail: Harrison et al., 1982) and possibly vice versa as folliculo-stellate cells express TSH receptors (TSHRs) (chicken: Grommen et al., 2009).

30.3.1.3 Macrophage

Based on the presence of a pan-macrophage antigen, there are macrophage or macrophage-like cells in the embryonic pituitary (chicken: Allaerts et al., 1999). These are scattered and located in the connective tissue (chicken: Allaerts et al., 1999). Microglial cells are a specialized form of macrophage that are normally found in the central nervous system. There is expression of colony-stimulating factor 1 receptor (CSF1R) in avian pituitary glands indicating the presence of microglial cells (Japanese quail: Walker et al., 2019). Posthatching stressing by unpredictable feed availability depressed pituitary expression of CSF1R (Japanese quail: Walker et al., 2019). However, it is not clear whether CSF1R-expressing microglial cells are found in the anterior and/or posterior pituitary gland.

30.3.2 Pars intermedia

In mammals, the pars intermedia are formed from adenohypophyseal cells and produces α-melanocyte-stimulating hormone (α-MSH). It is generally considered that the pars intermedia is not present in birds (chicken: Rahn, 1939; other birds: Rahn and Painter, 1941). However, it is not possible to preclude migration of cells from the primordial pars intermedia to the pars distalis and/or pars tuberalis.

30.3.3 Pars tuberalis

The pars tuberalis is derived from Rathke's pouch, specifically the upper anterior portion (Sasaki et al., 2003). The pars tuberalis develops along the median eminence between days 8 and 14 of incubation in the chick embryo (Kameda et al., 2000). Many pars tuberalis cells express the α-sub-unit of glycoprotein hormones, and this is seen as early as day three of embryonic development (Inoue et al., 2013). By day 10 of embryonic development, cells within the pars tuberalis exhibit high expression of both cytokine-like 1 and gap junction protein alpha 5 genes (Aizawa et al., 2016).

The pars tuberalis consists of adenohypophyseal located along the ventral surface of the median eminence. It consists of the following cell types: (1). pars distalis secretory specific cells, (2). pars distalis cell types including corticotropes, gonadotropes, lactotropes, somatotropes, and thyrotropes (Mohanty et al., 1997), (3). follicular cells (reviewed: Yasuo and Korf, 2011), and (4). macrophage.

The pars tuberalis can communicate in a retrograde manner with the median eminence and in an anterograde manner with the pars distalis. There is high expression of the α-subunit of LH, FSH, and TSH (Kameda et al., 2000) in the pars tuberalis.

30.3.4 Posterior pituitary gland or pars nervosa

The posterior pituitary gland consists of neurosecretory terminals that release either mesotocin (MT) or arginine vasotocin (AVT) (Table 30.2). These hormones are synthesized in cell bodies in nuclei in the hypothalamus and are transported to the pars nervosa (posterior pituitary gland) through modified axons in the infundibular stalk (Figure 30.1).

30.4 Gonadotropins

30.4.1 Gonadotropin subunits, genes, mRNA, and glycoproteins

Avian LH and FSH are glycoproteins with molecular weights of 30 KDa (turkey: Burke et al., 1979a). Both LH and FSH consist of two glycoprotein subunits: an α-subunit that is common to LH, FSH, and TSH and a hormone-specific β-subunit (with different β-subunits for LH, FSH, and TSH). Both subunits are required for biological activity (turkey: Burke et al., 1979b). The α-subunit is a sequence of 96 amino acid residues with an additional signal peptide of 24 amino acids (domestic duck: Hsieh et al., 2001). The amino acid residue sequences have been deduced from the nucleotide sequences of the cDNA for the α-subunit or β-subunit. For example, FSH β subunit is a glycoprotein with 111 amino acid residues [goose: Huang et al., 2015; wild birds (FSH β-subunit: burrowing owl XM_026850847.1; emu XM_026122133.1; Saker falcon: XM_005436169.1; white-throated sparrow: XM_005492327.2; willow flycatcher: XM_027902612)]. It is synthesized with a 20 amino acid signal peptide (goose: Huang et al., 2015). FSH-β-subunit has two disulfide bonds and two asparagine-linked glycosylation sites (Shen and Yu, 2002). Shen and Yu (2002) noted the "remarkable" degree of homogeneity among FSH β-subunit across avian species (see Figure 30.3).

Plasma concentrations of LH and FSH are illustrated in Table 30.4.

30.4.1.1 Expression of pituitary glycoprotein subunits

There is independent control of the expression of α-subunit and LH, FSH, and TSH β subunits as seen from the following:

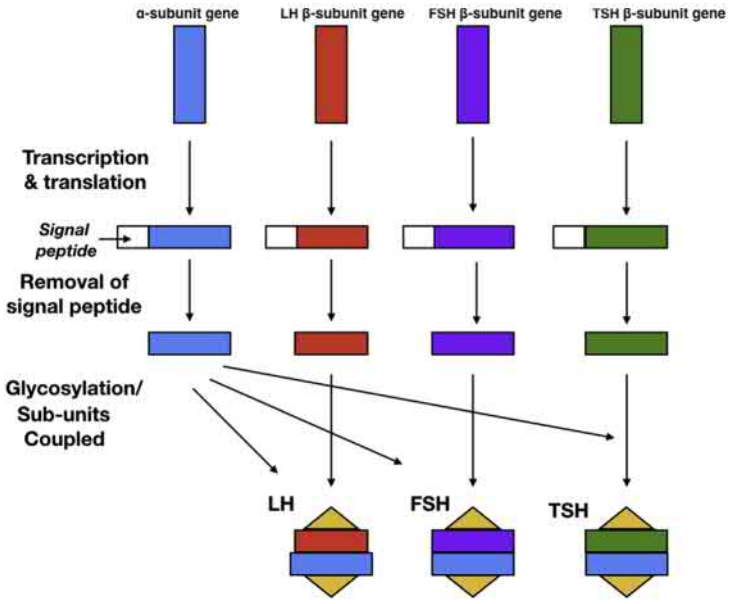

FIGURE 30.3 Synthesis of pituitary glycoprotein hormones.

TABLE 30.4 Basal plasma hormone concentrations in birds.

	Species	Plasma hormone concentration		References
		pg/mL	pmoles/L	
Follicle-stimulating hormone				
	Chicken	333	11	Han et al. (2017)
Luteinizing hormone				
	Chicken	5000	166	Dunn et al. (2017)
	Chicken	1400	47	Han et al. (2017)
Prolactin				
	Chicken	4000	200	Dunn et al. (2017)
α-melanocyte-stimulating hormone				
	Chicken	3095	1860	Shipp et al. (2017)
Adrenocorticotropic hormone

	Domestic duck	8.4	8.0	Gray and Maloney (1998)
	Japanese quail	7.0, 2.8	6.7, 2.7	Seth et al. (2004b); Minvielle et al. (2007)
	White-bellied sunbirds	22	21	Gray et al. (2004)
Mesotocin				
	Chicken	19, 15	18, 14	Robinzon et al. (1990); Chaturvedi et al. (2001)

[a]*Other studies reported a much higher basal concentration of arginine vasotocin in chickens, e.g., 12 ng/mL (11 nmol/L) Sirotkin et al. (2017); 22 ng/mL (21 nmol/L) Takahashi et al. (2011).*

- Pituitary expression of α-subunit is stimulated in vitro by incubation with either gonadotropin-releasing hormone (GnRH) or thyrotropin-releasing hormone (TRH) (domestic duck: Hsieh et al., 2001).
- GnRH-1 increased expression of LH β subunits (turkey: You et al., 1995).
- Pituitary expression of TSH β subunits is increased by glucagon-like peptide (GCGL) (chicken: Huang et al., 2014).

30.4.2 Actions of gonadotropins

For a more detailed discussion of the control of female and male reproduction, see Chapters 34 and 35.

30.4.2.1 Actions of luteinizing hormone in the female

30.4.2.1.1 Luteinizing hormone and ovulation

A major role of LH is to induce ovulation. Premature ovulation is provoked following injection of LH (laying hen chicken: Imai, 1973; broiler breeder chicken: broiler breeders: Liu et al., 2004; Japanese quail: Onagbesan and Peddie, 1988). Moreover, there is a small increase or surge in plasma concentrations of LH 4–6 h prior to ovulation (chicken: Furr et al., 1973; turkey: Liu et al., 2001; Liu et al., 2004) (also see Figure 30.4). Administration of LH is followed by a series of events in the most mature follicle: (1). breakdown of the germinal vesicle, (2). dissociation of the junctions between the granulosa projections and the oocyte surface, (3). development of a perivitelline space, and (4). formation of the first and then second maturation spindle (Japanese quail: Yoshimura et al., 1993). There is evidence that LH surges are synchronized by societal and other cues (e.g., to alternate days in glaucous-winged gulls Henson et al., 2011).

30.4.2.1.2 Luteinizing hormone and steroidogenesis

LH increases ovarian production of progesterone and androgens by the large yolky follicles. LH increased progesterone and testosterone in both the circulation and tissue from large follicles in vivo (laying hen chickens: Shahabi et al., 1975). The effects of LH are on both granulosa and theca cells. LH stimulates the production of progesterone and androstenedione by granulosa cells in vitro from the largest yolk-filled follicles while FSH is largely without effect (Scanes and Fagioli, 1980; Tilly and Johnson, 1987, 1988a, b). LH increases also expression of steroidogenic acute regulatory protein (StAR) in granulosa cells from the largest yellow (F1) follicles (Johnson and Bridgham, 2001). However, granulosa cells from 9 to 12 mm follicles or smaller did not respond to LH (Tilly et al., 1991a).

Moreover, LH increased androstenedione release from thecal cells from F2 follicles in vitro (Tilly and Johnson, 1989b). Theca cells from 6 to 8 mm follicles respond to LH with increased steroidogenesis (Kowalski et al., 1991).

30.4.2.1.3 Luteinizing hormone and follicular development

There are effects of LH on follicular development. For instance, LH increases proliferation of granulosa cells from large yolky F1–F3 follicles (broiler breeder chickens: Onagbesan et al., 1999). In addition, LH suppressed plasminogen activator activity in granulosa cells from the largest follicles (Tilly and Johnson, 1987).

30.4.2.1.4 Luteinizing hormone and ovarian inhibin/activin receptors

There are effects of LH on ovarian activin (Act) and inhibin receptors. LH increases expression of ActRIIA and inhibin

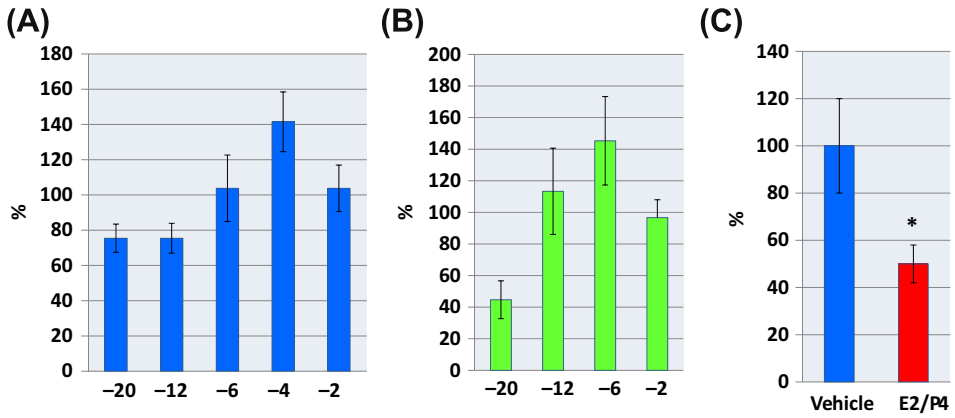

FIGURE 30.4 Changes in luteinizing hormone (LH) during the ovulatory cycle of the chicken. (A) Circulating concentrations of LH during the ovulatory cycle. (B) Pituitary gonadotropin-releasing hormone (GnRH) receptor expression during the ovulatory cycle (Data from Lovell et al. (2005)). (C) Effect of in vivo treatment with estradiol (E2) and progesterone (P4) in immature hens on pituitary expression of GnIH receptors by chicken anterior pituitary tissue (Maddineni et al., 2008).

co-receptor by theca cells from F1 follicles (chicken: Lovell et al., 2007). Expression of ActR type I, ActRIIA, ActRIIB, and inhibin co-receptor by granulosa cells from 6 to 8 mm and F1 follicles is increased by LH (chicken: Lovell et al., 2007).

30.4.2.2 Actions of follicle-stimulating hormone in the female

In vivo either FSH or equine chorionic gonadotropin (formerly pregnant mare serum gonadotropin) increases the number of large follicles but did not influence the number of 6–8 mm prerecruitment follicles (chicken: Ghanem and Johnson, 2019).

Granulosa cells from 6 to 8 mm follicles respond to FSH were reduced expression of activin receptor (ActR) (typeIIB) and ActRI but increased expression of ActRIIA and inhibin co-receptor in granulosa cells from either 6–8 mm or F1 follicles (Lovell et al., 2007). Among the downregulated differentially expressed genes after FSH treatment of granulosa cells in vitro are the following: follistatin, superoxide dismutase 1, fatty acyl-CoA reductase 1, transforming growth factor (TGF)-beta receptor-associated protein 1 (domesticated goose: Du et al., 2018).

30.4.2.2.1 Follicle-stimulating hormone and steroidogenesis

FSH increases progesterone from smaller follicles but not the largest follicles. FSH increased progesterone production by granulosa cells from 9 to 12 mm follicles (Tilly et al., 1991a). Granulosa cells from 6 to 8 mm follicles do not convert cholesterol to pregnenolone. However, after incubation with FSH, these cells can convert cholesterol to pregnenolone and there is increased expression of P450scc and StAR (Tilly et al., 1991; Li and Johnson, 1993; Johnson and Bridgham, 2001). Theca cells from 6 to 8 mm follicles respond to FSH with increased steroidogenesis (Kowalski et al., 1991).

30.4.2.2.2 Follicle-stimulating hormone and ovarian cell remodeling and proliferation

FSH increases proliferation of granulosa cells from prehierarchical follicles (6 to 8 mm in diameter) with the effect increased in the presence of activin A and transfection with FOXL2 plasmids (Qin et al., 2015). Apoptosis in prehierarcichal follicle granulosa cells is depressed in the presence of FSH (Johnson et al., 1996a). Moreover, FSH increases the expression of annexin A2 in follicular theca cells, and this may be increasing angiogenesis (chicken: Zhu et al., 2015). In addition, in a culture of embryonic ovarian cells, FSH stimulates proliferation of germ cells as indicated by counting cells with immune-reactivity to cell nuclear antigen (chicken: Xie et al., 2004; Liu et al., 2010).

30.4.2.3 Actions of luteinizing hormone in the male

In birds, as in mammals, LH stimulates both differentiation of Leydig cells and production of testosterone. The administration of chicken LH to hypophysectomized Japanese quail markedly increases the number of mature Leydig cells decreasing the number of fibroblasts and transitional cell types in the interstitium (Brown et al., 1975). In birds, testosterone production is increased by LH in vitro (Japanese quail: Maung and Follett, 1977; chicken: e.g., Opałka et al., 2004) and in vivo (Japanese quail: Maung and Follett, 1978).

30.4.2.4 Actions of follicle-stimulating hormone in the male

The major role of FSH is stimulating spermatogenesis and the supporting "nurse" cells, the Sertoli cells. When FSH is injected into hypophysectomized quail, there are increases in testicular size (8.8 fold) together with differentiation of Sertoli cells and promotion of spermatogenesis (Brown et al., 1975). In vitro, FSH increased the number of germ cells and expression of stem cell factor receptor c-kit (chicken: Mi et al., 2004). Administration of FSH elevates expression of tyrosine kinase receptor A, the receptors for nerve growth factor (chicken: Ma et al., 2015). Sertoli cells treated with FSH in vitro exhibit the following increases: proliferation, concentrations of 3β-hydroxysteroid dehydrogenase, and lactate production (chicken: Guibert et al., 2011). However, FSH had little effect on overall testosterone production by testicular cells (Maung and Follett, 1978).

30.4.2.5 Other actions of follicle-stimulating hormone

FSH increases lipid deposition into avian preadipocytes in vitro and weight of abdominal fat pad in vivo (broiler chickens: Cui et al., 2012). FSH also increases the expression of enzymes controlling lipid metabolism, namely, retinol dehydrogenase 10 (*Rdh10*), lipoprotein lipase (*Lpl*), retinoic acid receptor beta (*RarB*), and diglyceride acyltransferase (*Dgat*) genes (broiler chickens: Cui et al., 2012). FSHR is expressed by avian adipose tissue and expression is increased by FSH in vivo and in vitro (broiler chickens: Cui et al., 2012).

30.4.2.6 Luteinizing hormone receptors

The structures of avian luteinizing hormone receptor (cLH-R) have been deduced from the cDNA in initially in poultry species (chicken: Johnson et al., 1996b; turkey: You et al., 2000) and also in wild birds (e.g., emu: XM_026095388.1, rock pigeon: XM_021287698.1, hooded crow:

TABLE 30.5 Effect of growth factors on the expression of follicle-stimulating hormone receptor in granulosa cells from prehierarchal (6–8 mm diameter) follicles in chickens.

Hormone/growth factor	Direction of change	References
Follicle-stimulating hormone	↑	e.g., Haugen and Johnson (2010)
Transforming growth factor β1	↑	Woods and Johnson (2005)
Activin A	↑	Woods and Johnson (2005)
Bone morphogenetic protein (BMP) 4	↑	Kim et al. (2013)
BMP 6	↑	Ocón-Grove et al. (2012)
BMP 2	↓	Haugen and Johnson (2010)

XM_019282421.2, common starling: KM588217.1, and white-throated sparrow: XM_026796127.1).

Ovarian expression of LHR is influenced by tissue (theca vs. granulosa) and follicular development. In thecal tissue, expression of LH-R increases with follicle development to a maximum in the F2 follicle (chicken: Johnson et al., 1996). Moreover, expression of LH-R in granulosa cells is first detectible in 9–12 mm diameter follicles and progressively increases to preovulatory follicles. Expression of LHR is influenced by hormones and growth factors. For instance, expression of LHR by F1 follicle granulosa cells is increased activin, bone morphogenetic protein (BMP) 6, LH, and testosterone (chicken: Johnson et al., 2006; Al-Musawi et al., 2007; Rangel et al., 2009). Testosterone depresses testicular LH receptors based on LH binding (Ottinger et al., 2002).

The signal transduction mechanism by which LH exerts its effect in both thecal and granulosa cells is via adenylate cyclase and cAMP (chicken: e.g., Asem et al., 1987; Tilly and Johnson, 1988a, b, 1989) and calcium mobilization (chicken: Johnson and Tilly, 1988).

30.4.2.7 Follicle-stimulating hormone receptors

The structure of the FSH receptor has been deduced from cDNA in poultry (chicken: You et al., 1996; Genbank accessions duck: EU049608.1) and wild birds (e.g., brown kiwi XM_013949769.1, rock pigeon: FJ913876.1, peregrine falcon: XM_027782943, emperor penguin XM_009272697.1 and collared flycatcher XM_005042962). Variants FSH receptors transcripts have been identified in multiple species of birds of different families, orders, superorders, and infraclasses including the following: Infraclass *Palaeognathae*: Chilean tinamou; Infraclass *Neognathae*: Superorder *Galloanserae*: Order *Galliformes*: chicken, Japanese quail, helmeted guineafowl, Order *Anseriformes*: domestic duck, domestic geese; Superorder *Neoaves*: Order *Accipitriformes*: golden eagle, Order *Passeriformes*: great tit, blue tit, hooded crow, jungle crow, saffron-crested tyrant-manakin, white-throated sparrow and willow flycatcher.

In the male, FSH receptors (based on binding) are upregulated by FSH (Tsuisui and Ishii, 1980) but depressed by testosterone (Ottinger et al., 2002). In the females, expression of FSHR is influenced by stage of follicular development together with hormones and growth factors (see Table 30.5). The FSHR is expressed in the ovary with expression declining in both thecal and granulosa cells with follicular development (chicken: You et al., 1996). Expression of FSH-R is increased in granulosa cells by TGF β1, activin A, BMP6, and growth differentiation factor 9 (GDF9) and decreased by BMP2 (chicken: Woods and Johnson, 2005; Haugen and Johnson, 2010; Ocón-Grove et al., 2012; Qin et al., 2015). In granulosa cells transfected by Forkhead box L2 (FOXL2) plasmids, expression is further increased in the presence of either GDF9 or activin (Qin et al., 2015).

Signal transduction for FSH in Sertoli cells encompasses FSH binding to FSHR and activation of adenylate cyclase-cAMP-protein kinase A, phosphatidyl-inositol 3 kinase (protein kinase B), and mitogen-activated protein kinase (extracellular signal-regulated kinases, ERK1/2) pathways (chickens: Guibert et al., 2011; Faure et al., 2017).

30.4.3 Control of gonadotropin release

30.4.3.1 Introduction

In birds, release of LH and FSH is under predominantly stimulatory control by the hypothalamus based on deafferentation and lesioning studies (Japanese quail: Davies and Follett, 1980). GnRH stimulates the release of LH in birds while gonadotropin-inhibitory hormone (GnIH) inhibits LH release.

30.4.3.2 Gonadotropin hormone–releasing hormone

30.4.3.2.1 Chemistry

There are two GnRH peptides in the avian hypothalamus, each with separate genes, respectively, for prepro-GnRH 1 and prepro-GnRH-2 (Dunn et al., 1993; Ikemoto and Parks, 2006):

30.4.3.2.1.1 Chicken GnRH 1 (cGnRH1) pGlu-His-Trp-Ser-Tyr-Gly-Leu-Gln-Pro-Gly-amide [pEHWSYGLQPG-NH_2] (King and Millar, 1982).

30.4.3.2.1.2 Chicken GnRH 2 (cGnRH2) pGlu-His-Trp-Ser-His-Gly-Trp-Tyr-Pro-Gly-amide [pEHWSHG-WYPG-NH_2] (Miyamoto et al., 1984).

The structure of GnRH1 appears to be perfectly conserved across the *Aves* with identical structures in the ostrich (Powell et al., 1987), the chicken, the domestic goose (e.g., DQ023158.1), and several passerine species (zebra finch: Stevenson et al., 2009; Ubuka and Bentley, 2009; starling: Stevenson et al., 2009; Ubuka et al., 2009). There is, however, only 58% homology between the sequence of prepro-GnRH 1 in starlings and chicken (Ubaka et al., 2009).

30.4.3.2.2 Biological activity

The major secretagogue for LH is cGnRH1 with cGnRH2 having either a lesser or no role. This is supported by the presence of cGnRH1 but not cGnRH2 in the median eminence and the suppression of reproduction following immunization against cGnRH1 but not cGnRH2 (Sharp et al., 1990). Parenthetically, there is gonadal regression after active immunization against mammalian GnRH also (Quaresma et al., 2017); this being employed as an alternative to surgical castration/caponization. However, cGnRH2 is considerably more potent than cGnRH1 in stimulating LH release in vitro (chicken: Chou et., 1985; Millar et al., 1986) and in vivo (chicken: Wilson et al., 1989; Proudman et al., 2006). However, cGnRH1 is likely to be releasing hormone of LH.

The hypothalamic control of FSH release remains enigmatic. Neither cGnRH1 nor cGnRH2 appear to be physiological stimuli of FSH release as cGnRH1 or cGnRH2 either evoke only a very small increase in FSH release (Japanese quail: Hattori et al., 1986) or are completely ineffective (chicken: Krishnan et al., 1993; Dunn et al., 2003; Proudman et al., 2006).

30.4.3.2.3 Gonadotropin-releasing hormone receptors and signal transduction

There are two GnRH receptor subtypes in the chickens, namely, GnRHR1 and GnRHR3 with cGnRH2 being more potent cGnRH1 (Joseph et al., 2009). There is much higher expression of GnRHR3 than GnRHR1 in the anterior pituitary gland (chicken: Joseph et al., 2009). There is also expression of both GnRHR3 and GnRHR1 in the median eminence (chicken: Joseph et al., 2009). In the Muscovy duck, GnRHR is expressed in the pituitary gland together with the hypothalamus (Wu et al., 2015).

The actions of cGnRH1 or GnRH2 are mediated by binding to GnRHR and subsequently synthesis of cAMP and inositol phosphate (Bonney and Cunningham, 1977; Joseph et al., 2009).

30.4.3.2.4 Control of gonadotropin-releasing hormone release and synthesis

GnRH1 expression is chiefly located in cell bodies in the preoptic area (Stevenson et al., 2009). GnRH1 is released from neurosecretory terminals in the median eminence in response to stimuli. Neurotransmitters and neuropeptides stimulate or inhibit release of GnRH1 with release stimulated by norepinephrine (chicken: Knight et al., 1982) and neuropeptide Y (chicken: Fraley and Kuenzel, 1993; Contijoch et al., 1992) and inhibited by dopamine (chicken: Knight et al., 1982), β endorphin (chicken: Contijoch et al., 1993), and GnIH (see below).

GnRH-I expression is related to reproductive state being, for instance, greater in sexually mature than immature birds (zebrafinch: Ubuka and Bentley, 2009). In addition, hypothalamic expression of GnRH1 is elevated in photostimulated birds but falls to a very low level in photorefractory birds (starlings: Ubuka et al., 2009). While there is interaction between kisspeptins (Kiss) and its receptor Gpr54 and GnRH neurons in mammals, the Kiss/Gpr54 system appears to be absent in birds based on studies in the chicken and zebra finch (reviewed: Tsutsui et al., 2010; Joseph et al., 2013).

30.4.3.2.5 Changes in hypothalamic gonadotropin-releasing hormone content

The variation in hypothalamic GnRH immunoreactivity and/or expression is consistent with GnRH1 having a role in the control of reproduction in birds. Expression of GnRH in hypothalamus varies during posthatching development (chicken: Chen et al., 2019). In turkeys, hypothalamic cGnRH1 levels are higher in laying hens compared to nonphotostimulated birds (with photostimulated birds intermediate) (Rozenboim et al., 1993). Photostimulation of turkeys resulted in activation (c-fos expression) of cGnRH1 in the nucleus commissura palli and dopamine neurons in the nucleus premammillaris (Thayananuphat et al., 2007). In female chickens when incubating eggs, there is a decrease in hypothalamic expression of cGnRH1 (Dunn et al., 1996) and when young male chickens receive estradiol administration (Dunn and Sharp, 1999). The

number of neurons with cGnRH1 immunoreactivity in the nucleus commissurae pallii is lower in birds rearing chicks than those not rearing chicks (native chickens: Chaiyachet et a., 2013). There is markedly higher cGnRH1 expression in neurosecretory neurons in the preoptic area of the hypothalamus in photostimulated than nonphotostimulated birds (starling: Ukaka et al., 2009). There are effects of long- versus short-daylengths and the presence or absence of sulfamethazine in feed on expression of cGnRH1 expression in the septal–preoptic/anterior hypothalamic area and mid-hypothalamus (chicken: Kang and Kuenzel, 2015).

There are external influences on cGnRH1 expression. Both cGnRH1 and cGnRH1 gene expressions were depressed by rearing chickens in green LED lighting with the effect being lost following pinealectomy (Zhang et al., 2017). Administration of the serotonin synthesis inhibitor, parachlorophenylalanine (PCPA) to old male chickens increased expression of GnRH-I in the hypothalamus (old male chickens: Avital-Cohen et al., 2015). Administration of PRL depressed expression of GnRH-I in the hypothalamus in PCPA-treated birds (old male chickens: Avital-Cohen et al., 2015). Hypothalamic expression of GnRH-I is increased during sexual maturation (chicken: Han et al., 2017) and as birds come into lay (domestic goose: Bhattacharya et al., 2015). Hypothalamic expression of GnRH1 is influenced by exposure to long daylengths and/or treatment with sulfamethazine (2 weeks old chickens: Kang Kang and Kuenzel, 2015).

There are also changes in cGnRH2 in the hypothalamus with reproductive state. The hypothalamic contents of cGnRH2 are increased following photostimulation; they are higher in laying hens, but reduced in incubating and photorefractory birds (domestic turkey: Rozenboim et al., 1993). Similarly, there are more cGnRH2 neurons in breeding than not breeding zebra finches (Perfito et al., 2011).

30.4.3.2.6 Changes in pituitary responsiveness

There are shifts in the responsiveness of pituitary to GnRH with physiological state and due to external influences. For instance, plasma concentrations of LH but not FSH were elevated after GnRH challenge in 5 and 8 weeks old sexually immature females (chicken: Dunn et al., 2003). Moreover, the putative endocrine disruptor, phytosterol, reduced pituitary responsiveness to GnRH-1 and pituitary LH content after GnRH1 challenge (Japanese quail: Qasimi et al., 2018).

30.4.3.2.7 Extrahypothalamic production of gonadotropin-releasing hormone and gonadotropin-releasing hormone receptors

Both GnRH and GnRHR are expressed in the gonads (chicken: Sun et al., 2001). There is expression of GnRHR1 in the small intestine and testes GnRHR3 in the small intestine (chicken: Joseph et al., 2009). In the Muscovy duck, GnRHR is not only expressed in the pituitary gland but also in the ovary (Wu et al., 2015). There is higher expression of GnRH in thecal than granulosa tissue (chicken: Chen et al., 2019). There is evidence that cGnRH1 influences gonadal functioning. For instance, in the presence of cGnRH1, the LH increase in LHR expression in thecal cells is attenuated (chicken: Chen et al., 2019). GnRH immune-reactivity is reported in mast cells in the medial habenular region with the number and distribution of these cells dependent on reproductive behavior, e.g., courtship behavior (ring dove: Silver et al., 1992; Zhung et al., 1993).

30.4.3.3 Gonadotropin-inhibitory hormone

30.4.3.3.1 Chemistry and synthesis

There are three RF amide peptides derived from the GnIH precursor in birds:

1. GnIH 12 amino acids
2. GnIH-related peptide (GnIH-RP)-1
3. GnIH-RP-2

(for structures see Figure 30.5); RFamide peptides having been first identified as hormones in invertebrates. GnIH, GnIH-RP-1, and GnIH-RP2 share a C terminal LPXRF amide motif (where X = L or Q) (Kriegsfeld et al., 2015). GnIH was first isolated from quail brains (Tsutsui et al., 2000). Despite there being structural similarities between GnIH and neuropeptide NF, there are two genes. The existence of separate GnIH and NPNF genes was the result of one of the two gene duplications in early vertebrate evolution chromosome 2 (Tsutsui et al., 2018). The GnIH gene is found on chromosome 2 in chickens (Tsutsui et al., 2018).

30.4.3.3.2 Actions of gonadotropin-inhibitory hormone

GnIH decreases the release of FSH and LH from the avian anterior pituitary gland. Administration of GnIH depressed reproductive functioning in male Japanese quail with testicular atrophy, inhibition of spermatogenesis together with reductions in plasma concentrations of testosterone and LH (Ubuka et al., 2006). In vitro GnIH decreased release of both LH and FSH from pituitary tissue (chicken: Ciccone et al., 2004). GnIH-R co-locates in both gonadotropes exhibiting either LH or FSH (chicken: Maddineni et al., 2008). RNA interference of GnIH influences reproductive behavior (Japanese quail: Ubuka et al., 2013).

The number of GnIH cells in hypothalamus varies through the reproductive cycle with a peak at the beginning of incubation (European starling: Calisi et al., 2016). Hypothalamic GnIH cells are reduced by stress in the Spring but not Fall (house sparrow: Calisi et al., 2008).

FIGURE 30.5 Gonadotropin-inhibitory hormone and related peptides in avian species [Goose-domestic goose (Genbank: KC514473.1), chicken (AB120325.1), Japanese quail (AB120325.1), rock pigeon (MG589638.1), Eurasian tree sparrow (KT351598.1), white-crowned sparrow (AB128164.1), zebra finch (AB522971.1)].

GnIH decreases the synthesis of FSH and LH in the avian anterior pituitary gland. Expression of the common α subunit and LH β are reduced in Japanese quail receiving GnIH in vivo (Ukuka et al., 2006). Similarly, expression of α subunit and FSH β is depressed with GnIH treatment (chicken: Ciccone et al., 2004).

30.4.3.3.3 Gonadotropin-inhibitory hormone receptors

Two putative GnIH receptors have been characterized, albeit partially: GnIHR or RFRPR from chicken pituitary gland and NPFFR from the chicken diencephalon (Ikemoto and Park, 2005). The GnIHR is a G protein-coupled receptor (reviewed: Tsutsui et al., 2018). GnIH-R is expressed in the pituitary gland (Japanese quail and starling: Bentley et al., 2008).

30.4.3.3.4 Hypothalamic gonadotropin-inhibitory hormone content

Hypothalamic GnIH contents vary with reproductive state. Hypothalamic GnIH contents are greater in incubating than laying chickens (Ciccone et al., 2004). Pituitary expression of GnIH-R is greater in sexually immature than mature birds (chicken: Maddineni et al., 2008). Moreover, administration of estradiol and/or progesterone depresses pituitary expression of GnIH-R (see Figure 30.4) (chicken: Maddineni et al., 2008). Employing green light LEDs during growth was accompanied by increases in the number of GnIH-cells of the paraventricularis magnocellularis (chickens: Zhang et al., 2017). Expression of GnIH and GnIHR in the hypothalamus has been reported to be depressed following pinealectomy (chickens: Zhang et al., 2017).

30.4.3.3.5 Extrapituitary expression of gonadotropin-inhibitory hormone

GnIH is expressed in the brain, testes, epididymis, vas deferens, ovaries, and oviduct (Japanese quail and starling: Bentley et al., 2008). Moreover, GnIH-R is expressed in the brain, testes, epididymis, vas deferens, ovaries, and oviduct (Japanese quail and starling: Bentley et al., 2008).

30.4.4 Control of gonadotropin subunit expression

30.4.4.1 Control of common α-subunit expression

Expression of the common LH–FSH–TSH α-subunit changes with physiology: It is not clear whether these changes are isolated to specific cell types. Starvation depresses pituitary expression of the common α subunit of LH, FSH, and TSH (Japanese quail: Kobayashi et al., 2002). Increasing food intake in previously feed-restricted hens is followed by increased α-subunit expression (Ciccone et al., 2007). There appears to be a negative feedback effect on expression of the α-subunit, as this is increased following ovariectomy in chickens, and this effect is reversed by estradiol replacement therapy (Terada et al., 1997). In vivo GnIH reduces pituitary expression of the α-subunit in Japanese quail (Ubuka et al., 2006).

30.4.4.2 Control of follicle-stimulating hormone β-subunit expression

FSH β subunit is expressed in pituitary gland but also in the hypothalamus, ovary, and oviduct and in all four organs,

expression is increased as birds start egg production (domestic goose: Huang et al., 2015). Pituitary expression of FSH β-subunit changes with developmental stage by feedback from the gonadal hormones, and it seems to be affected by the hypothalamus. Chicken embryos as early as day 11 express the FSH β-subunit in their anterior pituitary glands (Grzegorzewska et al., 2009). Pituitary expression of FSH β-subunit is increased during sexual maturation (chicken: Han et al., 2017) but decreased with aging (chicken: Avital-Cohen et al., 2013). Inhibin exerts a negative feedback effect on the expression of the FSH β-subunit in birds. Turkeys immunized against inhibin show increased pituitary FSH β-subunit expression and more small yellow follicles, presumably due to elevated FSH (Ahn et al., 2001).

There is stimulatory central nervous control of FSH β-subunit expression, but the hypothalamic factors participating in birds have not been definitively identified. Evidence for the hypothalamic control comes from the following. Photostimulation is accompanied by increased FSH β-subunit expression (chickens: Li et al., 2009). Early puberty is induced by sulfamethazine with increased pituitary expression of the FSH β-subunit (chickens: Li et al., 2009). Similarly, exposure of two-week-old chickens to long daylengths is followed by increases in the expression of FSH β subunit in the pituitary gland with this effect much greater in birds receiving sulfamethazine treatment (Kang and Kuenzel, 2015). Expression of FSH β-subunits is reduced by starvation in Japanese quail (Kobayashi et al., 2002). Restraint stress is reported to be followed by reduced pituitary expression of FSH β-subunit (zebra finch: Ernst et al., 2016). Administration of the serotonin synthesis inhibitor, PCPA to old male chickens increased pituitary expression of FSH β subunit (old male chickens: Avital-Cohen et al., 2015).

30.4.4.3 Control of luteinizing hormone β subunit expression

Expression of the LH β-subunit is influenced by developmental stage and by hypothalamic and ovarian hormones. Pituitary expression of LH β-subunit is detected as early as day 11 of embryonic development (Grzegorzewska et al., 2009) and increases during sexual maturation (chicken: Han et al., 2017). There is reduced expression of LH β subunits in old versus young males (chicken: Avital-Cohen et al., 2013). GnRH1 increases in vitro pituitary expression of LH β-subunit (turkey: You et al., 1995) while GnIH exerts an inhibitory effect (Japanese quail: Ubuka et al., 2006). Expression of the LH β-subunit is also decreased, in a feedback manner, by ovarian hormones such as estradiol (Terada et al., 1997). PRL decreases expression of the LH β-subunit by turkey pituitary cells in vitro (You et al., 1995). LH β-subunit expression by anterior pituitary cells is elevated by prostaglandin D_2 (PGD2) or PGJ_2, downstream metabolites of prostaglandin-D synthase via a PPAR signaling pathway (Chen et al., 2010).

LH β-subunit expression is reduced by starvation (Japanese quail: Kobayashi et al., 2002), presumably due to decreased stimulation by GnRH1. Administration of PCPA to old male chickens increases expression of LH β subunit in the anterior pituitary gland (old male chickens: Avital-Cohen et al., 2015). Administration of PRL depressed expression of the LH β subunit in the pituitary of PCPA treated or control birds (old male chickens: Avital-Cohen et al., 2015).

30.4.5 Physiological control of gonadotropins

30.4.5.1 Episodic secretion of gonadotropins

There is episodic release of both LH and FSH with, for instance, pulse frequencies of 0.5 per hour for LH and 0.33 pulses per hour for FSH in unrestrained male broiler breeders (Vizcarra et al., 2004).

30.4.5.2 Feedback and gonadotropin release

Sex steroids influence gonadotropin release and synthesis in birds, via direct effect on the anterior pituitary gland or shifts in the release of releasing hormones from the hypothalamus. This is predominantly an inhibitory control. Gonadectomy leads to large increases in the circulating concentrations of both LH and FSH (e.g., Japanese quail: Davies et al., 1980). The inhibitory effect of androgens on LH secretion is mediated via androgen and estrogen receptors (quail: Davies et al., 1980) or predominantly estrogen receptors (chickens: Wilson et al., 1983; Fennell et al., 1990).

In females, estradiol exerts a negative feedback effect on LH secretion. Progesterone can either stimulate or inhibit LH release depending on the state of the bird, with the preovulatory LH surge in the hen induced by progesterone. In the ovariectomized domestic hen, plasma concentrations of LH are decreased by a single injection of either progesterone or estradiol (Wilson and Sharp, 1976a, b). Progesterone has a positive feedback effect on LH release in intact hens or in ovariectomized hens that have been primed with progesterone and estradiol (Wilson and Sharp, 1976a, b). Progesterone receptors are present in the chicken hypothalamus, with increases in immunoreactivity following estradiol administration (Gasc and Baulieu, 1988). Estrogens also induce the presence of progesterone receptors in gonadotropes (LH-producing cells) (Gasc and Baulieu, 1988).

Plasma concentrations of FSH are increased in broiler breeder pullets after ovariectomy (Bruggeman et al., 1998). Pituitary concentrations of both LH and FSH are depressed by estradiol in 5 and 8 weeks old sexually immature

females (chicken: Dunn et al., 2003). The ability of GnRH to elevate plasma concentrations of LH was abolished after estradiol treatment (chicken: Dunn et al., 2003).

30.4.5.3 Seasonal breeding (photoperiod, temperature, and rainfall)

It is critically important for wild birds to reproduce at a time when the offspring will have high-feed availably. Daylength is an excellent predictor of most advantageous season for breeding particularly in the temperate zone. Increasing daylengths increase LH and FSH secretion in temperate-zone birds (Japanese quail: Follett and Maung, 1978; Henare et al., 2011; starlings: Dawson et al., 1985). As little as one long day of increased daylength, there is increased release of LH and FSH (e.g., Japanese quail: Follett, 1978) together with expression of FSH β-subunit (great tit: Perfito et al., 2012). Light is detected by a photopigment, vertebrate ancient opsin, found in the avian hypothalamus (Nakane et al., 2010; Davies et al., 2012). Reproduction is induced when light coincides with the photoinducible phase; the latter being due to "clock genes." For instance, there are shifts in hypothalamic expression of PER2 gene (period circadian regulator 2) during the day (great tit: Perfito et al., 2012). The role of the pars tuberalis in photoperiodism is discussed in Section 30.9.1.

Reproduction is similarly induced by long daylengths in poultry (chickens, turkeys, and ducks). For instance, sexual development is induced by increasing photoperiod (broiler breeder chickens: Onagbesan et al., 2006). There are peaks in the plasma concentrations of LH and FSH at about 20 weeks of age, but these increases can be delayed by feed restriction (broiler breeder chickens: Onagbesan et al., 2006). There are also age-related effects with plasma concentrations of LH increased after transfer from short to long daylengths in eight weeks old but not 5 weeks old sexually immature females (chicken: Dunn et al., 2003).

Temperature is an environmental cue for timing reproduction, with low temperatures slowing the photoperiodic induction of reproduction (Wingfield et al., 2003; Visser et al., 2009). Increasing temperature accelerates the timing of reproduction (great tits: Silverin et al., 2008; Schaper et al., 2012). Conversely, very high temperatures reduce reproductive success (Cruz-McDonnell and Wolf, 2016). In arid-regions, reproduction is induced by the rainfall or, specifically, first rainfall (e.g., blue cranes: Altwegg et al., 2009; sociable weavers: Mares et al., 2017; zebra finch: Zann et al., 1995). Availability of water also increases the photoperiodic response in song sparrows (Wingfield et al., 2012). The importance of supplementary environmental cues becomes progressively more important at lower latitudes (Silverin et al., 2008).

30.4.5.4 Preovulatory luteinizing hormone surge

Plasma concentrations of LH are increased 4–6 h prior to ovulation (chicken: Furr et al., 1973; turkey: Liu et al., 2001; Liu et al., 2004) (also see Figure 30.4). The preovulatory LH surge has been related to the scotophase (e.g., turkeys: Yang et al., 2000). The preovulatory LH surge is provoked by progesterone in the presence of estrogen priming (Wilson and Sharp, 1976a, b). There are increases in the expression of GnRHR in the chicken anterior pituitary gland during the ovulatory cycle (Lovell et al., 2005) (Figure 30.4). Moreover, in immature hens treated with progesterone in the presence of estradiol, there are marked decreases in the expression of GnIH (Lovell et al., 2005). There is little change in the circulatory concentrations of FSH during the ovulatory cycle of the hen (Scanes et al., 1977; Krishnan et al., 1993; Lovell et al., 2005).

30.4.5.5 Nutrition and gonadotropin release

Nutrition influences gonadotropin release in birds. Plasma concentrations of LH but not FSH were depressed by starvation (Japanese quail: Kobayashi et al., 2002). Plasma concentrations of LH and FSH are depressed in broiler breeder pullets (16-week-old) or ovariectomized pullets subject to feed restriction (Bruggeman et al., 1998). Similarly, plasma concentrations of LH are very low in male chickens on a protein deficient diet (Buonomo et al., 1982).

30.4.6 Pituitary origin of gonadotropins

Based on studies in the chicken, avian gonadotropes seem to contain either LH or FSH (Proudman et al., 1999). The gonadotropes containing LH are considerably more numerous than the gonadotropes containing FSH (Proudman et al., 1999). Gonadotropes containing either LH or FSH are found in both the cephalic and caudal lobes of the anterior pituitary gland, particularly in the periphery (Proudman et al., 1999; McFarlane et al., 2011). Most gonadotropes producing LH also express the estrogen receptor α, while some also express the androgen receptor (Sun et al., 2012). FSH-producing gonadotropes express also betaglycan, the type 3 receptor for TGFβ and an accessory receptor for inhibin (chicken: Sweeney and Johnson, 2005).

FSH-producing gonadotropes are first observed on day seven while LH-producing gonadotropes are observed on day eight (chicken embryo: Maseki et al., 2004).

30.5 Thyrotropin

The genes for both *TSH* and the *TSHR* are located on chromosome 26 in chickens.

30.5.1 Thyrotropin subunits, genes, mRNA, and glycoproteins

Avian TSH is a heterodimer consisting of α- and β-subunits. Ostrich TSH has been purified and is a glycoprotein (Papkoff et al., 1982). The avian TSH β-subunit has been characterized based on the sequence of the cDNA (e.g., chicken: Gregory and Porter, 1997; Kato et al., 1998; domestic and mule duck: Hsieh et al., 2007; chuck-will's-widow: Genbank XM_010163622; crested ibis: AB089501.1; mallard: NM_001310425.1; yellow-throated sandgrouse: XM_010077796).

30.5.2 Actions of thyroid-stimulating hormone

30.5.2.1 Role

TSH stimulates the avian thyroid glands to increase in size (Robinson et al., 1976) and to release thyroxine (T_4). Injections of TSH are followed by increases in circulating concentrations of T_3 and T_4 (chickens: MacKenzie, 1981; Williamson and Davison, 1985; doves and Japanese quail: McNichols and McNabb, 1988) (see Figure 30.6). It is likely that TSH is directly increasing release of T_4 from the thyroid but only indirectly increasing circulating concentrations of T_3 as thyroid concentrations of T_3 are very low (McNichols and McNabb, 1988), and T_4 is readily converted to T_3 in the periphery (Decuypere et al., 1988).

30.5.2.2 Thyroid-stimulating hormone receptors

TSH acts by binding to TSHRs; these being linked to adenylate cyclase via G-proteins. The TSHR has been characterized in poultry species (e.g., chicken: Grommen et al., 2006) and wild birds (e.g., willow flycatcher: XM_027904358.1). In many birds, there are multiple TSHR transcript variants. TRHR is expressed in follicular cells of the avian thyroid and, in addition, the brain, pituitary gland, pineal, and retina (chicken: Grommen et al., 2006).

TSH increases cAMP release from thyroid tissue in vitro (chicken: Tonoue and Kitch, 1978) and elevates the thyroid cAMP content in vivo (Japanese quail: McNichols and McNabb, 1988).

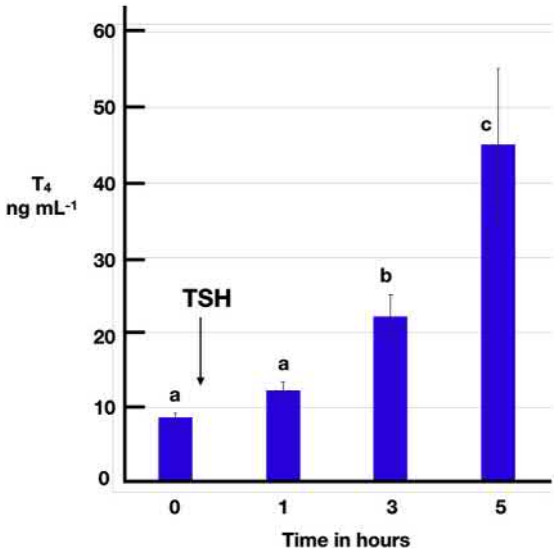

FIGURE 30.6 Effect of thyroid-stimulating hormone on the plasma concentrations of T_4 in chickens in vivo. *Data from MacKenzie, D.S., 1981. In vivo thyroxine release in day-old cockerels in response to acute stimulation by mammalian and avian pituitary hormones. Poult. Sci. 60, 2136–2143.*

30.5.3 Thyroid-stimulating hormone receptor and domestication

The TSHR has been proposed as a domestication locus with a domestic (a missense mutation from glycine to arginine) and wild-type allele (Rubin et al., 2010; Karlsson et al., 2015). The domestic allele is found in domesticated chickens (Karlsson et al., 2015). Male chickens homologous domestic allele exhibit less fear-related behaviors and reduced circulating concentrations of T_4 (Karlsson et al., 2015).

30.5.4 Control of thyroid-stimulating hormone release and subunit expression in the anterior pituitary gland

30.5.4.1 Thyrotropin-releasing hormone and thyroid-stimulating hormone release and subunit expression

The release of TSH from the anterior pituitary gland is under hypothalamic control by at least four releasing hormones or putative releasing hormones: (1). stimulators: thyrotropin-releasing hormone (TRH) or thyroliberin, corticotropin-releasing hormone (CRH), and GCGL and (2). inhibitors: somatostatin (SS or SRIH)

30.5.4.1.1 Thyrotropin-releasing hormone

The structure of TRH is the following:

Pyro-glutamyl-histidyl-proline-amide [pQHP-NH_2] (Bøler et al., 1969)

ProTRH is synthesized as prepro-TRH (see Figure 30.7). The signal peptide is then removed to form proTRH. There are five KRQHPGKR motifs in avian proTRH (e.g., chicken NM_001030383.2) together one other similar motif (KHQHPGRR). These are proteolytically cleaved to yield octapeptides (KHQHPGRR) followed by clipping off the flanking dibasic amino acid residues and then TRH-Gly is then converted to TRH (see Figure 30.7).

TRH stimulates release of TSH from avian pituitary tissue (chicken: Scanes, 1974; Huang et al., 2014) and, also, increases expression of TSH β subunits (duck: Hsieh et al.,

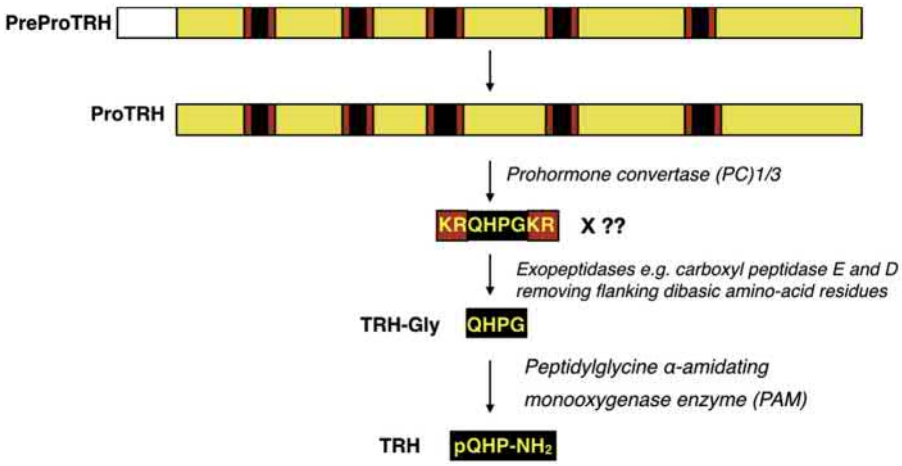

FIGURE 30.7 Synthesis of thyrotropin-releasing hormone. *Based on Nillni, E.A., 2010. Regulation of hypothalamic thyrotropin releasing hormone (TRH) neuron by neuronal and peripheral inputs. Front. Neuroendocrinol. 31, 134–156.*

2007; chicken: Huang et al., 2014). The structure of TRH receptor has been deduced from cDNA in poultry (e.g., chicken: NM_204930.1; domestic duck: XM_005022942.4) and wild birds (burrowing owl: XM_026843473.1; emperor penguin: M_009281974.1; emu: XM_026099712.1; willow flycatcher: XM_027905759.1).

TRH is expressed in the avian brain (nucleus preopticus periventicularis, nucleus preopticus medialis, regio lateralis hypothalami, paraventricular nucleus, nucleus periventricularis hypothalamic, and nucleus ventromedialis hypothalami (chicken: Aoki et al., 2007).

30.5.4.2 Corticotropin-releasing hormone and thyroid-stimulating hormone release and subunit expression

CRH induces TSH release from avian thyrotropes acting via CRH receptor type 2 (chicken: De Groef et al., 2003a; zebra finch: Watanabe et al., 2018).

30.5.4.3 Glucagon-like peptide and thyroid-stimulating hormone release and subunit expression

GCGL receptors are expressed in the cephalic lobe of the chicken anterior pituitary gland as are TSH β subunits (Huang et al., 2014). GCGL stimulates release of TSH and GH from chicken pituitary tissue together with elevating expression of GH and TSH β subunits (Huang et al., 2014).

30.5.4.4 Somatostatin and thyroid-stimulating hormone release

There is also inhibitory control of TSH release. Somatostatin depresses TSH release (chicken: Geris et al., 2003) acting via somatostatin receptors (SSTRs) type 2 and 5 (chicken: De Groef et al., 2003b; Geris et al., 2003).

30.5.4.5 Negative feedback

T_3 exerts a negative feedback effect on TSH release in birds. This is supported by the ability of goitrogens to increase thyrotrope numbers (Sharp et al., 1979). Moreover, T_3 or T_4 inhibits expression of TSH β subunit (chicken: Gregory and Porter, 1997; Gregory et al., 1998; duck: Hsieh et al., 2007).

30.5.4.6 Environmental factors and thyroid-stimulating hormone release

It is assumed that cold evokes a rapid increase in TSH release in birds. The absence of validated assays for TSH has restricted direct examination of this. However, circulating concentrations of T4 are increased with cold exposure (Japanese quail: Herbute et al., 1984). This is likely to be mediated by TRH as cold stress increases expression of prepro-TRH in the hypothalamus (chicken: Wang and Xu, 2008).

30.5.5 Control of thyroid-stimulating hormone β-subunit expression

As might be expended, releasing factors and thyroid hormones influence expression of the TSH β-subunit with pituitary expression increased by TRH in pituitary tissue in vitro (duck: Hsieh et al., 2007) (see Figure 30.8). Moreover, thyroid hormones inhibit expression of the TSH β-subunit with either T_3 or T_4 suppressing pituitary expression in vitro (chicken: Gregory and Porter, 1997; duck: Hsieh et al., 2007). Hypothyroidism increases expression of the TSH β-subunit by goitrogen-treatment (Japanese quail: Catena et al., 2003). In addition, glucocorticoids such as corticosterone depress expression of the

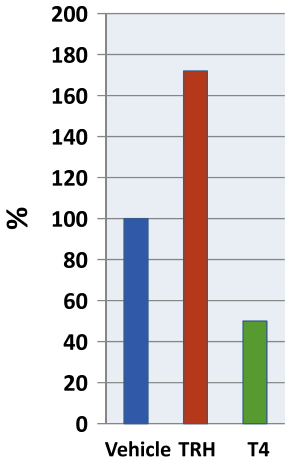

FIGURE 30.8 Effect of thyrotropin-releasing hormone and thyroxine (T_4) on the expression of thyroid-stimulating hormone β-subunit by duck anterior pituitary tissue in vitro. *Data from Hsieh, Y.L., Chowdhury, I., Chien, J.T., Chatterjee, A., Yu, J.Y., 2007. Molecular cloning and sequence analysis of the cDNA encoding thyroid-stimulating hormone beta-subunit of common duck and mule duck pituitaries: in vitro regulation of steady-state TSH beta mRNA level. Comp. Biochem. Physiol. B 146, 307–317.*

TSH β-subunit in duck pituitary tissue in vitro (Hsieh et al., 2007). There is no change in the expression of the TSH β -subunit with starvation in Japanese quail (Kobayashi et al., 2002; Kobayashi and Ishii, 2002).

Pituitary expression of TSH β subunit is increased following exposure to long daylengths in two weeks old chickens (Kang and Kuenzel, 2015). Studies in mule ducks (a hybrid of male Muscovy ducks and female domestic ducks) indicate preferential transcription of the TSH β-subunit from the maternal genome (Hsieh et al., 2007).

30.5.6 Origin of thyroid-stimulating hormone

30.5.6.1 Anterior pituitary gland

The thyrotropes, the cells producing TSH, are located almost entirely in the cephalic (or rostal) lobe of the anterior pituitary gland (Figure 30.1) based on studies immunocytochemistry with antisera to TSH β subunit (Sharp et al., 1979). Thyrotropes represent between 2% and 6% of the anterior pituitary cells (ring doves: Reichert, 1993). Some thyrotropes express androgen receptors (Sun et al., 2012), but the interactions between androgen and TSH secretion are not well-established. (Pars tuberalis TSH is discussed below).

30.5.6.2 Extrapituitary thyroid-stimulating hormone

There is evidence of extrapituitary TSH in birds with TSH β subunit immunoreactivity in various organs in the embryo. In chick embryos, TSH β subunit immunoreactivity has been reported in multiple tissues including the following: crop, diencephalon and mesencephalon, neural ganglia, trigeminal nerve, ependymal cells lining the spinal canal (and diocoele and mesocoele), hepatocytes, linings of the proventriculus, bronchial ducts, pleural and pericardial cavities, and trunk epidermal cells (Murphy and Harvey, 2001, 2002).

30.5.7 Ontogeny of thyroid-stimulating hormone

TSH and TRH are detectible in, respectively, the pituitary gland and hypothalamus by day six of embryonic

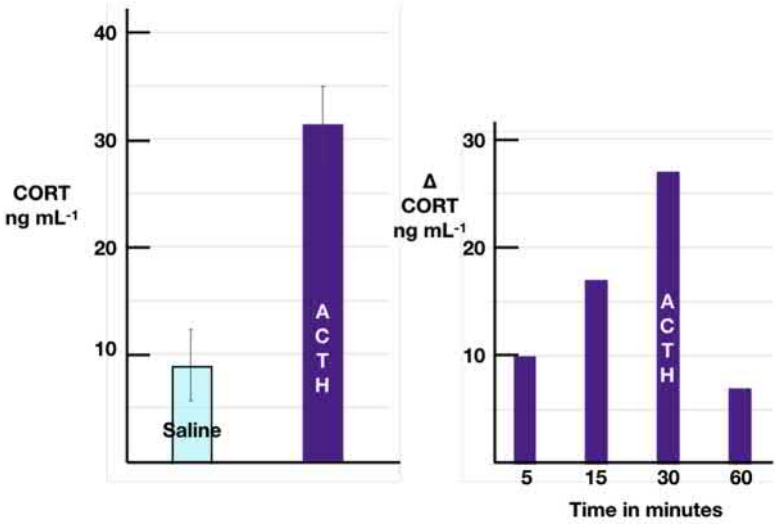

FIGURE 30.9 Effect of adrenocorticotropic hormone (ACTH) challenge on circulating concentrations of corticosterone in birds. Left: Effect of ACTH challenge or saline nestling northern mockingbirds. development (chicken: Thommes et al., 1983, 1985). Expression of TSH β subunit is first reported on day 11 with marked increases in late embryonic development (chicken: Gregory et al., 1998; Ellestad et al., 2011).

30.6 Growth hormone

30.6.1 Growth hormone gene, mRNA, and protein

The chicken GH gene consists of five exons and four introns encoding a 217 amino acid residue protein (Tanaka et al., 1992b) and is located in the G-band region 1q4 of chromosome 1 (Shaw et al., 1991). The promoter region includes a binding site for the pituitary-specific transcription factor, GHF-1/Pit-1 (Tanaka et al., 1992). The GH gene encodes a 217 amino acid residue protein consisting of a signal peptide and GH (Tanaka et al., 1992a). The structure of pre-GH has been determined from multiple avian species (e.g., emu: Genbank: XM_026099439.1; mallard: NM_001310345; Anna's hummingbird: XM_008502276; Adelie penguin XM_009326511; burrowing owl: XM_026864712.1; rifleman XM_009080681.1; Zebra finch: Arai and Iigo, 2010). There are two GH genes in the order *Passeriformes*, respectively, GH1A and GH1B (Yuri et al., 2008; Arai and Iigo, 2010). These resulted from gene duplication with Yuri et al. (2008) concluding that the "*duplication occurred in the ancestral lineage of extant passerines.*" Both GH1A and GH1B are expressed in the pituitary gland with GH1A also expressed in multiple tissues while GH1B is also expressed in erythrocytes and specific brain regions (Arai and Iigo, 2010).

30.6.2 Post-translational variants of growth hormone

There are charge and size variants of GH. Unlike the situation with human GH where there is a splicing variant, variants of avian GH are post-translational modifications. There are reports of glycosylated GH (Berghman et al., 1987), phosphorylated GH (Arámburo et al., 1990, 1992), a cleaved 15 Da GH (Arámburo et al., 2001), and dimeric and other oligomeric forms (Houston and Goddard, 1988) in the chicken.

There is evidence that the release of GH variants is differentially controlled. There are shifts in the ratio of variants during growth and with growth hormone–releasing hormone (GHRH) (chicken: Arámburo et al., 2000; Martínez-Coria et al., 2002). In addition, the ratio of glycosylated to nonglycosylated GH varies during growth (chicken: Berumen et al., 2004).

30.6.3 Actions of growth hormone

Studies on the role of GH being conducted predominantly on one species—the domesticated chicken. The effects of GH have been reported on hepatocyte gene expression comprehensively (chicken Wang et al., 2014).

30.6.3.1 Growth hormone and growth

The available evidence supports GH having some role in permitting birds to achieve their optimal growth rates. Growth is reduced by ~50% following hypophysectomy in chicks (King and Scanes; Kusnik et al., 2008). In contrast, hypophysectomy was reported to either have no effect (Proudman and Opel., 1990a) or reduce growth by ~30% (Proudman et al., 1994). The effect of hypophysectomy is partially overcome by GH replacement therapy in young chickens (King and Scanes; Scanes et al., 1986) but not turkeys (Proudman et al., 1994). In young intact birds, GH does not increase growth more than transiently (chickens: Leung et al., 1986; Burke et al., 1987; Cogburn et al., 1989; turkeys: Proudman et al., 1994). In mid-growth, pulsatile administration of GH was reported to increase growth (Vasilatos-Youngen et al., 1988). In contrast, in ovo administration of GH is followed by increased body weights, skeletal growth, and adipocyte size (chicken: Hargis et al., 1989). There is some evidence that polymorphisms in GH are associated with differences in overall growth (Anh et al., 2015 but not in Yan et al., 2003) and muscle growth (Yan et al., 2003). However, there were no effects differences in plasma concentrations of GH in faster than slower growing broiler chickens (Xiao et al., 2017).

30.6.3.1.1 Growth hormone and insulin-like growth factor 1

Circulating insulin-like growth factor 1 (IGF-1) is controlled by GH. In young birds, plasma concentrations of IGF-1 are reduced following hypophysectomy and partially restored by GH treatment (chickens: Huybrechts et al., 1985; turkeys: Proudman et al., 1994). Moreover, there were elevated plasma concentrations of IGF1 in intact young chickens receiving GH treatment and exhibiting increased growth (Vasilatos-Youngen et al., 1988). Both pulsatile and continuous administration of GH increased hepatic expression of IGF-1 (young chickens: Rosselot et al., 1995). Chronic administration of GH to adult chickens is followed by increased plasma concentrations of IGF-1 (males: Radecki et al., 1997; females: Scanes et al., 1999).

In vitro, GH increases IGF-1 release from avian hepatocytes, particularly in the presence of insulin (chicken: Houston and O'Neill, 1991). Plasma concentrations of both GH and IGF-1 are elevated posthatch when eggs are incubated under monochromatic green light than in darkness (chicken: Zhang et al., 2014). Plasma concentrations of IGF-1 are higher in faster than slower growing broiler chickens (Xiao et al., 2017). Myogenic growth is positively related to expression of IGF-1 or IGF1R (chickens: Davis et al., 2015).

30.6.3.1.2 Other mechanisms controlling insulin-like growth factor 1

There are other controls on expression of IGF-1 in muscles with acute exercise increasing expression of IGF-1 (white-throated sparrows and European starlings: Price et al., 2011). Moreover, exogenous glucocorticoids reduce circulating concentrations of IGF-1 (chicken: Leili and Scanes, 1998). There are relationships between prefledging plasma concentrations of IGF-1 and feather corticosterone in decreased broods (positive) and increased broods (negative) (great tits: Lodjak et al., 2016). Circulating concentrations of IGF-1 are decreased by capture handling stress but are not influenced by corticosterone administration (bearded reedlings: Tóth et al., 2018).

30.6.3.2 Growth hormone and lipid metabolism

GH exerts effects on lipid metabolism in birds. Growth hormone receptors (GHRs) are expressed in adipose tissue (chicken: Hausman et al., 2012). Administration of GH to chickens can influence the amount of adipose tissue, with the direction of the effect influenced by the mode of administration. For instance, body fat is decreased by pulsatile administration of GH (see Table 30.6) (Vasilatos-Younken et al., 1988; Rosebrough et al., 1991). In contrast, intravenous infusion of chicken GH (either pulsatile or continuous) was followed by increased body fat in male chickens (Moellers and Cogburn, 1995) as did subcutaneous injections of GH (Cogburn et al., 1989). In some studies, there were no effects of infusions of chicken GH on abdominal fat pad weights (Cravener et al., 1989; Moellers and Cogburn, 1995; Scanes et al., 1999).

Lipolysis can be influenced by GH. Acutely in vivo, GH increases circulating concentrations of nonesterified fatty acids acutely (chickens: Hall et al., 1987; Scanes, 1992; hypophysectomized ducks: Foltzer and Mialhe, 1976) but was without an effect in intact or hypophysectomized young turkeys (Proudman et al., 1994). GH stimulates in vitro lipolysis by avian adipose explants was reported to be increased in the presence of native and biosynthetic chicken and mammalian GH (chickens, turkeys, and pigeons: Harvey et al., 1977; adult male chicken: Campbell and Scanes, 1985) but not by reptilian and fish GH (Campbell et al., 1991). The effect of GH is blocked by a GH antagonist (chicken: Campbell et al., 1993) or by inhibitors of protein or RNA synthesis (chicken: Campbell and Scanes, 1988). In addition, GH exerts an effect on avian adipose that is analogous to the insulin-like effect of GH in mammals. Glucagon or cAMP-stimulated lipolysis in vitro by chicken adipose tissue explants is reduced in the presence of GH irrespective of whether of avian, mammalian, reptilian, or piscine origins (Campbell and Scanes, 1987; Campbell et al., 1991) and of a GH antagonist. The antilipolytic effect of GH was not influenced by inhibitors of protein or RNA synthesis (Campbell and Scanes, 1988). There has been GH influences lipogenesis in birds with the predominant effect being inhibitory. GH per se increases hepatic lipid biosynthesis (Cupo and Cartwright, 1989). GH suppressed insulin-stimulated synthesis of fatty acids by chick hepatocytes in vitro (Harvey et al., 1977). Similarly, GH depressed IGF-1 stimulated lipogenesis (Cupo and Cartwright, 1989). Moreover, pulsatile GH administration to young pullets in vivo reduced hepatic lipogenesis (see Table 30.6) (Rosebrough et al., 1991). The effect of GH on lipogenesis may be direct or due to the increase in plasma concentrations of T_3 (see below GH and thyroid hormones) with elevated T_3 depressing lipogenesis (Rosebrough et al., 1992). There were marked effects of GH treatment in vitro on the expression of genes related to lipid metabolism in hepatocytes (chicken: Wang et al., 2014).

30.6.3.3 Growth hormone and carbohydrate metabolism

There is some evidence that GH influences carbohydrate metabolism. A single injection of recombinant chicken GH was followed by increased plasma concentrations of glucose (chicken: Hall et al., 1987). However, in other studies, there were no effects of GH on glucose metabolism (e.g., Scanes et al., 1999).

30.6.3.4 Growth hormone and thyroid hormones

There are marked effects of GH on circulating concentrations of the thyroid hormone, triiodothyronine (T_3). It is not established whether GH influences thyroxine (T_4) release from the avian thyroid (chicken: MacKenzie, 1981). In young chicks, GH increases the circulating concentration of T_3 (Kuhn et al., 1985). This is due to GH reducing both the activity of hepatic type 3 monodeiodinase (the catabolic

TABLE 30.6 Effect of growth hormone on lipid metabolism in chickens (data are expressed as % of control ± SEM).

Parameter	Control	Continuous growth hormone	Pulsatile growth hormone	Reference
Abdominal fat pad	100 ± 6.9^a	90.0 ± 13.8^a	67.5 ± 7.0^b	Rosebrough et al. (1991)
Hepatic lipogenesis	100 ± 11.2^a	96.9 ± 23.2^a	18.7 ± 5.2^b	Rosebrough et al. (1991)
Plasma T_3	100 ± 11.8^a	152.9 ± 17.6^b	200.0 ± 17.6^b	Rosebrough et al. (1991)

^{a,b}Different superscript letters indicate difference $P < .05$.

enzyme metabolizes T_3 to T_2; Darras et al., 1992, 1993) and the expression of this deiodinase (Van der Geyten et al., 1999). This is a physiological effect of GH as type 3 monodeiodinase is elevated following hypophysectomy and partially restored to normal by GH replacement therapy (Darras et al., 1993).

30.6.3.5 Growth hormone and immune functioning

Immune functioning is influenced by GH. This appears to be due to both pituitary derived GH and to GH synthesized in immune tissues (discussed under extrapituitary GH). Thymus weights are decreased following hypophysectomy with this being partially overcome by GH replacement therapy (chicken: King and Scanes, 1986; Johnson et al., 1993). Administration of chicken GH to hypophysectomized chicks was followed by increased percentage of CD4+ peripheral blood lymphocytes (chicken: Johnson et al., 1993). Moreover, GH increases bursa weights in hypophysectomized birds also receiving T_3 (chicken: Scanes et al., 1986). In addition, GH increases proliferation of peripheral blood T cells to a mitogenic challenge in obese chicks (Marsh et al., 1992).

30.6.3.6 Growth hormone and reproduction

There is evidence that GH influences reproduction in females with polymorphisms in GH being associated with differences in egg production (chicken: Makhsous et al., 2013; Su et al., 2014). There is both GHR expression and immune-reactive GHR along the length of the oviduct, in the magnum, isthmus, and shell gland together with some in the infundibulum (chicken: Hrabia et al., 2013). Moreover, GHR is expressed in the ovary, particularly the F4 and F5 large yellow follicles (chicken: Ahumada-Solórzano et al., 2012). Administration of GH was also associated with increases in the plasma concentrations of progesterone, testosterone, and estradiol (fasted chickens: Socha et al., 2017).

Direct effects of GH on both ovarian and oviductal functioning have been reported. There is increased production of progesterone in the presence of GH from granulosa cells (Ahumada-Solórzano et al., 2012) or large yellow follicles (Hrabia et al., 2014a) incubated in vitro. In addition, GH stimulates proliferation of granulosa cells as well as increasing IGF-1 release from these cells in the ovary (chickens: Ahumada-Solórzano et al., 2016).

There are multiple effects of GH on oviductal functioning with increased weight, reduced apoptosis, and gene expression (Table 30.7) (sexually immature chickens: Hrabia et al., 2014b). Moreover, in fasted hens, GH administration increased magnum expression of progesterone receptor, estrogen receptor α, and avidin (chickens: Socha et al., 2017). Despite GH having no effect on overall egg production, some improvements in shell-thickness were noted (chicken: Donoghue et al., 1990).

What is not clear is whether GH acting on the ovary and/or oviduct is hormonal with GH from the pituitary or locally produced GH acting in a paracrine manner with GH being expressed in the ovary, particularly the F4 and F5 large yellow follicles (chicken: Ahumada-Solórzano et al., 2012).

30.6.3.7 Growth hormone and adrenocortical hormones

There is evidence that GH can influence the avian adrenal cortex stimulating production of corticosterone. Plasma concentrations of corticosterone are acutely increased following administration of recombinant chicken GH (Cheung et al., 1988) or chronically following continuous administration of native chicken GH (Rosebrough et al., 1991). There are shifts in in vitro corticosteroidogenesis in adrenal cells from hypophysectomized chicks or hypophysectomized chicks receiving GH administration (Carsia et al., 1985).

30.6.3.8 Growth hormone and apoptosis

GH reduces apoptosis of bursal lymphocytes cells in vitro (chicken: Luna-Acosta et al., 2015) and oviductal cells in vivo (Hrabia et al., 2014b). Similarly, GH has a neuroprotective role reducing apoptosis of retinal ganglion cells induced by glutamate (Japanese quail: Martínez-Moreno et al., 2016).

30.6.3.9 Growth hormone receptors and Signal Transduction

The GHR is a member of the class I cytokine receptor superfamily. Chicken GHR cDNA has been sequenced (Burnside et al., 1991). As with the mammalian GHR, the chicken GHR consists of three domains: an extracellular domain, a single transmembrane domain, and an intracellular domain. Binding of GH leads to receptor dimerization and activation JAK-2 and then STAT1, STAT3, and STAT5 signaling. In addition, GH binding to the GHR activates Src family kinase signaling pathway independently of JAK2 (reviewed: Dehkhoda et al., 2018). The amino acid sequence of avian GHR has been deduced from cDNA in Muscovy ducks (Ji et al., 2016) and other birds (burrowing owl: XM_026865892.1; collared flycatcher: XM_005060581.2; Okarito brown kiwi: XM_XM_026062927.1; rock pigeon: U20353.1). Incubation of chicken hepatocytes with GH resulted in shifts in expression of genes are proteins in the STAT and MAPK pathways (Wang et al., 2014).

The GHR gene is expressed in multiple tissues in birds including the liver, skeletal muscle, adipose tissue, hypothalamus, extrahypothalamic brain tissues, thymus,

spleen, and bursa (chicken: Hull and Harvey, 1998; Mao et al., 1998; young Muscovy duck: Ji et al., 2016). There are shifts in hepatic expression of GHR during growth and development being high in late embryonic development, decreasing at hatch and then rising (chicken: Burnside and Cogburn, 1992; Mao et al., 1997; Wu et al., 2011). GH downregulates expression of GHR in the liver, thymus, bursa, spleen, and brain (Hull and Harvey, 1998). Similarly, GH binding to liver membranes is increased following hypophysectomy and depressed by GH replacement therapy (Vanderpooten et al., 1991). Moreover, there is high correlation between GH and GHR expression in skeletal muscles in Muscovy ducks (Ji et al., 2016). Expressions of both GHR and IGF-1 are depressed with heat stress in both liver and muscle (Japanese quail: Gasparino et al., 2013). Muscle expression of GHR is also elevated with cold stress (Japanese quail: Gasparino et al., 2013). A single nucleotide polymorphism (SNP) in the GHR gene is associated with growth and fat deposition (chicken: Ouyang et al., 2008).

Sex-linked dwarf chickens exhibit reductions in growth together elevated plasma concentrations GH together with reduction in the plasma concentrations of both T_3 (Scanes et al., 1982) and IGF-1 (Huybrechts et al., 1985). The lesion in sex linked dwarf chickens is a mutation in the GHR leading to GHR malfunctioning (Burnside et al., 1991, 1992).

30.6.3.10 Growth hormone binding protein

There are specific GH binding proteins (GHBPs) in the circulation of birds (chicken e.g., Tobar-Dupres et al., 1993). GHBP is generated by alternative splicing of the GHR gene transcript (chicken: Bingham et al., 1994; Hull et al., 1999) and/or proteolytic cleavage of GHR (Vleurick et al., 1999).

30.6.4 Control of growth hormone release

30.6.4.1 Introduction

Release of GH from the avian pituitary gland is under hypothalamic control with multiple stimulatory-releasing hormones including GHRH, ghrelin, neuropeptide W, TRH, and the inhibitory releasing hormone (SS). In addition, there are neuropeptides that stimulate GH release and/or somatotropes and that are putative releasing hormones. Examples of the later include PACAP and GCGL (Table 30. 3).

30.6.4.2 Growth hormone–releasing hormone

GHRH or somatoliberin is a peptide with 47 amino acid residues. It is synthesized as prepro-GHRH and is cleaved to pro-GHRH and then to GHRH (see Figure 30.10). The structure of GHRH is similar across avian species (see Figure 30.10).

GHRH is expressed in the avian hypothalamus and also in the small intestine, kidneys, lung, ovary, anterior pituitary gland, spleen, and testes (chicken: Wang et al., 2007). There is high expression of GHRH in the embryo day eight, but, subsequently, this declines to a low plateau level on days 12–20 (Wang et al., 2006). GHRH increases GH release in vivo and in vitro (chicken: Scanes et al., 1984). Avian somatotropes respond to GHRH with increased intracellular calcium (chicken: Scanes et al., 2007) (Table 30.7).

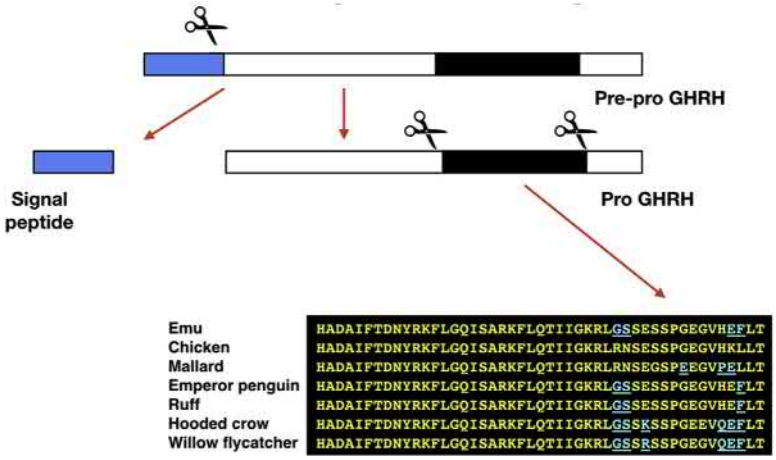

FIGURE 30.10 Processing of prepro-gonadotropin-releasing hormone to pro-gonadotropin-releasing hormone and then gonadotropin-releasing hormone. Also shown is the structures of GHRH in example avian species, namely the following: in the Infraclass *Paleognathae*: Emu (Genbank XM_026093031) and in the Infraclass *Neognathae*: Superorder *Galloanserae*: Order *Galliformes*: Chicken (NM_001040464), Order *Anseriformes*: Mallard (XM_013103655), in the Infraclass *Neoaves*: Order *Sphenisciformes*: E. penguin—Emperor penguin (XM_009275539), Order *Charadriiformes*: Ruff (XM_014941254), Order *Passeriformes*: H. crow—Hooded crow (XM_010397141) and W. flyc—Willow flycatcher (XM_027885084.1). Letters with red font indicate difference from sequence in chicken. Letters with blue font indicate difference from sequence in other birds in the Superorder *Neoaves*.

30.6.4.3 Ghrelin/growth hormone secretagogue receptor

30.6.4.3.1 Action and chemistry

Ghrelin stimulates release of GH and increases in intracellular calcium in birds acting via the GH secretagogue receptor (GHS-R) (chicken: Ahmed and Harvey, 2002; Scanes et al., 2007) (Table 30.8). Interestingly, only a minority of somatotropes (about one fifth) respond to ghrelin with increased intracellular calcium (Scanes et al., 2007).

The structure of chicken ghrelin has been deduced (Kaiya et al., 2002). The ghrelin gene is transcribed to form preproghrelin (or preproghrelin/obestatin). This is processed to the ghrelin peptide together with another peptide, obestatin (Figure 30.11). There are marked differences between the sequence of amino acid residues in human and avian ghrelin with chicken ghrelin being 46% different from human ghrelin. Moreover, there are differences between the structures of ghrelin in avian species with, for instance, 23.1%, 34.6%, and 38% differences between chicken and, respectively, ostrich, mallard, and rifleman ghrelins (Figure 30.11). The amino acid sequences of avian obestatins are markedly different from human obestatin but exhibit less amino acid substitutions within the Aves than for ghrelin (Figure 30.11). These differences emphasize the need in experimentation to employ synthesized ghrelin or obestatin identical or at least very similar to that of the species of interest. There is no information on the effects of obestatin on pituitary functioning in birds.

30.6.4.3.2 Growth hormone secretagogue receptor

Ghrelin acts via the GHS-R with avian GHS-R characterized (Japanese quail: Kitazawa et al., 2009). There are at least two forms of GHS-R in the avian anterior pituitary gland: GHS-R1a and GH-SR1c. Expression of these is depressed by ghrelin, GHRH, and corticosterone (chicken: Geelissen et al., 2003). Based on comparison of lines of chickens with three genotypes expressing GHS-R with adjacent SNPs in the GHS-R, there are physiological effects of GHS-R on both GH and growth (El-Magd et al., 2016).

TABLE 30.8 Effects of neuropeptides on the intracellular concentrations in responsive chicken somatotropes

Neuropeptide	% Of somatotropes responding	$\Delta[Ca^{2+}]_i$ Mean ± SEM
Growth hormone–releasing hormone	100	120 ± 6
Thyrotropin-releasing hormone	73	222 ± 16
Ghrelin	21	94 ± 16
PACAP	85	90 ± 14
Leptin	58	83 ± 10

Data from Scanes, C.G., Glavaski-Joksimovic, A., Johannsen, S.A., Jeftinija, S., Anderson, L.L., 2007. Subpopulations of somatotropes with differing intracellular calcium concentration responses to secretagogues. Neuroendocrinology 85, 221–231.

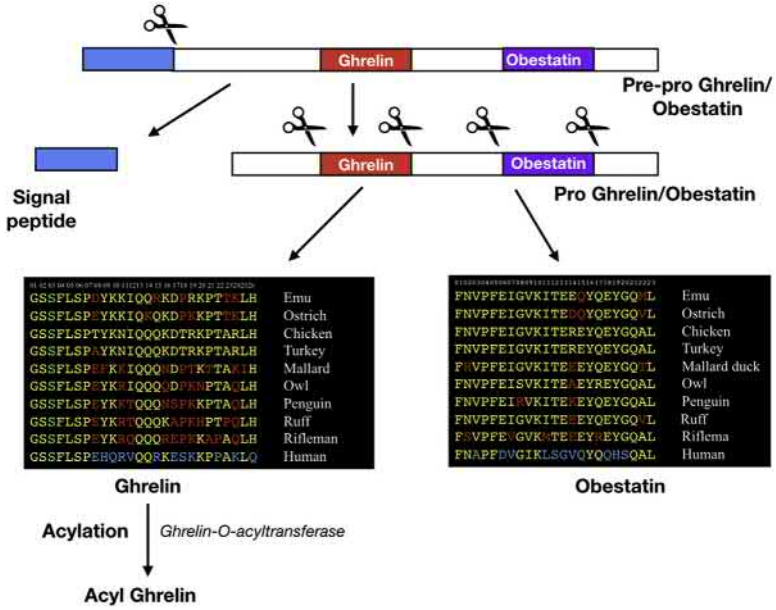

FIGURE 30.11 Synthesis of ghrelin and obestatin from preproghrelin obestatin (preproghrelin). Also shown are the structures of ghrelin and obestatin from poultry and selected wild birds. Subclass *Paleognathae*: Emu (*Dromaius novaehollandiae*) (XM_026099658.1), Ostrich (*Struthio camelus*) (XM_009681128.1), Subclass *Neognathae,* Superorder *Galloanserae*: Order *Galliformes*: chicken (*Gallus gallus*) (AB075215.1), turkey (*Meleagris gallopavo*) (AY497549.1), Order *Anseriformes*: mallard duck (*Anas platyrhynchos*) (XM_027467410.1), Superorder *Neoaves*: Order *Strigiformes*: Owl—burrowing owl (*Athene cunicularia*) (XM_026857822.1), penguin—Order *Sphenisciformes*: Adelie penguin (*Pygoscelis adeliae*) (XM_009320113.1), Order *Charadriiformes*: Ruff (*Calidris pugnax*) (XM_014946895.1), Order: *Passeriformes*: rifleman (*Acanthisitta chloris*) (XM_009082274.1), and human (AB029434.1). *Red letters* indicate difference with chicken ghrelin or obestatin, *blue letters* indicate where human ghrelin or obestatin differs from chicken ghrelin or obestatin. Light green indicates site of acylation (with octanyl) in ghrelin.

30.6.4.3.3 Extrapituitary actions of ghrelin

There is abundant evidence that ghrelin has effects on nonpituitary tissues including the gastrointestinal tract with ghrelin synthesis and demonstrated effects (duck: Shao et al., 2010; chicken: Kitazawa et al., 2017), bursa Fabricius with ghrelin, ghrelin-o-acyltransferase, and GHS-R expression (chicken: Yu et al., 2019), and central nervous system. For instance, there is evidence that ghrelin exerts effects with the hypothalamus. For instance, expression of ghrelin and GHS-R in the hypothalamus differs in lines of chickens with high or low-residual feed intake (Sintubin et al., 2014; Gastón et al., 2015).

30.6.4.4 Neuropeptide W

Chicken neuropeptide W (NPW) 23 but not NPB28 inhibits GHRH induced release of GH from chicken pituitary cells (Bu et al., 2016). There is high expression of NPW and NPBWR1 in the hypothalamus and of NPBWR1 in the pituitary gland (chicken: Bu et al., 2016). In addition, there is some expression of NPB in both the hypothalamus and pituitary gland (chicken: Bu et al., 2016).

30.6.4.5 Thyrotropin-releasing hormone

TRH stimulates release of GH from pituitary tissue (chicken: Huang et al., 2014).

30.6.4.6 Glucagon-like peptide

GCGL stimulates both release of GH from chicken pituitary tissue together with GH expression (Huang et al., 2014).

30.6.4.7 Somatostatin and cortistatin

Two genes for somatostatin are present in birds, namely the following:

1. Somatostatin 1 (SST) encoding the peptides: SST14 and SST28 (see Figure 30.12)
2. Cortistatin (CST) or SST 2 encoding the peptide, CST (see Figure 30.12).

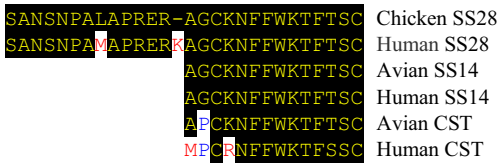

FIGURE 30.12 **Comparison of the structures of avian and human SS14, SS28, and cortistatin.** *Red letters* indicate difference between avian and human sequences, *blue letters* indicate difference between SS14 and CST] [structures of avian CST are based on deduced sequences for the following: (Bengalese finch) XM_021529840.1; chicken: NM_204455.1, duck: XM_005021277.4, emperor penguin: XM_009289625.1; emu) XM_026095553.1].

There are five avian somatostatin receptors (SSTR1-5) with SST14, SST28, and CST being equipotent for SST1R-4 (chicken: Meng et al., 2014). In contrast, SST18 is markedly more potent than CST and SST14 with SSTR5 (chicken: Meng et al., 2014).

Infusion of SS14 depresses both basal and either GHRH or TRH-stimulated GH release in vivo (chicken: Scanes and Harvey, 1989). In the presence of SS14 or SS28 or CST14, both basal and GHRH induced GH release is inhibited (chicken: Meng et al., 2014). What is not clear is the extent to which SS14 and/or SS28 and/or CST14 are physiologically controlling GH release in birds. There is little information of the effects of peptides derived from other members of the somatostatin family (urotensin II or urotensin II-related peptide) on the release GH or other pituitary hormones in birds.

30.6.5 Control of growth hormone expression

GH expression is under multiple stimulatory and inhibitory influences:

- Stimulatory:
  - GHRH ↑ GH mRNA in vivo (Vasilatos-Younken et al., 1992) and in vitro (Radecki et al., 1994) via a cAMP-dependent protein kinase pathway (Kansaku et al., 1998).
  - Other hypothalamic releasing factors/hormones: TRH ↑, PACAP ↑, and ghrelin ↑stimulates expression (Porter et al., 2006).
  - Corticosterone ↑ in embryonic pituitary cells (Bossis and Porter, 2003; Heuck et al., 2009).
- Inhibitory:
  - SRIF ↓ (chicken: Porter et al., 2006),
  - T_3 ↓ (chicken: Radecki et al., 1994), and
  - GH or IGF-1 ↓ when administered continuously in vivo (chicken: Scanes et al., 1999).

The changes in GH expression during growth are similar to those of plasma concentrations of GH (chicken: McCann-Levorse et al., 1993). The pattern of gene expression during the development of avian somatotropes can be described by self-organizing maps (Ellestad et al., 2006).

30.6.6 Environmental factors and growth hormone release

Plasma concentrations of GH are elevated in birds when receiving insufficient nutrition, for example, being increased with fasting (chicken: Harvey et al., 1978; turkey: Anthony et al., 1990), protein deficient diets (chicken: Scanes et al., 1981), and overall dietary restriction (American kestrels: Lacombe et al., 1993). There is evidence that stressors inhibit release of GH with plasma concentrations of GH depressed in chickens following anesthesia (Harvey and Scanes, 1977) and insulin-induced hypoglycemia (Harvey et al., 1978).

30.6.7 Pituitary origin of growth hormone

The somatotrophs are located in the caudal lobe of the anterior pituitary gland (chicken: Mikami, 1980; dove: Reichardt et al., 1993; zebra finches: Christensen and Vleck, 2015) (Figure 30.1). During late embryological development and early posthatch life, the number of somatotrophs increases rapidly until a plateau level is achieved (dove: Reichardt et al., 1993; chicken: Malamed et al., 1997). There are ontogenic changes in the structure of the somatotroph. The number of secretory granules per unit volume of the cell increases during late embryonic development (chicken: Malamed et al., 1993), and there are also more in the adult than the young (chicken: Malamed et al., 1985, 1988).

30.6.8 Extrapituitary expression of growth hormone

There is evidence that GH is expressed in multiple extrapituitary tissues. Posthatching, GH immunoreactivity has been observed in the following organs in chickens: lymphoid tissues (bursa Fabricius, thymus, and spleen) (Luna et al., 2005), testes (Luna et al., 2004), ovary (Hrabia, 2015), and cerebellum (Alba-Betancourt et al., 2011). GH is released from ovarian granulosa cells (chickens: Ahumada-Solórzano et al., 2016). In addition, GH stimulates proliferation of these cells as well as increasing IGF-1 release from granulosa cells (chickens: Ahumada-Solórzano et al., 2016). There is expression of GH in both breast and leg muscles in Muscovy ducks (Ji et al., 2016). In chick embryos, GH immunoreactivity has been reported in multiple tissues including the following: crop, diencephalon and mesencephalon, neural ganglia, trigeminal nerves, dorsal and ventral root ganglia, dorsal and ventral horns of the spinal cord, hepatocytes, intracostal muscles, limb bud cartilage, lungs, and Müllerian duct (Harvey et al., 2000; Murphy and Harvey, 2001; Beyea et al., 2005). In addition, GH expression is seen in embryonic lung tissue (Beyea et al., 2005).

30.6.9 Ontogeny of growth hormone

30.6.9.1 Pou 1 (Pit1)

Pituitary specific transcription factor-1 (*Pit-1* or POU class 1 homeobox 1) plays an important role in the differentiation of somatotropes and lactotropes. In birds, Pit-1 can transactivate a promoter for the GH gene (chicken: Murase et al., 2011). Avian Pou 1 (Pit 1) has been characterized (turkey:

Wong et al., 1992; chicken: Tanaka et al., 1999) and is first expressed on embryonic day five (chicken: Van As et al., 2000). Two Pou 1 (Pit 1) transcripts, Pit1α and Pit1γ, are expressed in both the cephalic and caudal lobes of the chicken pituitary gland, with expression increasing in posthatching growth in a manner parallel to that of GH (chicken: Tanaka et al., 1999). Pou 1 (Pit 1) has been demonstrated to be present in somatotrophs (turkey: Weatherley et al., 2001). While no changes in Pou 1 (Pit 1)-expressing cells occur with corticosterone (chicken: Fu and Porter, 2004), TRH increases expression of Pou 1 (Pit 1) (Van As et al., 2004).

Polymorphisms in Pit-1 gene are associated with improved growth rate and feed efficiency (chickens: Nie et al., 2008; Bhattacharya et al., 2012; Jin et al., 2018) and egg production (Muscovy duck: Xu et al., 2015).

30.6.9.2 Somatotrophs and their differentiation

Somatotropes increase in numbers of somatotrophs beginning about day 14 of incubation (chicken: Porter et al., 1995). GHRH increases the number of somatotrophs (Porter et al., 1995). This increase is due to stimulatory effects of corticosterone and probably also of GHRH and thyroid hormones (Dean and Porter, 1999; Liu and Porter, 2004). The glucocorticoid induction of somatotroph differentiation involves both type 1 (mineralocorticoid) and type 2 (glucocorticoid) receptors (Bossis et al., 2004). Corticosterone induction of the GH gene is via a cis-acting glucocorticoid responsive element (Heuck-Knubel et al., 2012). Glucocorticoids act via the ERK1/2 pathway with Ras effector downstream (Ellestad et al., 2015). It is likely that the corticosterone inducing differentiation of somatotrophs is of adrenal origin, but steroidogenic enzymes are expressed in the embryonic anterior pituitary gland (Zheng et al., 2008).

30.6.9.3 Secretion

A common pattern of circulating concentrations of GH has been observed in all species of birds examined. This consists of progressively rising circulating concentrations of GH in late embryonic development and early posthatch development, high plasma concentrations of GH during the period of rapid posthatching growth, and low GH concentrations in older and adult birds (e.g., chicken: Harvey et al., 1979a, b; American kestrel: Lacombe et al., 1993; European starlings and Japanese quail: Schew et al., 1996). The mechanistic basis for this ontogenic profile includes changes in GH synthesis, somatotroph numbers, and pituitary sensitivity to secretagogues.

30.7 Prolactin

30.7.1 Prolactin gene, mRNA, and protein

There are genes for PRL and prolactin-like protein (*PRL-L*):

- *PRL* gene is on chicken chromosome 2
- *PRL-L* gene is on chicken chromosome 1

(Wang et al., 2010). The structure of PRL from multiple avian species has been deduced from the cDNA [e.g., ostrich (XM_009688738), mallard duck (JQ677091), chicken (NM_205466), rock pigeon (XM_005506024), chimney swift (XM_010004518), Adelie penguin (*Pygoscelis adeliae*) (XM_009326511), canary (XM_009093894)].

A polymorphism of intron 1 of the PRL gene is associated with increased egg production (domestic duck: Bai et al., 2019). Plasma concentrations of PRL in birds are illustrated in Table 30.4.

30.7.2 Post-translational variants of prolactin

There are post-translational variants of PRL in birds. Two glycosylated PRL variants (one *O*- and one *N*- glycosylated) have been identified as well as a nonglycosylated form (turkeys: Corcoran and Proudman, 1991). The glycosylated PRL variants exhibit reduced radioreceptor activity (turkeys: Corcoran and Proudman, 1991). In chickens, PRL variants have been reported as either glycosylated (Berghman et al., 1992) or phosphorylated (Arámburo et al., 1992). Physiological state influences PRL variants. For instance, there are shifts in the proportion of variants in the pituitary between nonlaying, laying, and incubating hens (chicken: Hiyami et al., 2009).

30.7.3 Actions of prolactin

30.7.3.1 Prolactin and the crop sac gland

In columbiform birds, PRL stimulates the production of "crop milk" from the crop sac from both males and females. The composition of pigeon crop milk initially is the following:

- Protein 64.1%
- Lipid 29.7%
- Water 6.2%

(Hu et al., 2016). There are changes in the composition of crop milk with lipid falling from 30% of dry weight to day one of chick rearing to 5% on day 20 (Xie et al., 2017).

The milk is fed to newly hatched chicks or squabs. In both males and females, plasma concentrations of PRL

increase during the period that they are incubating eggs peaking at the time the chicks hatch (ring doves: Goldsmith et al., 1981; pigeon: Hu et al., 2016; Xie et al., 2018). PRL acts via prolactin receptor (PRLR) to induce increases in crop size; the maximal size of the crop being on day three of "lactation" in domestic pigeons (Hu et al., 2016) but at the same time as hatching in ring doves (Goldsmith et al., 1981). Expression of PRLR crop increases during incubation, remaining high during the first 7 days of chick rearing (Xie et al., 2018). Moreover, expressions of the following enzymes related to lipid metabolism are consistently elevated in crop tissue with maxima immediately prior to the chicks hatching: fatty acid translocase (FAT/CD36), fatty acid-binding protein 5 (EFABP), acyl-CoA-binding protein (ACBP), acetyl-CoA carboxylase (ACC) and fatty acid synthase (FAS) (Xie et al., 2017). In vitro, PRL increases lipid production by pigeon crop tissue (Wan et al., 2019).

Other hormones play a role in crop development and production of crop milk. Crop concentrations of EGF and IGF-1, together with EGF expression, follow the same profile as plasma concentrations of PRL (Xie et al., 2018). There is decreased expression of progesterone receptor, estrogen receptor, and GHR at hatching in the parents (Xie et al., 2018). PRL acts via binding to the PRLR and the insulin receptor substance 1(IRS1)/Protein kinase B (Akt)/TOR signaling pathway (Hu et al., 2016). The ability of PRL to stimulate the crop sac has been used as a biossay for PRL (Nicholl, 1967).

30.7.3.2 Prolactin and behavior

In different birds, PRL induces or at least influences behaviors including those related to incubation and/or broodiness (care of chicks). Administration of PRL induces broodiness (chickens: Riddle et al., 1935; turkeys: Youngren et al., 1991). Incubation behavior is completely suppressed in turkey hens actively immunized against PRL (Crióstomo et al., 1998).

There is evidence that PRL directly influences behavior as there are discrete PRL binding sites in the brain (ring doves: Buntin et al., 1993). In addition, PRL induces phosphorylation of STAT5 (Signal Transducer and Activator of Transcription 5) by JAK2 (Janus kinase 2) in specific sites in the forebrain (ring doves: Buntin and Buntin, 2014).

30.7.3.3 Prolactin and reproduction

PRL increases as the birds incubate eggs and declines during the period when the adults are caring for the chicks (zebra finch: Smiley and Adkins-Regan, 2016). Prebreeding plasma concentrations of PRL were a good predictor of numbers of offspring fledged (house sparrows: Ouyang et al., 2011). PRL can act directly on the gonadotropes that secrete LH, with PRL depressing LH release from turkey anterior pituitary cells in vitro (turkey: You et al., 1995). Prebreeding plasma concentrations of PRL were a good predictor of numbers of offspring fledged (house sparrows: Ouyang et al., 2011).

30.7.3.4 Other roles of prolactin and adrenocortical functioning

There is evidence that PRL influences adrenocortical functioning in birds. Net production of corticosterone by chicken adrenal cells in vitro is increased by PRL; the effect being due to inhibition of 5α-reductase (Carsia et al., 1984, 1987). Similarly, plasma concentrations of CORT are elevated following injection of either mammalian PRL in chickens (Decuypere and Kühn, 1985; Skwarlo-Sonta et al., 1987) or native or mono-polyethylene glycol (PEG)ylated chicken PRL (chicken: Oclon et al., 2018).

30.7.3.5 Prolactin receptor

The PRLR is a member of the class I cytokine receptor superfamily and activates the JAK-2/STAT 5 signaling pathway. The PRLR gene was first cloned from kidney tissue (chickens: Tanaka et al., 1992b). There is a duplicated PRLR gene in the late-feathering chickens carrying the K (i.e., late-feathering) locus (chickens: Bu et al., 2013b). A different mutation in the PRLR is responsible for late feathering in turkeys (Derks et al., 2018).

- Type I PRLR high expression in the kidneys and small intestine plus some in the brain and pancreas.
- Type II PRLR expression in the brain, intestine, kidneys, lung, skeletal muscle, testes, ovaries, pituitary, and pancreas plus some in the heart, liver, and spleen
- Type-v1 PRLR high expression in the brain, intestine, kidneys, and pituitary gland plus some in the heart, liver, lungs, muscle, ovary, testis, and pancreas.

(chicken: Bu et al., 2013a). PLP exhibited very limited ability to activate the PRLR (potency <0.1% that of PRL) (chicken: Bu et al., 2013a).

Expression of PRLR in the ovary differs by functional unit with highest expression in the stroma followed by small follicles and a decline with follicular growth/maturation (chicken: Hu et al., 2017). In addition, PRLR expression is markedly higher in granulosa than theca tissue in large follicles (chicken: Hu et al., 2017). Moreover, PRLR expression is increased in granulosa cells from 6 to 8 mm, F3 and F2 follicles following treatment with FSH or glycosylated or nonglycosylated PRL (chicken: Hu et al., 2017).

30.7.4 Control of prolactin release

In birds, PRL secretion is predominantly under stimulatory hypothalamic control, although there are some inhibitory influences. What is not clear is how the multiple PRL secretagogues interact physiologically and why there are so many hypothalamo-hypophysiotropic factors in birds.

30.7.4.1 Vasoactive intestinal peptide and prolactin release

30.7.4.1.1 Introduction

Vasoactive intestinal peptide is a major hypothalamo-hypophysiotropic factor acting physiologically to stimulate PRL release (Table 30.3). PRL release in birds can be stimulated by VIP in vivo (chickens: Macnamee et al., 1986; turkeys: Opel and Proudman, 1988; white-crowned sparrow: Maney et al., 1999; nonincubating zebra finch: Christensen and Vleck, 2008) and in vitro (turkeys: Proudman and Opel, 1988). VIP is found in the avian hypothalamus, particularly in the median eminence (chickens: Macnamee et al., 1986). VIP is synthesized as prepro-peptide histidine isoleucine (PHI) VIP, and this is subject to proteolytic cleavage to generate the peptides, VIP and PHI (Figure 30.13). VIP is expressed in the hypothalamus together with the pituitary gland, small intestine, and other tissues (domestic goose: Liu et al., 2014). The amino acid sequence for a VIP from several avian species is shown in Figure 30.13.

Dopamine stimulates release of VIP from the hypothalamus via D_1 dopamine receptors (turkey: Youngren et al., 1996; Chaiseha et al., 1997). In addition, serotonin increases PRL secretion via hypothalamic effects on dopaminergic neurons and, then, release of VIP (turkey: El Halawani et al., 1995; Chaiseha et al., 2010).

30.7.4.2 Arginine vasotocin

AVT has some PRL releasing activity (Table 30.3). Posterior pituitary extracts can provoke PRL release from turkey pituitary cells due to both AVT and VIP. AVT stimulates prolactin release, while antiserum to AVT partially neutralizes the PRL-releasing effects of posterior pituitary extracts (El Halawani et al., 1992).

30.7.4.3 Prolactin-releasing peptide

30.7.4.3.1 Chemistry

Prolactin-releasing peptide (PrRP)is an RF-amide peptide. The precursor (pre-proprolactin-releasing peptide) for avian PrRP has been characterized in the chicken from its cDNA; there are PrRPs with 20- and 31-amino acid residues (Tachibana et al., 2011). Moreover, PrRP20 and PrRP31 have a consistent structure across birds (Canary: Genbank XM_009086200; Rhinoceros hornbill: XM_010138474; Rifleman: XM_009079364; Saker falcon: XM_005437134):

PrRP31	SRPFKHQIDNRSPEIDPFWYVGRGVRPIGRF-NH_2
PrRP20	SPEIDPFWYVGRGVRPIGRF-NH_2

There is expression of PrRP in specific regions of the chicken brain, including the hypothalamus, hindbrain, and telencephalon together with the pituitary gland (Wang et al., 2012).

30.7.4.3.2 Actions

Avian PrRP is thought to influence PRL secretion in birds. There is a small increase in circulating concentration of PRL after peripheral administration of an intermediate dose of PrRP31 in chickens, presumably reflecting increased prolactin release (Tachibana et al., 2011) (Table 30.3). In contrast, central administration of PrRP31 into the brain consistently depresses circulating concentrations of PRL, indicating an ultrashort feedback effect (Tachibana et al., 2011).

30.7.4.3.3 Receptors

The structure of PrRP receptor (PRLHR1) and PrRP receptor like (PRLHR2) has been deduced from cDNA

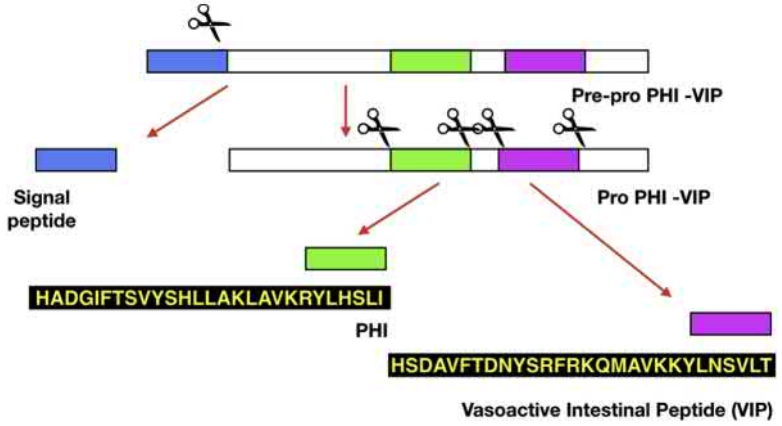

FIGURE 30.13 Synthesis of peptide histidine isoleucine (PHI) and vasoactive intestinal peptide (VIP) as prepro-PHI VIP cleaved to pro-PHI VIP and subsequent proteolytic cleavage to PHI and VIP. The structures of avian PHA [identical in chicken (Genbank U09350.1) and goose (JQ941869) and VIP [identical in chicken (Genbank U09350.1), domestic goose (JQ941869) and rock pigeon (FJ913875.1)] are shown.

from multiple avian species (e.g., PRLHR1: chicken: Genbank AY847003.1; rock pigeon: XM_005515615; starling: XM_014872461.1; PRLHR2: burrowing owl: XM_026863027; chicken: NM_001024585; Chilean tinamou: XM_026042650; emu: XM_026114221; Okarito brown kiwi: XM_026064463). These receptors exhibit homologies to the NPY receptor and are derived from redundant NPY receptors early in vertebrate evolution (Lagerstrom et al., 2005). There is expression of PRLHR1 and PRLHR2 in the pituitary gland and specific regions of the chicken brain, including the hypothalamus, hindbrain, and telencephalon (Wang et al., 2012).

30.7.4.4 Neuropeptide W

Chicken NPW23 but not NPB28 inhibits VIP induced release of PRL from chicken pituitary cells with the effect mediated by binding to the NPBWR1 (Bu et al., 2016).

30.7.4.5 Dopamine

The neurotransmitter, dopamine directly inhibits prolactin release and expression from avian lactotropes. For instance, dopamine or the dopamine D_2 agonist, quinpirole, inhibited prolactin expression by pituitary cells in vitro as induced by either VIP or forskolin (chicken: Lv et al., 2018). Dopamine acts via binding to dopamine receptors (members of the G Protein-coupled receptor). There is high expression of two dopamine receptors: DRD2 (D_2) and DRD4 (D_4) in the cephalic lobe of the anterior pituitary gland (chicken: Lv et al., 2018; domestic goose: Wang et al., 2014).

30.7.4.6 Other stimulatory factors

Other peptides stimulate PRL secretion in birds. PRL release is stimulated by TRH (turkey in vivo: Saeed and El Halawini, 1986) and PHI (turkey: Proudman and Opel, 1990b).

30.7.5 External influences on prolactin release

30.7.5.1 Photoperiod and prolactin release

Nocturnal plasma concentrations of prolactin are increased in young pullets after a single long day (chickens: Dunn et al., 2017). Moreover, expression of TSH β subunit is increased (Dunn et al., 2017).

30.7.5.2 Stress and prolactin release

Plasma concentrations of prolactin can be increased, decreased, or not affected by stress in birds. For instance, plasma concentrations of prolactin were increased by handling stress birds prior to incubation but were decreased in incubating birds (Manx shearwater: Riou et al., 2010). Similarly, plasma concentrations of prolactin were reported to the increased after capture and handling stress in failed breeders but stress decreased plasma concentrations of prolactin in breeding and incubating birds (Cape petrel: Angelier et al., 2013). In another study, plasma concentrations of prolactin are depressed after capture stress (pigeon: Angelier et al., 2016) while handling stress tended to depress plasma concentrations of prolactin (mourning doves: Miller et al., 2009). There were no effects of heat stress on plasma concentrations of prolactin (chicken: Elnagar et al., 2010). Similarly, acute restraint stress does not influence plasma concentrations of prolactin (Gambel's white-crowned sparrow: Krause et al., 2015).

30.7.6 Prolactin expression

Expression of PRL is under hypothalamic control. Photostimulation of young chickens is accompanied by increased PRL expression in the anterior pituitary gland (Li et al., 2009). Moreover, PRL expression is greatly increased during incubation (turkey: Wong et al., 1991). VIP increases PRL expression (turkey: Kang et al., 2004). Moreover, immunizing turkeys against VIP decreases pituitary PRL expression (El Halawani et al., 2000; Ahn et al., 2001). In addition, there is ultra-short loop feedback with PRL influencing PRL expression; administration of PRL increasing expression of PRL in the anterior pituitary gland in control together with either VIP or PCPA treated birds (chickens: Avital-Cohen et al., 2015). Expression of PRL in the anterior pituitary gland was depressed in old males following either PCPA or VIP treatment (chickens: Avital-Cohen et al., 2015).

30.7.7 Adenohypophyseal cells producing prolactin

Prolactin expression is limited to the cephalic lobe of the anterior pituitary gland (chicken: Lv et al., 2018) (Figure 30.1). Lactotropes are predominantly located in the ventral aspect of the cephalic lobe of the anterior pituitary gland (zebra finches: Christensen and Vleck, 2015).

30.8 Pro-opiomelanocortin-derived peptides—adrenocorticotropic hormone, lipotropic hormone, melanocyte-stimulating hormone, and β-endorphin

30.8.1 Pro-opiomelanocortin: gene, processing, and derived peptides

ACTH is synthesized as part of POMC (Table 30.1). The POMC gene is present on chromosome 3 (Rancourt et al., 2018). SNPs mutations in POMC gene are related to pelvis breadth, body weight, and chest depth (chickens: Bai et al., 2012).

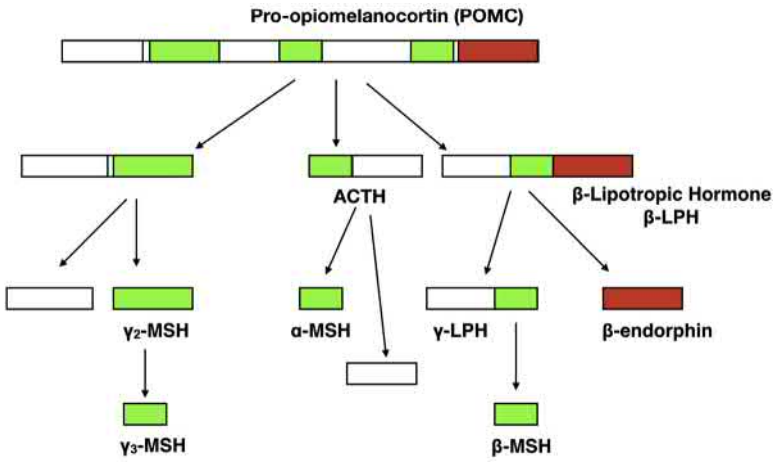

FIGURE 30.14 Post-translational changes (proteolytic cleavage) of pro-opiomelanocortin generating adrenocorticotropic hormone, melanocyte-stimulating hormone (MSH) (α-MSH, β-MSH, and γ_2 MSH) (green), β-lipotropic hormone, and β-endorphin (red).

POMC also contains the sequences of β-endorphin (β-EP), which in itself is part of β-lipotropin (β-LPH), together with α- and β-MSH. The cDNA for chicken POMC has been characterized (Takeuchi et al., 1999) (Figure 30.14). ACTH, β-EP, and β-LPH have been purified from several avian species (see Figure 30.2). Avian ACTH, like its mammalian homolog, is a simple polypeptide containing 39 amino acids (Li et al., 1978; Chang et al., 1980; Hayashi et al., 1991). Plasma concentrations of ACTH and MSH in birds are illustrated in Table 30.4.

30.8.2 Actions of adrenocorticotropic hormone

30.8.2.1 Control of adrenocorticotropic hormone release

Stress induces the release of ACTH from the anterior pituitary gland stimulated by CRH and AVT. ACTH subsequently elevates secretion of corticosterone.

There is evidence of endocannabinoid signaling in the stress response presumably acting at the hypothalamic level. Administration of the cannabinoid receptor (CB)1 antagonist, AM251, increased the increase in plasma concentrations of corticosterone in response to restraint stress (European starling: Dickens et al., 2015).

30.8.2.1.1 Corticotropin-releasing hormone

CRH stimulates ACTH secretion acting via CRH receptor type 1 (Table 30.2). Immunoreactive CRH is present in the hypothalamus, particularly the median eminence (chicken: Jozsa et al., 1984). CRH receptor type 1 is limited to the corticotropes (chicken: De Groef et al., 2003b).

The cDNAs for CRH precursors from multiple avian species have been sequenced. CRH precursor is proteolytically cleaved to generate CRH and this is identical across *Aves* including in chickens (Genbank AJ621492.3; Vandenborne et al., 2005a), ducks (XM_027452300.1), emu (XM_026115236), falcon (XM_005443202), Okarito brown kiwi (XM_026077064), rock pigeon (XM_005506466), Saker falcon (XM_005443202), willow flycatcher (XM_027894702) and zebra finch (NM_001245612) and mammals. The structure of avian CRH is the following:

SEEPPISLDLTFHLLREVLEMARAEQLAQQAHSN-RKLMEIIGK

Release of CRH is influenced by neurotransmitters/neuropeptides such as NPY. Intraventricular administration of NPY is accompanied by an increase in plasma concentrations of corticosterone (chicken: Kuenzel et al., 2016); this being presumably via increased CRH release. Similarly, central administration of ghrelin increases circulating concentrations of corticosterone in young chickens (Saito et al., 2005), presumably due to elevated CRH release.

30.8.2.1.1.1 *Other effects of corticotropin-releaseing hormone* CRH increases pituitary expression of cocaine- and amphetamine-regulated transcript (CART) 1 acting via CRHR1 (chicken: Mo et al., 2015). Moreover, administration of CRH to embryos on day 18 of incubation accelerates hatching (chicken: Watanabe et al., 2017).

30.8.2.1.2 Arginine vasotocin, mesotocin, and adrenocorticotropic hormone release

Both AVT and MT stimulate ACTH release (Castro et al., 1986) with AVT synergistically increasing CRH stimulated ACTH release (Mikhailova et al., 2007; Cornett et al., 2013). CRH and AVT are not co-localized in hypothalamic neurons (chicken: Nagarajan et al., 2014). There is evidence that the mechanism involves dimerization of the CRH-R1 and VT2R (Mikhailova et al., 2007; Cornett et al.,

2013). Acute stress reduces the number of AVT-immunoreactive neurons in specific areas within the hypothalamus (chicken: Nagarajan et al., 2014).

30.8.2.1.3 Calcium-related hormones and adrenocorticotropic hormone release

Calcium-related hormones influence ACTH release with parathyroid hormone—related peptide (PTHrP) per se increasing ACTH in vitro (chicken: Nakayama et al., 2011a) and calcitonin augmenting the effect of CRH on ACTH release in vitro (chicken: Nakayama et al., 2011b). It is not clear whether PTHrP acts via PTH1R or PTH3R (Pinheiro et al., 2012).

30.8.2.1.4 Feedback

Glucocorticoids inhibit the release of ACTH via effects at both the hypothalamic and pituitary levels. This has demonstrated in vivo (Herold et al., 1992) and in vitro (Carsia et al., 1986). Corticosterone also reduces expression of CRH in the hypothalamus (chicken: Vandenborne et al., 2005b). While corticosterone does not affect CRH-R expression in the anterior pituitary gland (chicken Vandenborne et al., 2005b), paradoxically pituitary expression of VT2R, presumably in corticotropes, is upregulated by corticosterone (Sharma et al., 2009b). Protein-deprived chicks that have elevated circulating concentrations of corticosterone also have reduced circulating concentrations of ACTH (Carsia et al., 1988), presumably due to increased glucocorticoid negative feedback.

30.8.3 Control of proopiomelanocortin expression

There are stress-related shifts in pituitary POMC expression. Anterior pituitary concentrations of POMC mRNA are paradoxically reduced 15 min after immobilization stress (chicken: Jayanthi et al., 2014). In contrast, pituitary concentrations of heteronuclear RNA are elevated by immobilization stress and in in vitro studies, by CRH, AVT, and CRH together with AVT (chicken: Jayanthi et al., 2014). Expression of POMC mRNA in the chicken anterior pituitary gland is decreased by either water deprivation (when there is elevated AVT release) or testosterone administration (Sharma and Chaturvedi, 2011). Moreover, the effect of CRH together with AVT is markedly attenuated in the presence of an antagonist of the avian vasotocin 4 receptor (chicken: Jayanthi et al., 2014). Prolonged water deprivation reduces pituitary expression of POMC (chickens: Sharma et al., 2009a). Corticosterone administration in vivo does not influence expression of POMC in the anterior pituitary gland, but corticosterone is effective in reducing anterior pituitary expression of POMC in vitro (chicken: Vandenborne et al., 2005b; Sharma et al., 2009).

Expression of POMC and PC1 lower in the pituitary of domesticated chickens than jungle fowl (Løtvedt et al., 2017). POMC expression greater in males (chickens: Rancourt et al., 2018).

30.8.4 Pituitary origin of adrenocorticotropic hormone

POMC is expressed and processed to ACTH in corticotropes. POMC is expressed and processed to ACTH in corticotropes; these being located in the cephalic lobe of the anterior pituitary gland (chicken: Gerets et al., 2000) (Figure 30.1). The chicken anterior pituitary gland has a high content of ACTH (1.6 μg) but low levels of α-MSH (10 ng) (Hayashi et al., 1991), with ACTH and α-MSH coexisting in the same cells (Iturriza et al., 1980; Hayashi et al., 1991). The number of chicken anterior pituitary cells that express POMC increases when cultured in the presence of CRH (Pals et al., 2006). VT2R is found in avian corticotropes (Jurkevich et al., 2005).

30.8.5 Extrapituitary production

POMC is expressed in multiple organs in addition to the anterior pituitary gland. Expression of POMC has been reported in the brain, kidneys, adrenal glands, adipose tissue, gonads, and uropygial gland (chicken: Takeuchi et al., 1999). There are perikarya in the infundibular nucleus and median eminence together with fibers in the preoptic area and in the medial basal hypothalamus that contain POMC (Gerets et al., 2000). In addition, immunoreactive POMC products are present in immune tissues such as both the thymus and bursa Fabricius (Franchini et al., 1999). POMC and prohormone convertase 1 and 2 (PC1 and PC2) are expressed in feather follicles (Yoshihara et al., 2011).

The MCR is expressed in multiple tissues. There is expression of MC2-R in the spleen (Takeuchi et al., 1998). There is expression of both MC4-R and MC5-R in the brain, adrenal glands, gonads, and adipose tissues of the chicken, with expression of MC4-R also in the spleen and that of MC5-R also in the kidneys and the uropygial gland (Takeuchi and Takahashi, 1998b). The roles of these POMC products are not well established. Feather follicles also express MC1-R, which binds α-MSH or ACTH and thereby changes feather coloration (Yoshihara et al., 2011).

30.8.6 Ontogeny of adrenocorticotropic hormone

Corticotropes are first observed on day seven in embryonic development (chicken: Jozsa et al., 1979). Plasma concentrations of ACTH and corticosterone increase between embryonic days 11 and 17 (Jenkins et al., 2007). The rising circulating concentrations of corticosterone during

embryonic development subsequently induce increase in somatotropes in the anterior pituitary gland (chickens: Jenkins et al., 2007; domestic goose: Yu et al., 2018).

30.8.7 Melanocyte-stimulating hormone and lipotropic hormone

Information on MSH and LPH in birds is limited. It is assumed that the MSH is of little importance due to the absence of a pars intermedia (Rahn, 1939; Rahn and Painter, 1941). However, release of pro-γ-MSH and LPH from the anterior pituitary gland has been reported (ostrich: Naudé et al., 2006). Early work demonstrated the presence of biologically active MSH in the anterior pituitary gland (chicken: Rahn and Drager, 1941). There were also increasing pituitary concentrations during embryonic development following by plateau concentrations but elevated contents in postnatal growth (chicken: Rahn and Drager, 1941). Moreover, there are relatively high concentrations of α-MSH in the circulation (Table 30.4) (chicken: Shipp et al., 2017) and anterior pituitary gland (duck: Estivariz et al., 1980). Avian corticotropes, or at least a major subset of these, contain both α-MSH and ACTH (duck: Estivariz et al., 1980b).

The physiological roles for either MSH or LPH in birds are not well-established. Although there is evidence that α-MSH has biological activity exerting marked lipolytic activity in birds (chickens: Shipp et al., 2017).

30.8.8 β-Endorphin

30.8.8.1 Chemistry of β-endorphin

POMC and a β-EP domain are found in all birds examined (reviewed: Scanes and Pierzchala-Koziec, 2018). β-EP is a peptide with 31 amino acid residues with an N terminal met-enkephalin YGGFM motif (reviewed: Scanes and Pierzchala-Koziec, 2018). There are few amino acid substitutions in the structure of β-EP across the class *Aves* except in the Passeriforms (reviewed: Scanes and Pierzchala-Koziec, 2018).

30.8.8.2 Physiology of β-endorphin release

There is limited information of the physiology of β-EP in birds. β-EP is released from the anterior pituitary gland along with ACTH, LPH, and pro-γ-MSH (ostrich: Naudé et al., 2006). Circulating concentrations of β-EP are similar to than those of ACTH (domestic geese: Barna et al., 1998a). The reason for plasma concentration of β-EP being higher than that of ACTH may reflect slower clearance of β-EP. Plasma concentrations of both ACTH and β-EP are increased following ether stress (domestic geese: Barna et al., 1998b). There is some evidence for differential release of ACTH and β-EP with either castration or endotoxin challenge increasing plasma concentrations of ACTH but not those of β-EP (domestic geese: Barna et al., 1998a; b).

30.8.8.3 Physiological role of β-endorphin

β-endorphin acts via binding to mu (μ) opioid peptide receptor. It is presumed that β-EP acts to reduce pain.

30.8.9 Extrapituitary production of proopiomelanocortin peptides

POMC is expressed by multiple tissues in birds. For instance, POMC is expressed in feather follicles (chicken: Yoshihara et al., 2011), in the hypothalamus with the POMC gene subjected to methylation (Rancourt et al., 2018), in the adrenal gland with expression increased 15 min after stressing (chicken and jungle fowl: Fallah-sharoudim et al., 2015). In addition, immunoreactive POMC peptides are observed in the thymus and bursa of Fabricius (Franchini and Ottaviani, 1999).

30.9 Other anterior pituitary gland peptides/proteins

In addition to the "classical" hormones of the anterior pituitary gland, other hormones or hormone-like proteins are expressed. Examples of these are discussed below in alphabetical order:

30.9.1 Adiponectin

Adiponectin is a 30 KDa adipose hormone and considered a member of the adipokine family of hormones. In birds and mammals, adiponectin is glycosylated and circulates in multiple forms: light, medium, and heavy (>670 kDa) (Hendricks et al., 2009). The anterior pituitary expresses the adipose hormone, adiponectin (chicken: Maddineni et al., 2005) together with its receptor (ApipoR1 and ApipoR2) (chicken: Ramachandran et al., 2007). Pituitary expression of adiponectin and its receptors are influenced by the physiological and energy status of the bird. Expression of adiponectin is increased while that ApipoR1 and ApipoR2 are decreased by 48 h of feed withdrawal (chicken: Maddineni et al., 2005; Ramachandran et al., 2007).

30.9.2 Chromogranin A

Chromogranin A is an acidic peptide that can be secreted along with protein hormones. The structure of the chromogranin A precursor protein has been deduced from the cDNA from numerous birds including the burrowing owl (*Athene cunicularia*) (XM_026849996.1), chicken (*Gallus*

gallus) (XM_025153471), emu (*Dromaius novaehollandiae*) (XM_026111552), rock pigeon (*Columba livia*) (XM_021292417), Saker falcon (*Falco cherrug*) (XM_005438875.2), and Tibetan ground-tit (*Pseudopodoces humilis*) (XM_014249753.1).

While the function of chromogranin A is not fully established, there is some information on its cellular distribution and change with physiological state. Chromogranin A immunoreactivity is found in LH containing gonadotropes from young chickens and somatotropin from adults but not in lactotropes (chickens and turkeys: Proudman et al., 2003). While this is correlated with low hormone secretion, contrary to this, pituitary chromogranin-A protein concentrations are increased as the birds come into egg production (domestic goose: Luan et al., 2014).

30.9.3 Cocaine- and amphetamine-regulated transcript peptides

Two CART genes have been identified in birds, respectively, CART1 and CART2 (chicken: Cai et al., 2015). CART1 encodes a 111 amino acid containing precursor protein. This can be proteolytically cleaved to form biologically active peptides, CART1(42−89) and CART1(49−89); these having high homology to mammalian CART peptides (Cai et al., 2015). Expression of CART1 is greatest in the anterior pituitary gland (both cephalic and caudal lobes) but with some observed in brain regions, particularly the hypothalamus (chicken: Cai et al., 2015; Mo et al., 2015). CART2 is also expressed in the anterior pituitary gland (Cai et al., 2015). Pituitary expression of CART1 is depressed by fasting (chicken: Cai et al., 2015) and elevated by CRH (via CRHR1) (chicken: Mo et al., 2015).

30.9.4 Synaptotagmin-1

Synaptotagmin-1 is a transmembrane protein. There are large increases in pituitary expression of the transmembrane protein, synaptotagmin-1, during early egg laying and further increases at peak egg laying (domestic goose: Luan et al., 2014).

30.9.5 Interleukins

There is pituitary expression of the proinflammatory cytokine, interleukin 1-beta (IL-1β), and the anti-inflammatory cytokine, IL-10 (Japanese quail: Walker et al., 2019).

30.10 Pars tuberalis

The pars tuberalis has the same embryonic origin as the anterior pituitary gland, namely the adenohypophysis. It is not surprising that pars tuberalis contain the same repertoire of hormones as the anterior pituitary gland. Immunocytochemical studies indicate the presence of LH containing cells in the pars tuberalis (chicken: Kameda et al., 1998) and Indian birds, namely the Coraciiform kingfisher (*Halcyon smyrnensis*) together with the Passeriform munia (*Lonchura striata*) and drongo (*Dicrurus adsimilis*) (Mohanty et al., 1997). Moreover, pars tuberalis cells from Indian birds exhibit reactivity with antisera to GH, PRL, POMC, and TSH (Mohanty et al., 1997).

30.10.1 Functioning of the pars tuberalis

An exciting area of pituitary research is the role of the pars tuberalis in circadian functioning and photoperiodism.

30.10.1.1 Pars tuberalis and photoperiodism

There is now abundant evidence that the pars tuberalis plays an important role in avian circadian rhythmicity and photoperiodism. In the Japanese quail, photoperiodic stimulation for 14 h increases expression of the TSH β-subunit in the pars tuberalis (Nakao et al., 2008). TSH is thought to act in a retrograde manner on ependymal cells in the hypothalamus triggering a cascade including up-regulation of type II iodothyronine deiodinase and local accumulation of T_3 and thereby inducing seasonal breeding (Yoshimura et al., 2003; Nakao et al., 2008; reviewed, e.g., Korf, 2018). Organic anion transporting polypeptides (Oatp) are expressed in the ventrolateral walls of basal tuberal hypothalamus (Nakao et al., 2006) with these Oatp transporting thyroid hormones into target cells.

30.10.2 Pineal effects on the pars tuberalis

Communication with the pineal gland and the pars tuberalis is supported by the presence of melatonin-binding sites (Japanese quail: Cozzi et al., 1993) and melatonin receptor (Mel(1c)) expression in the pars tuberalis (Kameda et al., 2002). Moreover, pars tuberalis expression of the common LH−FSH−TSH glycoprotein α-subunit is increased following pinealectomy (chicken: Kameda et al., 2002). Moreover, the diurnal changes in the expression of the pituitary glycoprotein hormone α-subunit in the pars tuberalis are controlled by pineal melatonin (chicken: Arai and Kameda, 2004).

30.10.3 Circadian rhythms and the pars tuberalis

There are diurnal changes in the expression of glycoprotein α-subunits in the pars tuberalis (chicken: Arai and Kameda, 2004). There are endogenous circadian rhythms within the pars tuberalis. Circadian genes Cry1 and BMAL1 are expressed in the pars tuberalis of the Japanese quail (Yasuo et al., 2004; Ikegami et al., 2009). BMAL1 is also

expressed in the pars distalis as well as the median eminence, infundibular nucleus, and medial suprachiasmatic nucleus (Japanese quail: Ikegami et al., 2009). There is communication between the pars tuberalis and both photoreceptors in other tissues. Neurons containing the photoreceptive protein opsin-5 extend to the outer region of the median eminence adjacent to the pars tuberalis (Halford et al., 2009; Nakane et al., 2010). Fibers from opsin 5-containing neurons extend to areas of the median eminence immediately adjacent to the pars tuberalis (chicken: Nakane et al., 2010). Expression of the pituitary glycoprotein hormone α-subunit in the pars tuberalis is decreased by continuous light regimens and increased by extended darkness irrespective of whether the birds are intact or pinealectomized (Kameda et al., 2002).

30.11 Neurohypophysis

30.11.1 Introduction

The anatomy of the hypothalamic neurosecretory tracts (neurons) leading to their secretory terminals in the pars nervosa is shown in Figure 30.1. The two hormones of the neurohypophysis are AVT and MT (Table 30.1) equivalent to, respectively, arginine vasopressin and oxytocin in mammals. There are two genes. The first is the avian OXT encoding preprooxyphysin, the proteolytic products being MT and neurophysin-1. The second is the avian AVP gene encoding the precursor protein for AVT and neurophysin-2. Both genes are located on chromosome 4 in chickens. MT and AVT are synthesized with their binding protein as, respectively, neurophysin-1 and neurophysin-2. The structure of prepro-MT—neurophysin-1 (VLDV-neurophysin) has been deduced in from cDNA (Figure 30.15) in multiple birds [chicken (XM_025,150,346.1), common cuckoo (XM_009566863.1), domestic goose (XM_013182245.1), emperor penguin (XM_009290727.1), golden eagle (XM_011588837.1), hooded crow (XM_010402115.2), kea (XM_010009290.1), little egret (XM_009639558.1), Okarito brown kiwi (XM_026072773.1), turkey (XM_010710575.2), white-throated sparrow (XM_005494991.3)]. The structure of prepro-AVT—neurophysin-2 (MSEL-neurophysin) has similarly been deduced in chickens (NM_205185.2) and golden eagle (XM_011588908.1).

AVT and MT are produced by and secreted from predominantly separate neurosecretory neurons. The cell bodies of the AVT and MT neurons are located in both separate and overlapping areas within the hypothalamus (mallard and Japanese quail: Goosens et al., 1977; Bons, 1980; Tennyson et al., 1985). The AVT- and MT-containing cell bodies and axons develop in the chicken embryo between days 6 and 17 (Tennyson et al., 1986).

The hormones of the avian neurohypophysis, AVT and MT, are shown in Figure 30.15. AVT differs from arginine

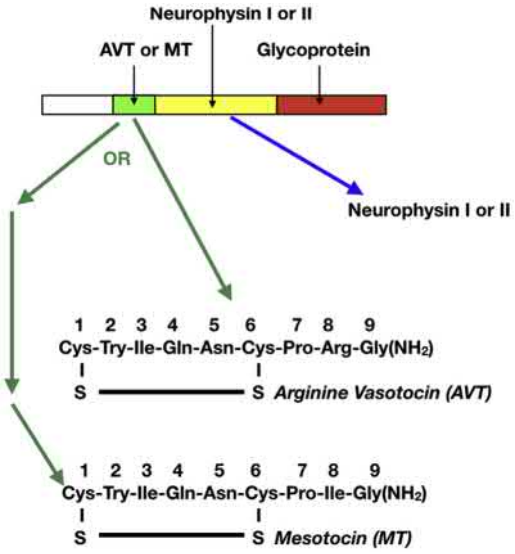

FIGURE 30.15 Synthesis of the Avian Neurohypophyseal Hormones [Mesotocin (MT) and arginine vasotocin (AVT)] with the precursor containing MT or AVT together with either neurophysin I or II. The precursors are subjected to proteolytic cleavage to generate MT or AVT. The structures of the avian nonapeptides (AVT and MT) are shown.

vasopressin, the mammalian antidiuretic hormone, by a single amino acid residue substitution (isoleucine at position three for phenylalanine). MT differs from the mammalian homolog, oxytocin, by the substitution of isoleucine for leucine (position 8). Based on the cDNA structure, MT is replaced by 8-lysine oxytocin in Anna's hummingbird (XM_008491101.1). The posterior pituitary gland contains high levels of AVT and MT (chicken: 4.0 μg AVT and 0.9 μg MT) (Robinzon et al., 1988a). Low concentrations of these neuropeptides are also found throughout the brain (Robinzon et al., 1988a) and in the ovary (Saito et al., 1990). It is presumed that the major source of circulating concentrations of AVT and MT is the posterior pituitary gland, although there is significant ovarian production (Saito et al., 1990).

The anatomy of the hypothalamic neurosecretory tracts (neurons) leading to their secretory terminals in the pars nervosa is shown in Figure 30.1. The two posterior pituitary gland hormones are the following:

- AVT
- MT

(Table 30.2). AVT is equivalent to vasopressin in mammals, and MT is the homolog of mammalian oxytocin. Plasma concentrations of AVT and MT are illustrated in Table 30.4.

30.11.2 Receptors for arginine vasotocin and mesotocin

Avian vasotocin receptors are proteins with seven transmembrane domains and members of the large rhodopsin-

TABLE 30.9 Arginine vasotocin and mesotocin receptors in birds.

Avian receptor	Mammalian homolog[a]	Location	Role	Relative activity	References
VT1R	V2R	Shell gland + brain	Induction of oviposition	AVT > MT	Tan et al. (2000)
VT2R	V1bR	Anterior pituitary gland	Control of ACTH release	AVT > MT	Cornett et al. (2003)
VT3R	OTR	Shell gland	Induction of oviposition	MT > AVT	Gubrij et al. (2005)

OTR, Oxytocin receptor; *VR*, Vasopressin receptor; *VTR*, Vasotocin receptor.
[a]*Equivalent to mammalian AVP/OT receptor.*
Based review by Cornett, L.E., Kang, S.W., Kuenzel, W.J., 2013. A possible mechanism contributing to the synergistic action of vasotocin (VT) and corticotropin-releasing hormone (CRH) receptors on corticosterone release in birds. Gen. Comp. Endocrinol. 188, 46–53.

like family of G-protein-coupled receptors. There are at least four avian vasotocin receptors (Table 30.9). Some years ago, Goldstein (2006) concluded that the "*receptors for AVT in avian kidney-either on renal vasculature or on the tubules-have yet to be localized or identified.*" There is still need to clarify the renal AVT receptor in birds.

There are physiological effects on the expression of VT receptors. For instance, prolonged water deprivation reduces pituitary expression of VT2R but increased immunereactive VT2R (chickens: Sharma et al., 2009b). Moreover, glucocorticoid administration increases VT2R expression and immunoreactive concentration in the anterior pituitary gland (Sharma et al., 2009b). Acute immobilization stress is followed by shifts in VTR expression in the anterior pituitary gland with expression of VT4R decreased and that of VT4R decreased (Selvam et al., 2013).

VT4R immune-reactivity is found in corticotropes but not other adenohypophyseal cell types (Selvam et al., 2013). In contrast, VT2R immune-reactivity is found in corticotropes together with some lactotropes (Jurkevich et al., 2008).

30.11.3 Actions of arginine vasotocin

The major roles of AVTH are in renal and cardiovascular functioning together with reproduction.

30.11.3.1 Arginine vasotocin and renal functioning

AVT is the major antidiuretic hormone in birds decreasing the following:

1. Urine flow
2. Glomerular filtration rate (GFR)

(reviewed: Goldstein, 2006). Urine volume is largely increased after surgical removal of the posterior pituitary gland and, therefore, in the absence of AVT (chicken: Shirley and Nalbandov, 1956). In intact birds, AVT reduces urine flow (Figure 30.16) (chicken: Brummermann and Braun, 1995; Takahashi et al., 1995; house sparrow: Goecke and Goldstein, 1997). The effect on urine flow is mediated via V2R (house sparrow: Goecke and Goldstein, 1997). In addition, AVT depressed GFR via a VT1R mechanism (house sparrow: Goecke and Goldstein, 1997).

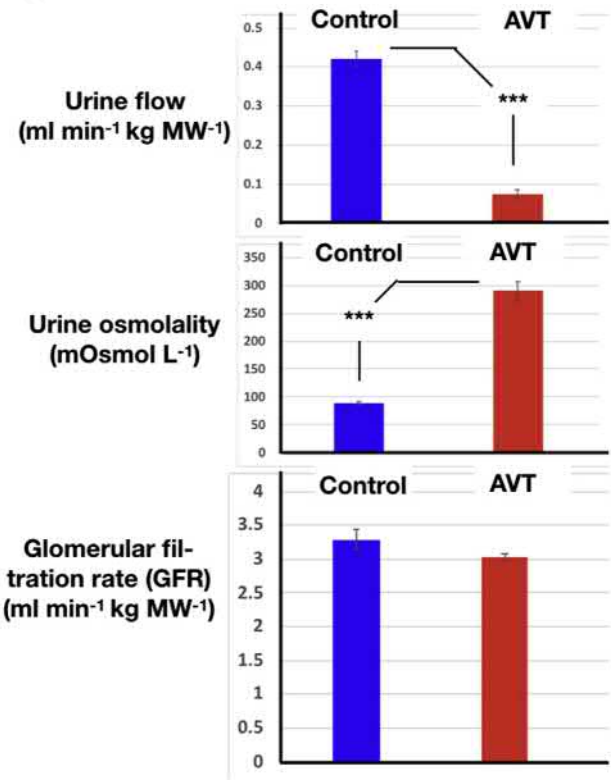

FIGURE 30.16 Effect of arginine vasotocin on urine flow with a concomitant increase in urine osmolality but no change in glomerular filtration rate in adult male chickens. *Data from Brummermann, M., Braun, E.J., 1995. Renal response of roosters with diabetes insipidus to infusions of arginine vasotocin. Am. J. Physiol. 269, R57–R63.*

There is evidence of the importance of AVT and its receptors from lines of birds with different genetic mutations. In control chickens, AVT infusion decreases urine flow (Brummermann and Braun, 1995). In birds with hereditary diabetes insipidus, AVT was without effect on urine flow but increased GFR (Brummermann and Braun, 1995). In addition, chickens with diabetes insipidus had elevated plasma concentrations of AVT (Brummermann and Braun, 1995). These observations are consistent with there being a lesion at or downstream from, the AVT receptor level. Moreover, there were no impacts on plasma concentrations of AVT in a line of Japanese quail with polyuria (increased urine volume) (Minvielle et al., 2007). This was despite the reduced renal aquaporin 2 (AQP2) expression (Japanese quail: Yang et al., 2008).

AVT influences adenylyl cyclase in regions of avian medullary nephrons:

- Thin descending limb—no effect
- Thick ascending limb—stimulated
- Collecting duct—markedly stimulated

(house sparrow: Goldstein et al., 1999). There is evidence that AVT acts by increasing expression of AQP2 and AQP3 and, hence, movement of water in the collecting ducts of both looped and loop-less nephrons (Japanese quail: Yang et al., 2004; Lau et al., 2009; reviewed: Nishimura and Yang, 2013) and, thereby, increasing water reabsorption and reducing urine volume.

30.11.3.2 Arginine vasotocin and oviposition

AVT causes oviposition, the physical process of laying eggs or expelling the egg from the vagina of the oviduct. The hen uterus contracts in response to AVT but not MT alone (chicken: Koike et al., 1988). However, the effect of AVT is potentiated by MT (Figure 30.17) (Takahashi and Kawashima, 2008a). The mechanism by which AVT provokes premature oviposition is not fully established but may involve AVT stimulating local production of prostaglandins (probably E_1) by the uterus and this in turn induces uterine contractions (chicken: Rzasa, 1978; 1984). Circulating concentrations of both AVT and MT increase at the time of oviposition (Figure 30.17) (Takahashi and Kawashima, 2008a). Both VT1R and VT3R are expressed in both the endometrium and myometrium of the shell gland (chicken: Seth et al., 2004a; Gudrij et al., 2005).

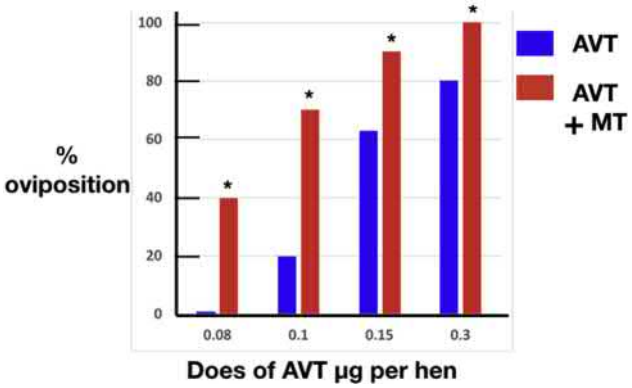

FIGURE 30.17 Arginine vasotocin and mesotocin and oviposition. (A) Ability of MT to potentiate AVT induction of oviposition in female chickens. The ability of AVT to induce oviposition in female chickens. *Data from Takahashi, T., Kawashima, M., 2008a. Mesotocin increases the sensitivity of the hen oviduct uterus to arginine vasotocin. Poult. Sci. 87, 2107–2111.*

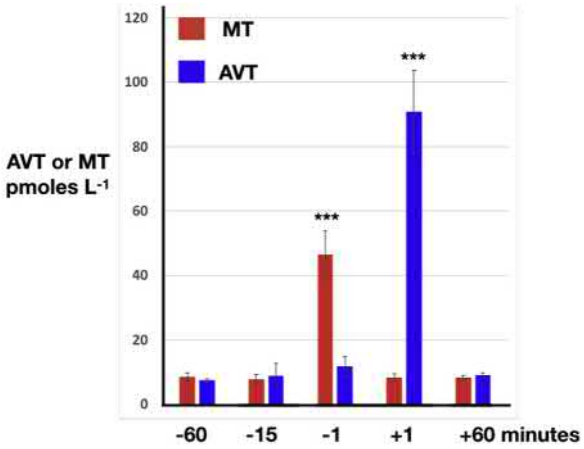

FIGURE 30.17B Plasma concentrations of mesotocin and arginine vasotocin around the time of oviposition in hens. *Data from Takahashi, T., Kawashima, M., 2008a. Mesotocin increases the sensitivity of the hen oviduct uterus to arginine vasotocin. Poult. Sci. 87, 2107–2111.*

30.11.3.3 Cardiovascular effects of arginine vasotocin

AVT can have both vasodressor and vasopressor activity in birds. Bolus injections of AVT to conscious adult chickens or either adult or young domestic ducks results in a marked drop in mean arterial pressure (Wilson and West, 1986; Robinzon et al., 1988b). In contrast, infusion of AVT can increase arterial blood pressure in conscious chickens (Robinzon et al., 1993). In an analogous manner, bolus injection of AVT elevates hear rate while infusion of AVT depresses heart frequency (Wilson and West, 1986; Robinzon et al., 1988b, 1993).

30.11.3.4 Other effects of arginine vasotocin

Infusion of AVT is followed by decreased temperature of the comb and shank but did not influence either cloacal or skin temperatures (chickens: Robinzon et al., 1988a). Infusion of AVT increased the circulating concentrations of prolactin but decreased those of aldosterone (chickens: Robinzon et al., 1988a).

30.11.4 Actions of mesotocin

30.11.4.1 Mesotocin and renal functioning

MT at low concentrations reduced urine volume but increased urine volume at high concentrations (chickens Takahashi et al., 1995). There is specific binding of MT to membrane fractions from the medulla and cortex of the kidney with binding displaced by MT but not AVT in the medulla but by both MT and AVT in the cortex (chicken: Takahashi et al., 1997).

30.11.4.2 Mesotocin and oviposition

The ability of AVT to induce oviposition is potentiated by MT (Figure 30.17A and B) (Takahashi and Kawashima, 2008a). Moreover, there is specific binding of MT (i.e., not inhibited by AVT) to uterine membranes (chickens: Takahashi and Kawashima, 2008b). There is decreased binding of MT to uterine membranes is decreased after oviposition (chickens: Takahashi and Kawashima, 2008b).

30.11.4.3 Other effects of mesotocin

Infusion of MT is followed by decreased temperature of the comb and shank but did not influence either cloacal or skin temperatures (chickens: Robinzon et al., 1988). Infusion of MT also decreased the circulating concentrations of AVT and aldosterone (chickens: Robinzon et al., 1988). There was a transient increased in respiratory rate with infusion of MT (chickens: Robinzon et al., 1988a).

30.11.5 Neurohypophyseal hormones and behavior

There is growing evidence that MT influences avian behavior in both wild Passeriform birds and in poultry species. For instance, subcutaneous administration of an oxytocin receptor antagonist reduced the time that female zebra finch (*Taeniopygia guttata*) spent with conspecifics (Goodson et al., 2009). Similarly, knock-down of MT synthesis in the paraventricular nucleus reduces gregariousness in female zebra finch (Kelly and Goodson, 2014). In addition, s.c. administration of an oxytocin receptor antagonist reduced time on the nest in female zebra finch (Klatt and Goodson, 2013a). Moreover, intraventricular administration of oxytocin receptor antagonist to socially monogamous zebra finch was followed by reduced duration of pairing in females (Klatt and Goodson, 2013b). Furthermore, intramuscular administration of an oxytocin receptor antagonist was associated with increased latency to pair bonding together with reduced pair bonding in zebra finch (Pedersen and Tomaszycki, 2012). Another effect of administration (sc) of oxytocin antagonist was reduced aggression in both male and female violet-eared waxbills (*Uraeginthus granatinus*) (Goodson et al., 2015). These reports are consistent with MT released from the posterior pituitary gland and/or locally produced MT within the CNS influencing behaviors.

In poultry species, there is evidence for behavioral effects of MT. In chicken and pigeon, AVT increases sexual behavior (Kihlstrom and Danninge, 1972). When turkey hens incubating eggs are exposed to young poults, there is induction of c-fos expression in MT-containing neurons in the nucleus paraventriculus magnocelluaris (PVN) and nucleus supraopticus paraventralis (SOv) (Thayananuphat et al., 2011). Moreover, intraventricular administration of OT receptor antagonist reduced brooding behavior when turkey hens were exposed to poults (Thayananuphat et al., 2011). Further evidence that MT is involved in female behaviors comes from the changes in the number of MT-neurons in the hypothalamus [specifically the nuclei supraopticus, pars ventralis (SOv), preopticus medialis (POM), and paraventricular (PVN)] with reproductive state:

- Nonlaying hens—low
- Laying hens—high
- Incubating hens—high
- Rearing chicks—very high
- Not-rearing chicks—low
- Incubation disrupted—low

(native chickens: Chokchaloemwong et al., 2013; Sinpru et al., 2017).

30.11.6 Control of arginine vasotocin and mesotocin release

The release of AVT and MT from the posterior pituitary gland is under independent control. For instance, heat stress increases plasma concentrations of AVT but depresses those of MT (Wang et al., 1989). Similarly, plasma concentrations of AVT were increased gradually following anesthesia and/or carotid cannulation while those of MT declined (Bottje et al., 1990). Furthermore, there are changes in the circulating concentrations of AVT and MT during the day/night in hens with peak concentrations of AVT but nadir concentrations of MT at the beginning of the scotophase (chickens: Chaturvedi et al., 2001). The diurnal shifts in neither AVT nor MT were observed in water-deprived hens (chickens: Chaturvedi et al., 2001).

30.11.6.1 Control of arginine vasotocin release

Table 30.10 summarizes the effects of physiological factors that influence circulating concentrations of AVT. Physiological factors influencing AVT release can be categorized as osmotic related, other stressors, and reproduction. Angiotensin II administration increases plasma concentrations of AVT (chicken: Takahashi et al., 2011). Plasma concentrations of AVT are increased following flight (pigeons: Giladi et al., 1997).

TABLE 30.10 Factors influencing circulating concentrations of aginine vasotocin in birds.

Physiological factor	Chicken	Other birds
Osmotic factors		
Withholding water (water deprivation)	↑↑	↑↑ (domestic ducks, house sparrow, Japanese quail)
Hemorrhage	↑↑	↑↑ (domestic ducks)
Sodium chloride loading	↑↑	↑↑ (domestic ducks)
Feeding high concentrations of sucrose	NA	↑↑ (white-bellied sunbirds)
Angiotensin II	↑↑	NA
Calcitonin	↑↑	NA
Other stresses/factors		
Anesthesia	↓	NA
Heat stress	↑↑	NA
Lipopolysaccharide (LPS)	NA	↑↑ (domestic ducks)

NA, *Information not available.*
Table is based on Scanes, C.G., 2015. Pituitary gland. In: Scanes, C.G. (ed.), Sturkie's Avian Physiology. sixth ed., Amsterdam: Elsevier. pp. 497–553 supplemented with reports discussed in the text.

30.11.6.2 Osmotic-related arginine vasotocin release

AVT is released when blood osmolality is high (see Table 30.10) in order to reduce water loss. Water deprivation is followed by large increases in plasma concentrations of AVT together with elevated hypothalamic AVT expression and number of AVT neurons (Japanese quail: Seth et al., 2004b; Minvielle et al., 2007). Similarly, plasma concentrations of AVT are increased with feeding elevated concentrations of sucrose to nectarivorous white-bellied sunbirds (*Nectarinia talatala*) (Gray et al., 2004).

30.11.6.3 Other effects on arginine vasotocin

Plasma concentrations of AVT are increased following the administration of lipopolysaccharide (domestic ducks: Gray and Maloney, 1998). There is no effect of estradiol or testosterone on plasma concentrations of AVT despite either increasing numbers of AVT neurons (Japanese quail: Seth et al., 2004b). (Japanese quail: Seth et al., 2004b). Calcitonin administration increased the plasma concentration of AVT in hens (Nakayama et al., 2010).

30.11.6.4 Arginine vasotocin and mesotocin and oviposition

AVT stimulates oviposition. Administration of AVT induced premature oviposition by induction of the contractions of the smooth muscles of the vagina but also the nervous reflex of bearing down (Takahashi and Kawashima, 2003).

30.11.7 Arginine vasotocin and mesotocin expression

MT is expressed in cell bodies in the paraventricular nucleus, specifically the parvocellular, magnocellular, and periventricular subgroups (chicken: Barth et al., 1997). Some cell bodies express both MT and AVT (Barth et al., 1997). AVT is expressed in cell bodies in the supraoptic nucleus and specifically the ventral and external subgroups (chicken: Barth et al., 1997). Expression of the AVT gene is increased both at the time of oviposition (Japanese quail: Seth et al., 2004a; chicken: Seth et al., 2004b) and with water deprivation (Japanese quail: Seth et al., 2004a; Minvielle et al., 2007). Water deprivation increases the number of neurons containing AVT immunoreactivity (Japanese quail: Seth et al., 2004a). Water restriction did not influence renal expression of AVT (Orlowski et al., 2017). There is increased expression of AVT following administration of either estradiol or testosterone (Japanese quail: Seth et al., 2004b).

30.11.8 Hormonal influences on the posterior pituitary gland

There is specific binding of a series of hormones to a membrane fraction from chicken posterior pituitary glands, and there is variation in binding with physiological state. For instance, not only is there is binding of estradiol to membrane fraction from the posterior pituitary gland but

also binding is lower in laying hens than pullets (Takahashi and Kawashima, 2009a). Moreover, binding changes during the ovulation/oviposition cycle with reduced binding between 3 h before oviposition and the time of oviposition (Takahashi and Kawashima, 2009). Moreover, there is binding of the angiotensin II (Takahashi et al., 2011), calcitonin (Nakayama et al., 2011c), and prostaglandin $F_{2\alpha}$ (Takahashi and Kawashima, 2009b). Administration of estradiol is followed by decreased binding of angiotensin II (Takahashi et al., 2011), calcitonin (Nakayama et al., 2011), estradiol (Takahashi and Kawashima, 2009a), and prostaglandin $F_{2\alpha}$ (Takahashi and Kawashima, 2009b). Interestingly, there is a marked decline in binding of both calcitonin and angiotensin II to neurohypophyseal cell membranes at the time of oviposition (Nakayama et al., 2010; Takahashi et al., 2011). In addition, binding of angiotensin II was depressed after administration of either angiotensin II (Takahashi et al., 2011). The physiological relevance of hormone binding to neurohypophyseal cell membranes is unclear.

30.11.9 Infundibular peptides

A unique neurosecretory peptide, neurosecretory protein GL (NSGL), was identified in the chicken infundibulum (Ukena et al., 2014). Growth was enhanced with intracerebroventricular infusion of NSGL (chicken: Shikano et al., 2018a). The NSGL did not influence expression of GH, PRL, POMC, or TSH beta subunit when administered peripherally (Shikano et al., 2018b).

Chapter 31

Thyroid gland

Veerle M. Darras
Department of Biology, KU Leuven, Leuven, Belgium

31.1 Introduction

Thyroid hormones (THs) are iodinated peptides produced and stored in the thyroid gland. Upon secretion, they are transported by the blood stream and taken up by cells throughout the body. THs are essential for the correct development of all tissues in the avian embryo. During posthatch life, they remain important for further development and growth, they control metabolism, and they are needed for reproduction. Many of these functions involve interactions with other hormones either in a permissive or a synergistic way.

31.2 Thyroid gland structure and development

31.2.1 Structure of the mature thyroid gland

The avian thyroid gland is a paired organ, well-vascularized, and located ventrally alongside the trachea. Each oval lobe is connected to the common carotid artery on the medial side and the jugular vein on the lateral side (Fig. 31.1A). The histology and ultrastructure of the avian thyroid gland is like that of other vertebrate classes. It consists of follicles of epithelial cells, thyrocytes that surround a colloid-filled lumen (French and Hodges, 1977; Merryman and Buckles, 1998) (Fig. 31.1B and C). The colloid contains thyroglobulin, the TH-containing protein, which provides for large extracellular stores of hormone. Such extracellular hormone storage is unique to the thyroid and is considered an adaptation to the scarcity of the trace element iodine, a key component of THs [for a review see (McNabb, 1992)]. Calcitonin cells, which are parafollicular in mammals, are lacking in the avian thyroid; they are contained in separate ultimobranchial organs (see Chapter 32).

31.2.2 Thyroid gland development

The thyroid gland arises from the ventral pharyngeal wall and appears very early in development (e.g., day two of the 21 day incubation in chicken embryos). This mass of epithelial cells is initially attached to the pharynx, but then detaches, and the thyroid lobes assume their mature positions (by day five). In precocial birds such as chicken and quail, follicle formation is initiated early and proceeds rapidly, along with functional maturation of the gland during the first half of embryonic life and establishment of hypothalamic-pituitary control in the latter half of embryonic life (McNabb, 1987; Thommes, 1987). In altricial birds such as ring doves, although some follicles appear early, most histological and functional development occurs after hatch (McNabb, 1987). Significant advances have been made in understanding both the intrinsic and extrinsic signals involved in the early steps of thyroid gland development, showing a common pattern throughout vertebrate evolution (De Felice and Di Lauro, 2011; Fernandez et al., 2015; Haerlingen et al., 2019).

31.3 Thyroid hormone synthesis and release

31.3.1 Thyroid hormone synthesis

31.3.1.1 Iodide uptake and transport

TH synthesis and release has been studied in most detail in mammals, but the mechanisms were found to be similar in other vertebrates including birds [review (McNabb, 1992; Rousset et al., 2000; Citterio et al., 2019) (Fig. 31.2)]. Essential for TH synthesis is the availability of iodine, a trace element present predominantly as iodide in food and water. Iodide is taken up from the blood at the level of the basolateral membrane of the thyrocytes by a sodium-dependent iodide (Na-I) symporter (NIS). Another transporter, pendrin, is responsible for transport of iodide into the colloid through the apical membrane [review on mammalian iodide transport (Bizhanova and Kopp, 2009)]. The avian thyroid gland contains very high iodide concentrations and has prolonged iodide retention. Although avian thyroidal iodide can be influenced by extremes of iodide availability, studies in quail showed

(B) Hematoxylin and eosin staining of a section through a thyroid lobe of a week-old duckling containing follicles of various sizes, and (C) magnification of a few follicles showing cuboidal thyrocytes surrounding a colloid-filled lumen. Scale bar = 100 μm.

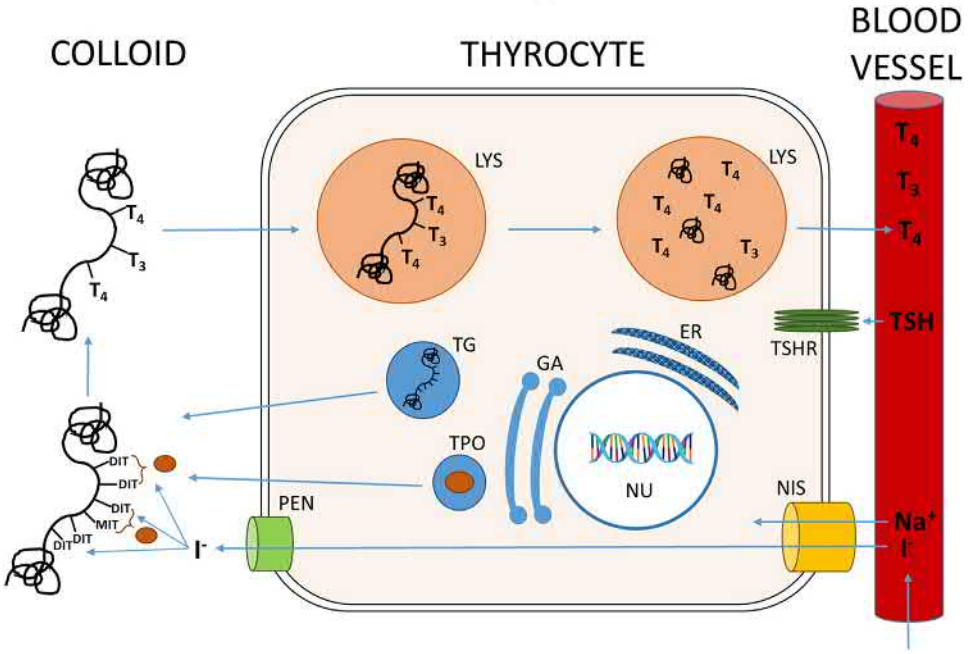

FIGURE 31.2 **Thyroid hormone synthesis.** Iodide is taken up from the blood at the level of the basolateral membrane by the sodium-dependent iodide symporter. Another transporter, pendrin, is responsible for transport of iodide into the colloid through the apical membrane. Thyroglobulin, the hormone storage protein, and thyroid peroxidase, the enzyme catalyzing hormone synthesis, are produced in the thyrocytes and extruded into the colloid by exocytosis. Thyroid peroxidase first oxidizes iodide and subsequently couples iodine atoms to the aromatic ring of the tyrosine residues present in thyroglobulin, forming monoiodotyrosine (MIT) and diiodotyrosine (DIT). What follows is the coupling of two DIT molecules to form 3,5,3′,5′-tetraiodothyronine or thyroxine, shortly called T_4. Some DIT molecules may be coupled to a MIT giving rise to 3,5,3′-triiodothyronine or T_3. Hormone release from the thyroid involves endocytosis of droplets of colloid by the follicle cells and their fusion with lysosomes. Following digestion of thyroglobulin by lysosomal enzymes, T_4 and T_3 are released into the circulation at the basolateral membrane. *ER*, endoplasmic reticulum; *GA*, Golgi apparatus; *LYS*, lysosome; *NIS*, sodium-dependent iodide symporter; *NU*, nucleus; *PEN*, pendrin; *TG*, thyroglobulin; *TPO*, thyroid peroxidase; *TSH*, thyroid stimulating hormone; *TSHR*, thyroid stimulating hormone receptor.

that circulating THs and thyroid gland hormone content are well regulated over a wide range of iodide intakes in adult animals. Embryos and chicks also show a considerable amount of iodide regulation although less than in adults (McNabb et al., 1985; McNabb et al., 1985; Stallard and McNabb, 1990).

31.3.1.2 Iodination and coupling in the colloid

TH synthesis begins with the iodination of tyrosine residues contained in thyroglobulin, the hormone storage protein of the colloid (Fig. 31.2). Thyroglobulin is produced in the thyrocytes, transported by vesicles to the apical cell border and extruded into the colloid by exocytosis (Citterio et al., 2019). Thyrocytes also produce the enzyme thyroid peroxidase which first oxidizes iodide and subsequently couples iodine atoms to the aromatic ring of the tyrosine residues present in thyroglobulin, forming monoiodotyrosine (MIT) and diiodotyrosine (DIT). What follows is the coupling of two DIT molecules to form 3,5,3′,5′-tetraiodothyronine or thyroxine, shortly called T_4. Some DIT molecules may be coupled to a MIT giving rise to 3,5,3′-triiodothyronine or T_3. However, as long as enough iodide is available, the avian thyroid gland predominantly synthesizes and secretes T_4 [review (McNabb, 1992; Rousset et al., 2000)]. In embryos, the capability for hormone synthesis precedes organization of the thyroid gland into follicles. In precocial chicken embryos, thyroidal iodide concentration and some hormone production occurs already during the first 1/4-1/3 of incubation, but in altricial ring doves, these events only start around mid-incubation (review (McNabb et al., 1998):).

31.3.1.3 Release into the circulation

Hormone release from the thyroid involves endocytosis of droplets of colloid by the follicle cells, their fusion with lysosomes, and digestion of thyroglobulin by lysosomal enzymes. While part of the amino acids and iodine are recycled within the thyrocyte, T_4 as well as a small amount of T_3 are released into the circulation at the basolateral membrane [review (McNabb, 1992; Rousset et al., 2000)]. TH secretion rates are in the range of 1−3 μg T_4/100 g of body weight per day in chickens, quails, and pigeons, but can increase or decrease due to external factors (see Section 31.6).

31.3.2 Hypothalamic-Pituitary-Thyroid Axis

31.3.2.1 Control by the pituitary

Activity of the avian thyroid gland is primarily controlled by the hypothalamic-pituitary-thyroid (HPT) axis. Thyroid stimulating hormone or thyrotropin (TSH), produced by the thyrotrophs of the anterior pituitary, is the major stimulator of TH synthesis and release. It is a glycoprotein consisting of two subunits: the α subunit, common to several pituitary hormones, and the β subunit that ensures its specificity. Binding of TSH to its receptors in the basolateral membrane of the thyrocyte stimulates the expression and synthesis of NIS and thyroglobulin, and increases TH production in the colloid. It also stimulates colloid endocytosis and subsequent hydrolysis of thyroglobulin, resulting in increased TH release into the circulation. Increased and sustained stimulation by TSH leads to both hypertrophy and hyperplasia of the thyrocytes which may result in formation of a goiter (Norris, 2007).

31.3.2.2 Control by the hypothalamus

The production and secretion of TSH is in turn regulated by three hormones from the avian hypothalamus: thyrotropin releasing hormone (TRH) and corticotropin releasing hormone (CRH) that are stimulatory and somatostatin (SRIH) that is inhibitory (De Groef et al., 2005) (Fig. 31.3). Although TRH, the major stimulator in mammals, was shown to stimulate TSH release from the chicken pituitary [review (Decuypere and Kühn, 1988)], more recent studies in birds, reptiles, amphibians, and fish have shown that CRH, rather than TRH, is often the most important hypothalamic stimulator of pituitary TSH in nonmammalian vertebrates [review (De Groef et al., 2006; Watanabe et al., 2016)]. This stimulation occurs by binding to the type 2 CRH receptor that is expressed on thyrotrophs but not on corticotrophs (De Groef et al., 2003). The most important role of TRH in influencing thyroid function in birds may be through its growth hormone (GH) releasing action, leading to inhibition of T_3 degradation by type 3 deiodinase (see Section 31.4.1). While hormones from the hypothalamus and pituitary stimulate thyroid gland activity, THs released by the gland in turn exert a negative feedback on the pituitary and hypothalamus (Fig. 31.3).

31.3.2.3 Development of the hypothalamic-pituitary-thyroid axis

During development, the establishment of HPT axis control over the thyroid gland occurs about mid-incubation (embryonic days 10.5−11.5) in precocial chickens. This was originally shown by the fact that removing the pituitary by decapitation did not alter plasma T_4 until day 11.5, but prevented the plasma T_4 increase that occurs after day 11.5 (Thommes et al., 1988). More recently, the timing was confirmed in detail by measurements of gene expression, showing a clear increase in mRNA levels of CRH, CRHR2, type 1 TRH receptor (TRHR1), and TSHβ between embryonic days 10 and 12 (Ellestad et al., 2011). Maturation

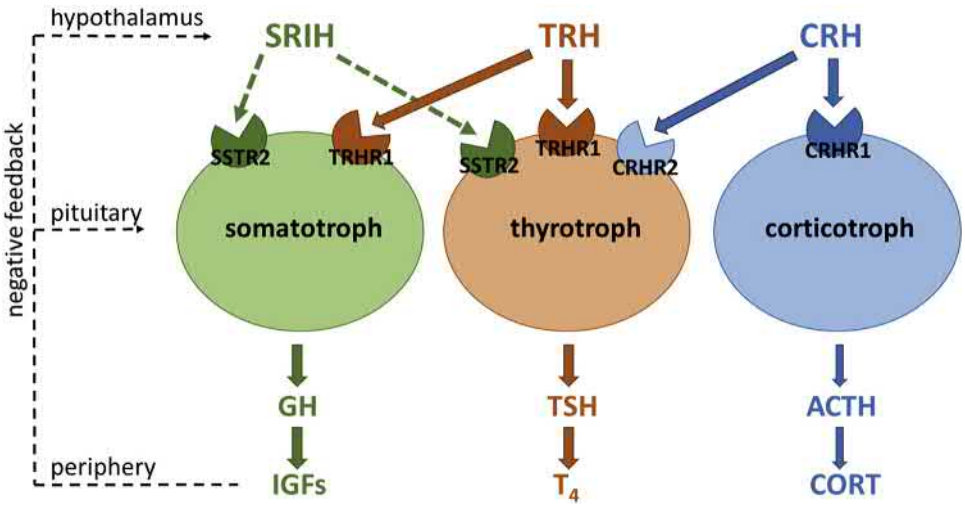

FIGURE 31.3 Avian hypothalamic-pituitary-thyroid axis. Hormone synthesis and release by the thyroid gland is stimulated by thyroid stimulating hormone or thyrotropin (TSH). The production and secretion of TSH in birds is regulated by three hypothalamic hormones: thyrotropin releasing hormone (TRH) and corticotropin releasing hormone (CRH) that are stimulatory and somatostatin (SRIH) that is inhibitory. TRH stimulation occurs by binding to the type 1 TRH receptor while the stimulatory effect of CRH occurs by binding to the type 2 CRH receptor that is expressed on thyrotrophs and not on corticotrophs. Thyroid hormones released by the gland exert a negative feedback on both the pituitary and the hypothalamus. *ACTH*, adrenocorticoptropic hormone; *CRHR1*, type 1 CRH receptor; *CRHR2*, type 2 CRH receptor; *CORT*, corticosterone; *GH*, growth hormone; *IGFs*, insulin-like growth factors; *SSTR2*, type 2 somatostatin receptor; *TRHR1*, type 1 TRH receptor.

of the feedback response of pituitary thyrotrophs has been confirmed by embryonic day 19 by demonstrating that goitrogen suppression of circulating T_4 increased TSHβ mRNA (Muchow et al., 2005). Likewise, T_4 feedback on SRIH inhibition of TSH production also matures between day 19 and hatch (De Groef et al., 2007). Studies on ring doves suggest that in altricial species, pituitary control of the thyroid is established after hatch. In this species, the thyroid is insensitive to exogenous TSH until the second day posthatch and circulating THs remain very low, then gradually increase during the first 3 weeks posthatch. Studies of the circulating TH patterns in other altricial species (red-winged blackbirds and starlings) are consistent with this developmental pattern [review (McNabb, 2007)].

31.3.3 Thyroid hormones in circulation

31.3.3.1 Avian thyroid hormone distributor proteins

Historically, circulating THs were first measured as protein-bound iodine, then by competitive binding assay, then by radioimmunoassay and enzyme-linked immunosorbent assay, and most recently by liquid chromatography and mass spectrometry. As in other vertebrates, the major THs present in avian plasma are T_4 and T_3, while concentrations of 3,3′,5′-triiodothyronine or reverse T_3 (rT_3) in posthatch birds are normally low (Hylka et al., 1986). In comparison with mammals, avian plasma contains similar concentrations of T_3 but less T_4 (i.e., often 10-fold less). The lower T_4/T_3 ratio is at least partially linked to the evolutionary difference in TH distributor proteins (formerly called TH binding proteins or TH carrier proteins) (Chang et al., 1999). Since THs are lipophilic, these proteins act to efficiently distribute them in the blood and the cerebrospinal fluid and also increase their stability. The half-life of T_4 in chicken is much shorter than in mammals and more similar to the half-life of T_3 [between 1 and 2 h for both (Bartha et al., 1994)]. The major TH distributor proteins in birds are transthyretin (TTR), which is high affinity and low capacity, and albumin, which is low affinity and high capacity. Birds lack the very high-affinity T_4-binding protein, thyroxine binding globulin (TBG), that is present in the blood of many mammals. Also, in contrast to mammals, the affinity of TTR from birds and other nonmammalian vertebrates is higher for T_3 than for T_4 [review (Richardson, 2014)]. Both albumin and TTR are produced in the avian liver, but TTR is the only TH distributor protein that is also produced in the brain in the choroid plexus. There it has a role, together with transmembrane transporters (see Section 31.4.2), in the transfer of THs between the general circulation and the cerebrospinal fluid (Richardson et al., 2015).

31.3.3.2 Factors influencing thyroid hormone levels in circulation

Adult birds of many species have plasma or serum T_4 concentrations in the range of 5−20 ng T_4/mL (6−25 pmol/mL) and T_3 concentrations in the range of 0.5−4 ng T_3/mL

(0.7−6 pmol/mL). Diurnal cycles of plasma THs have been demonstrated, with a peak of plasma T_4 during the dark period and a peak of plasma T_3 during the light period when birds are feeding (Klandorf et al., 1978; Harvey et al., 1980). Food intake is indeed a key factor influencing peripheral T_3 production and degradation and patterns of plasma THs (see Section 31.6). Temperature also may be important; cold temperatures increase and warm temperatures depress plasma T_3 within these diurnal patterns (Cogburn and Freeman, 1987).

The ontogenic profile of plasma THs differs in birds with precocial versus altricial development. In precocial species, in which thyroid gland function and its control mature before hatching, plasma T_4 rises several fold during the latter half of embryonic life while plasma T_3 remains low. Shortly before hatching, both hormones rise dramatically to reach some of the highest concentrations that have been measured in avian plasma. The perihatch peaks in THs are associated with the initiation of pulmonary respiration and thermoregulatory responses to cooling that occur in precocial species during this period. After the perihatch peak, plasma THs decrease markedly, then gradually increase again during posthatch life to reach adult concentrations (Decuypere and Kühn, 1988; McNabb, 1988). In altricial species, plasma concentrations of T_3 and T_4 are very low during embryonic life and the perihatch period, then gradually increase during the first 2−3 weeks posthatch to approach adult levels. Endothermic responses to cooling first appear several days to a week after hatching in these altricial birds, and the young are only homeothermic by the time of fledgling (McNabb and Olson, 1996; Vyboh et al., 1996).

31.4 Thyroid hormone metabolism and action

31.4.1 Thyroid hormone activation and degradation

Once secreted by the thyroid gland, THs can be metabolized in peripheral tissues by different pathways. Oxidative deamination and decarboxylation of the alanine side chain, as well as ether link cleavage, lead to irreversible TH degradation. Sulfation and glucuronidation of the phenolic hydroxyl group are reversible processes that facilitate hormone solubility and subsequent excretion. The most important pathway, however, is deiodination consisting of removal of a single iodine from the phenolic outer ring (5′D or ORD) or from the tyrosyl or inner ring (5D or IRD) (Fig. 31.4), processes catalyzed by enzymes called iodothyronine deiodinases. Next to providing most of T_3 present in circulation, stepwise deiodination is also responsible for the low levels of rT_3 as well as different forms of diiodothyronine (T_2).

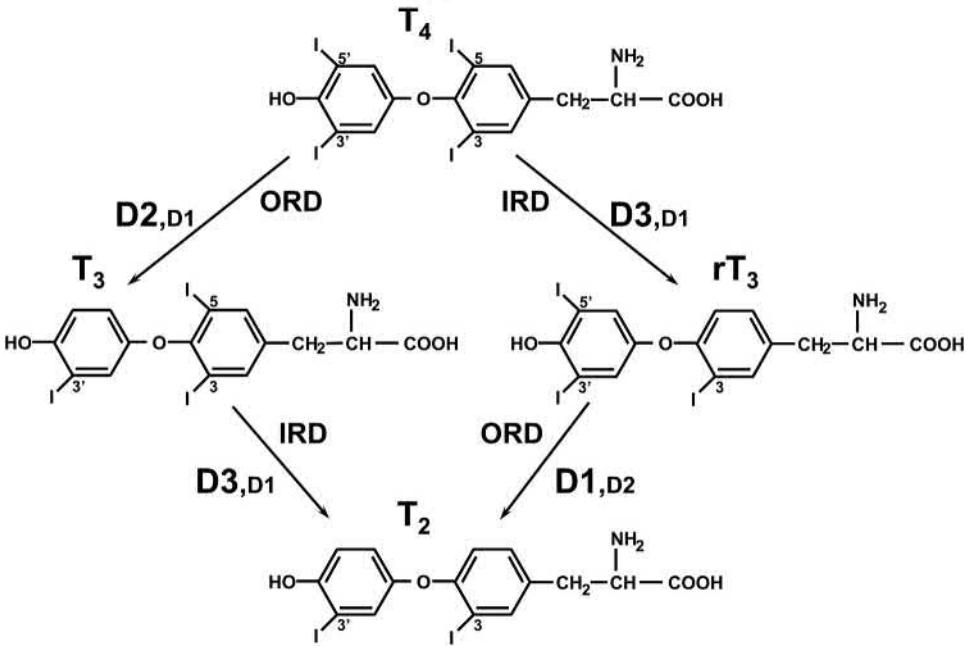

FIGURE 31.4 Thyroid hormone activation and inactivation by deiodinases. Deiodination by different types of iodothyronine deiodinases is a major mechanism regulating intracellular availability of T_3. The relative size of the symbols D1, D2, and D3 indicates their importance in the respective pathway. *T_4*, 3,5,3′,5′-tetraiodothyronine or thyroxine; *T_3*, 3,5,3′-triiodothyronine; *D1*, type 1 deiodinase; *D2*, type 2 deiodinase; *D3*, type 3 deiodinase; *IRD*, inner ring deiodination; *ORD*, outer ring deiodination; *rT_3*, 3,3′,5′-triiodothyronine; *T_2*, 3,3′-diiodothyronine.

31.4.1.1 Characterization of avian deiodinases

The first direct proof for peripheral T_4 to T_3 conversion in birds was obtained in 1978 in Peking ducks (Astier and Newcomer, 1978). As for mammals, biochemical characterizations of deiodinating activities in birds first used liver homogenates, sampled from chicken (Borges et al., 1980; Rudas, 1986), quail (McNabb et al., 1986), and ring doves (Rieman and McNabb, 1991), and this was later extended to other tissues such as kidney, intestine, and brain. The subsequent cloning of three chicken iodothyronine deiodinases: type 1 (D1 encoded by *DIO1*), type 2 (D2 encoded by *DIO2*), and type 3 (D3 encoded by *DIO3*) (Van der Geyten et al., 1997; Gereben et al., 1999) confirmed the high homology with their mammalian homologs [review (Bianco et al., 2002; Darras and Van Herck, 2012)]. By now, databases also include sequences for several other birds, including both precocial and altricial species. All avian deiodinases are selenoproteins with a selenocysteine in their catalytic site. Therefore they depend on the presence of a selenocysteine insertion sequence element in the 3′ untranslated region of their mRNA to allow selenocysteine incorporation (Bianco et al., 2002). The D1 enzyme is a nonselective enzyme catalyzing both ORD and IRD. In contrast, D2 only catalyzes ORD while D3 only catalyzes IRD and is a purely inactivating enzyme (Fig. 31.4).

31.4.1.2 Role of deiodinases

D1 is highly expressed in avian liver, kidney, and small intestine and contributes to peripheral T_3 production and degradation of rT_3. D2 is predominantly expressed in brain where it is important in the local conversion of T_4 that has entered the brain to T_3. D3 is found in variable amounts in almost all avian tissues and is believed to protect cells from overexposure to T_3 in specific situations such as early development, disease, and starvation [review (Darras et al., 2006)].

As the major secretory product of the avian thyroid gland is T_4, deiodinases in peripheral tissues are responsible for most of the T_3 found in the general circulation. This is clearly illustrated during the perihatch period in precocial birds. D3 expression is particularly high in embryonic chicken liver. The sharp decline in hepatic D3 activity occurring in the last days before hatching is the major factor contributing to the perihatch peak in circulating T_3 (Galton and Hiebert, 1987; Darras et al., 1992). At the same time, differential expression of deiodinases also allows individual tissues to adjust local T_3 concentrations dynamically according to their specific developmental or metabolic need, irrespective of circulating levels.

31.4.2 Cellular uptake of thyroid hormones

Since THs are quite lipophilic, it was originally assumed that they cross the plasma membrane simply by passive diffusion. However, studies in rat hepatocytes already showed around 1980 that T_4 and T_3 enter the cell at least partially by active transport and via separate transport systems (Krenning et al., 1981). It took 30 more years before the first TH transporter proteins were identified (Friesema et al., 2001, 2003), but we now know that several transmembrane proteins facilitate the transport of THs in and out of cells. They include proteins belonging to the families of the monocarboxylate transporters (MCTs), the Na-independent organic anion transporting polypeptides (OATPs), and the L-type amino acid transporters (LATs), as well as the Na-taurocholate cotransporting polypeptide (NTCP) [reviews (Visser et al., 2008; Schweizer et al., 2014)].

31.4.2.1 Characterization of avian thyroid hormone transporters

Based on data in chicken, the characteristics of TH transporters in birds are identical to those of their mammalian orthologs (Bourgeois et al., 2016). As in humans and rodents, OATP1C1 (encoded by *SLCO1C1*) is a high-affinity transporter for T_4 while MCT8 (encoded by *SLC16A2*) and MCT10 (encoded by *SLC16A10*) efficiently transport both T_3 and T_4. Also similar to mammals, the transporter LAT1 (encoded by *SLC7A5*) has a somewhat lower affinity for T_3 and T_4 and its preferred substrate is 3,3′-T_2. LAT2, however, appears to be missing in birds (Bourgeois et al., 2016). TH transporters are already present in the embryo where they regulate TH uptake in developing tissues, including brain [(Geysens et al., 2012; Bourgeois et al., 2016), see Section 31.5.1.2]. In the adult quail hypothalamus, OATP1C1 is believed to be involved in the TH-dependent stimulation of seasonal reproduction [(Nakao et al., 2006), see Section 31.5.3.2 and Chapter 43]. It is important to mention that TH transporters do not only facilitate cellular TH uptake but also TH export. This is important in the regulation of exchange of THs between different cell types and between cells and the general circulation.

31.4.3 Mechanism of action of thyroid hormones

In birds, as in other vertebrate classes, most TH actions are mediated through nuclear TH receptors (TRs) which are members of the nuclear receptor superfamily. TRs, also referred to as T_3 receptors because of their high affinity for T_3, are responsible for the transcriptional effects of THs (i.e., the receptors are transcription factors that act on TH-responsive genes). Since the affinity of TRs for T_4 is relatively low, with respect to transcriptional effects, T_4 is considered to be mainly a prohormone. The direct responses mediated by THs are of two types, developmental and metabolic (see Sections 31.5.1 and 31.5.2), but there are also indirect or permissive effects of THs as well as interactive effects with other hormones (see e.g., Section 31.5.1.1.2).

31.4.3.1 Genomic actions via nuclear thyroid hormone receptors

31.4.3.1.1 Characterization of thyroid hormone receptors in birds

The first steps into the identification of the molecular structure of vertebrate TRs were made in birds by the finding that the protein encoded by the previously described chicken *C-ERB-A* gene was a high affinity TH receptor (Sap et al., 1986). TRs are coded for by two genes, *THRA* and *THRB*, that generate a number of receptor isoforms. Some variation exists in the number and type of isoforms among vertebrate classes. So far, TRα is the only transcript of the *THRA* gene described in birds, and it has a structure and activity similar to the mammalian TRα1 isoform. Two isoforms have been identified for the *THRB* gene, TRβ0 and TRβ2. Their structure and function correspond to those of mammalian TRβ1 and TRβ2, respectively, with the exception that the amino-terminal domain of chicken TRβ0 is shorter than that of mammalian TRβ1 [review (Darras et al., 2011)]. Each isoform has distinct functions but in some cases functions overlap. The TRα receptor is generally expressed ubiquitously while TRβ expression is restricted to fewer tissues and characteristically varies strongly in relation to development (Darras et al., 2011). TRβ2 is also the major TR involved in TH feedback at the level of the HPT axis (Grommen et al., 2008).

31.4.3.1.2 Thyroid hormone action mechanism via nuclear Thyroid hormone receptors

The molecular mechanisms of TR-mediated TH action at the level of the nucleus have mainly been studied in mammals, but what we know from birds is very similar [reviews (Cheng et al., 2010; Darras et al., 2011)] (Fig. 31.5). TRs act as dimers that bind to TH-response elements (TREs), specific sequences in the promotor region of TH-responsive genes. The most effective dimer is a heterodimer of TR with retinoid X receptor, while TR homodimers are less effective. When no T_3 is bound to the TR, the heterodimer interacts with co-repressor proteins that inhibit/repress transcription of positively regulated genes. Upon ligand binding, co-repressors are replaced by co-activators and gene transcription is stimulated. In the case of negatively regulated genes (e.g., *TRH* and *TSHB*), ligand binding results in the opposite switch (Dupre et al., 2004). The extent of receptor binding of T_3 (i.e., binding saturation) strongly depends on local T_3 availability which is in turn largely dependent on cellular TH uptake and metabolism (see Sections 31.4.1 and 31.4.2). Other important factors regulating local TR-mediated signaling

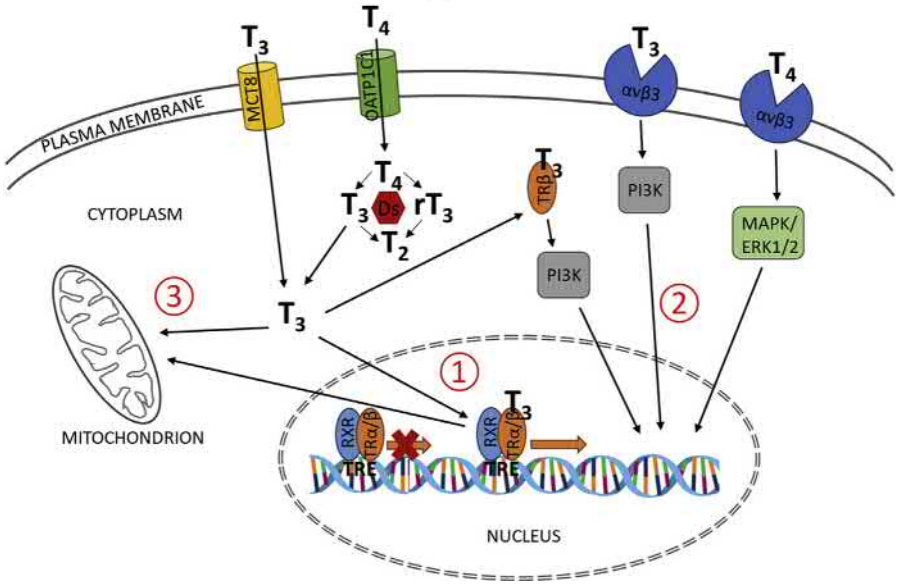

FIGURE 31.5 **T_3 and T_4 uptake, metabolism, and action mechanisms.** Thyroid hormone (TH) transporters such as MCT8 and OATP1C1 are located in the plasma membrane and facilitate T_4 and T_3 uptake. Within the cell, THs are activated/inactivated by enzymes, mainly deiodinases. Classical TH action ① occurs by binding of predominantly T_3 to TH receptors (TRs) present on TH-responsive genes in the nucleus. Hormone binding typically induces a shift from gene repression to activation of gene transcription. Nonclassical actions of THs ② that may eventually also lead to changes in gene transcription start either at the level of the plasma membrane by binding of T_4 or T_3 to integrin αvβ3 leading to activation of PI3K and/or the MAPK/ERK1/2 pathway, or in the cytoplasm where binding of T_3 to TRs residing in the cytoplasm can also activate the PI3K pathway. Finally, THs are also key regulators of mitochondrial respiration and biogenesis ③ involving both direct and indirect mechanisms. *Ds*, deiodinases; *MCT8*, monocarboxylate transporter 8; *OATP1C1*, organic anion transporting polypeptide 1C1; *RXR*, retinoid X receptor; *TR*, thyroid hormone receptor; *TRE*, thyroid hormone response element.

are the relative abundance of different TR isoforms and the presence of different co-repressors and co-activators. Differences in the regulation of the different receptor isoforms in target tissues have been demonstrated in birds, as in mammals, by altering thyroid status with a goitrogen (e.g., methimazole) combined or not with TH supplementation. Hypothyroidism, sufficient to decrease growth and several developmental markers in ducklings, did not affect mRNA levels for THRα but did result in decreased levels of transcript for TRβ0 in some but not all muscles analyzed. Hyperthyroidism also did not alter TRα mRNA but increased TRβ0 mRNA in cardiac, leg, and pectoralis muscles above that in euthyroid controls (Bishop et al., 2000).

31.4.3.2 Alternative routes of thyroid hormone action

Next to this long-known classical or "genomic" action within the nucleus, it is now clear that THs also have actions at the level of plasma membranes, in cytoplasm and in mitochondria, i.e., the so-called "nongenomic" actions. These effects too have mostly been investigated in mammals [review (Cheng et al., 2010)]. THs can bind to a recognition site on integrin αvβ3, a structural protein of the plasma membrane which is also found in birds as shown for instance in chicken ovary (Sechman, 2013). Without entering the cell, they can activate MAPK/ERK1/2 and initiate complex cellular events such as angiogenesis and tumor cell proliferation. Interestingly, T_4 binds with greater affinity than T_3 to this membrane receptor. T_3 can also activate the PI3K pathway starting either from the plasma membrane or by binding to TRβ, and possibly also TRα, residing in the cytoplasm. Data from experiments on chick embryo hepatocytes clearly indicated that T_3 and T_4, as well as the naturally occurring metabolite 3,5-diiodothyronine (3,5-T_2), can have rapid actions at the level of the cytoplasm. They can stimulate the PKC-MAPK and PI3K-AKT pathways, finally leading to stimulation of the growth process (Incerpi et al., 2002; Alisi et al., 2004; Scapin et al., 2009). Although the above-mentioned mechanisms are initially nongenomic, they potentially influence gene expression, independent of TREs, and therefore may serve as nonclassical pathways for transcriptional regulation (Moeller and Broecker-Preuss, 2011) (Fig. 31.5).

THs are also key regulators of mitochondrial respiration and biogenesis. While stimulation of mitochondrial respiration occurs via a rapid, nongenomic mechanism, increase in mitochondrial biogenesis involves both TH-responsive nuclear genes and direct action of TH at mitochondrial binding sites (Vaitkus et al., 2015). Recent data confirmed that mitochondria isolated from breast muscle indeed contain TRs, more specifically TRα, in both chicken and quail (Lassiter et al., 2018). It has been shown in rodents that next to T_3 and T_4, 3,5-T_2 is able to directly and rapidly stimulate mitochondrial activity (Vaitkus et al., 2015).

31.5 Physiological effects of thyroid hormones

31.5.1 Thyroid hormone effects on development

31.5.1.1 General development and hatching

THs influence both aspects of avian development, i.e., growth and differentiation/maturation. Growth, i.e., increase in mass, involves primarily cell proliferation (hyperplasia), but also may result from increases in cell size (hypertrophy). In general, THs appear to act permissively or indirectly, in concert with other control substances, in their stimulation of growth in birds [review (McNabb and King, 1993)]. The primary direct hormonal stimulation of body growth results from circulating growth factors [such as insulin-like growth factor-1 (IGF1)], which are primarily under the control of GH from the pituitary (see Chapter 30).

31.5.1.1.1 Precocial versus altricial birds

Differentiation and maturation of most, if not all, avian tissues is highly dependent on THs. As a matter of fact, this impact of THs on development is probably their most ancient role that is present in both vertebrate and invertebrate chordates, and has even been documented in some mollusks and flatworms (Taylor and Heyland, 2017). In birds, this has been predominantly studied in precocial species where hatching, a crucial transition in avian life span, is accompanied by a peak in circulating T_4 and T_3. Both increased T_4 production by the thyroid gland and changes in peripheral T_3 metabolism (mainly a decrease in D3 activity) contribute to this peak (Darras et al., 1992). A wide variety of studies showed that blocking this TH peak by goitrogens or other thyroid inhibiting compounds severely delayed or even completely blocked hatching. In contrast, a single injection of TH resulted in premature yolk sac retraction and pipping [reviews (Decuypere et al., 1991; De Groef et al., 2013)].

Altricial birds have no perihatch peak in circulating THs, and many aspects of tissue maturation are shifted to the first weeks posthatch, concomitant with maturation of the HPT axis. It is still unclear why altricial birds can hatch in the absence of high TH concentrations, but it is possible that the low levels that are present, mainly of maternal origin (see Section 31.5.1.3), are sufficient to allow maturation of tissues such as the lungs to a stage where pipping and transition to air breathing is possible. It has therefore been suggested that the high levels of THs occurring in

precocial birds during the perihatch peak are mainly needed for the initiation of thermogenesis (McNabb, 2006).

31.5.1.1.2 Interaction with other hormones

In many tissues, the stimulatory effect of THs on differentiation/maturation involves interaction with other hormones. In chicken embryonic gut, THs alone can stimulate cellular differentiation and induce digestive enzymes, but combination with glucocorticoids is necessary for the maturation of intestinal glucose transport [review (McNabb, 2006)]. Skeletal muscle differentiation and growth require both GH and THs. GH alone seems to be sufficient to increase muscle weight in hypothyroid chickens, but both hormones are needed to restore normal myosin development. The appearance of specific myosin isoforms critical to functional maturation during late embryonic development is also modulated by T_3 [review (McNabb, 2006)]. THs also interact with IGF1, e.g., in skeletal development. In vitro studies of pelvic cartilages from early chicken embryos have shown that THs trigger cartilage differentiation/maturation by stimulating matrix production and ossification. In this case, T_3 stimulates chondrocyte hypertrophy, but does not influence cell proliferation, which is only stimulated in the presence of IGF1 [review (McNabb, 2006)].

Lung maturation, crucial for the switch from chorioallantoic to lung respiration during pipping, is controlled by the combined action of THs and glucocorticoids. No direct effect of THs was found so far on surfactant phospholipid synthesis. They may however be important in regulating blood flow in the maturing lungs and expression of TRβ increases strongly toward the end of incubation [review (De Groef et al., 2013)].

Next to functioning in a cooperative/synergistic way with THs for tissue maturation, GH and corticosterone (CORT) also have a stimulatory impact on T_3 availability. Both hormones acutely inhibit hepatic expression of the *DIO3* gene while CORT additionally increases *DIO2* expression in developing brain [review (Darras et al., 2006)]. In turn, THs modulate somatotroph differentiation and abundance during chicken pituitary development (Liu and Porter, 2004) adding another link to the complex interplay between TH, GH, and CORT during avian development.

31.5.1.2 Development of the brain

The vertebrate organ that depends most heavily on THs for normal development is the brain. This has been known since long for the later stages of brain development, but more recently, it became clear that THs are also crucial for the early development of the central nervous system [reviews (Morreale de Escobar et al., 2004; Preau et al., 2015; Vancamp and Darras, 2017)]. TRα is expressed in chicken neuroectoderm from the start of development and receptor expression increases during neurulation (Flamant and Samarut, 1998). THs of maternal origin are present in the early embryonic brain and TTR, TH transporters, deiodinases, and TRs show a dynamic and region-specific expression pattern in brain throughout embryonic development (Forrest et al., 1991; Darras et al., 2009; Van Herck et al., 2012, 2015). THs are needed for the development of normal brain architecture and neuronal connections critical to the function of signaling networks as shown for instance in cerebellum of hypothyroid embryos and posthatch chicks (Bouvet et al., 1987; Verhoelst et al., 2004). Studies in chicken embryos have also been particularly helpful in elucidating the important role of locally expressed deiodinases and TH transporters in central nervous system development (Verhoelst et al., 2005; Van Herck et al., 2015; Delbaere et al., 2016). Site-specific knockdown of MCT8 revealed the need for facilitated transmembrane T_3 transport for normal corticogenesis in mesencephalon and cerebellum and for the formation of the retina and differentiation of the photoreceptors (Delbaere et al., 2017; Vancamp et al., 2017, 2018).

THs also are essential for early learning, both in precocial and altricial birds. It was shown in chicken that they determine the start of the sensitive period for filial imprinting shortly after hatching and may prime the brain for later learning (Yamaguchi et al., 2012). This property seems to be based on a rapid nongenomic action where binding of T_3 to a TR upregulates the phosphorylation level of nucleotide diphosphate kinase 2 (Yamaguchi et al., 2016). In zebra finch, it was found that expression of the TH-activating enzyme D2 is specifically high in the song control nuclei in male birds during the sensorimotor phase of song learning, suggesting that locally increased T_3 levels are needed for the correct development and maturation of the song control circuit (Raymaekers et al., 2017).

31.5.1.3 Role of maternal thyroid hormones

Although THs are needed from the start of development to coordinate the correct sequence of cell proliferation, differentiation, and maturation in different tissues, the embryonic thyroid gland only matures around mid-incubation in precocial birds and around hatching in altricial species. In the absence of a continuous TH supply through the placenta as in mammals, avian embryos rely on maternal THs deposited in the eggs. Iodine too is deposited and is used for embryonic TH production. The vast majority of egg TH content is present in the yolk; concentrations vary between species but the reported T_4/T_3 ratio (calculated on a molar basis) is always above two [reviews (McNabb and Wilson, 1997; Darras, 2019)]. Maternal TH deposition in general changes in line with maternal TH status but some

extent of regulation seems possible. Regulation of maternal TH availability subsequently occurs within the embryo, starting at the level of the yolk sac membrane where TH distributor proteins, transporters, and deiodinases are expressed (Too et al., 2017). The dynamic expression pattern of these regulators in the yolk sac membrane and in different embryonic tissues allows to precisely control local amounts of maternal THs at the tissue level and even to compensate to some extent for maternal hypo- or hyperthyroidism [review (Darras, 2019)].

While strong fluctuations of maternal TH deposit clearly have adverse effects on embryonic development, more subtle changes could also have an adaptive function. Both inter- and intraindividual variations have been observed in yolk content of THs, as well as CORT and androgens, in both precocial and altricial species. In an ecological context, this may be a way in which factors such as laying sequence, temperature, and food availability influence maternal hormone deposition and hence embryonic development and offspring fitness-related traits (Ruuskanen, 2015; Ruuskanen and Hsu, 2018; Della Costa et al., 2019; Hsu et al., 2019).

31.5.2 Thyroid hormone effects on metabolism and thermoregulation

31.5.2.1 Effects on intermediate metabolism

Although it has been known for long that THs are involved in the metabolism of mammals and birds, their exact role in avian lipid, carbohydrate, and protein metabolism is far from fully understood. As in mammals, hypothyroidism in poultry is associated with increased fatness, while hyperthyroidism decreases fat deposition (Decuypere et al., 1987). However, T_3 influences both hepatic lipogenesis and lipolysis and the resulting effect seems to vary according to the thyroid status of the animal (Rosebrough and McMurtry, 2003; Rosebrough et al., 2009). Moreover, in migratory birds, plasma TH levels are increased during the period preceding vernal migration and inhibition of the thyroid completely abolishes premigratory fattening and body mass gain (Perez et al., 2016). The effects of THs on avian growth and intermediate metabolism are probably mainly indirect, and the result of their impact on/interaction with other metabolic hormones such as GH, glucagon, insulin, and CORT (Raheja et al., 1980; Buyse et al., 1990; Harden and Oscar, 1993). In this regard, it is interesting to note that rT_3, which has hypometabolic properties, was found to suppress the rise in free fatty acids induced by glucocorticoids, catecholamines, and insulin, mainly by reducing lipolysis (Bobek et al., 2002; Niezgoda et al., 2005).

31.5.2.2 Effects on thermogenesis

The maintenance of a high and constant body temperature in homeothermic birds and mammals involves different forms of heat production: (1) essential heat, (2) obligatory heat production (together basal metabolic rate, within thermoneutral zone), and (3) adaptive or facultative heat production (below thermoneutrality). THs are known to directly regulate obligatory heat production in mammals while they act permissively on facultative thermogenesis by increasing the capacity to respond to sympathetic nervous system stimulation (Danforth and Burger, 1984). As in mammals, there is a clear positive association between THs and basal metabolic rate in birds. Induction of hypothyroidism reduces heat production while TH administration was found to increase heat production in several avian species [review (Ruuskanen et al., 2020)]. Studies in a number of passerine birds also indicated that increased thermogenic capacity during the cold season was always accompanied by higher plasma T_3 levels (Zheng et al., 2013; Zheng et al., 2014).

The higher endothermic heat production in homeothermic birds and mammals, compared to ectothermic lower vertebrates, involves the uncoupling of the mitochondrial electron transport chain from ATP production, a phenomenon facilitated by anion carrier proteins in the inner mitochondrial membranes. In mammals, uncoupling protein 1 (UCP1) in brown adipose tissue plays a key role in thermogenesis, but birds do not have brown adipose tissue, so this thermogenesis must occur in other tissues. The avian homolog avUCP in chicken and duckling is predominantly expressed in skeletal muscle and its expression is strongly regulated by thyroid status [review (Collin et al., 2005)]. However, its role in avian heat production has been questioned by data showing that adenine trinucleotide translocase, which is also under the control of THs, may be the key uncoupling protein in birds (Walter and Seebacher, 2009), although avUCP may still play a role through interactions involving the β-adrenergic system (Joubert et al., 2010). A few additional potential mediators for TH-induced thermogenesis in birds have been proposed, including peroxisome proliferator-activated receptor gamma coactivator 1 and ATP hydrolysis by sarco/endoplasmic reticulum Ca^{2+}-ATPase (SERCA), but their molecular regulation by THs requires further research. The presence of TRα in mitochondria of avian skeletal muscle has recently been shown (Lassiter et al., 2018), supporting the role of THs, possibly including also 3,5-T_2, in regulation of mitochondrial function which may be both genomic and nongenomic [review (Ruuskanen et al., 2020)].

31.5.3 Thyroid hormone effects on reproduction

31.5.3.1 Role in gonadal development and function

31.5.3.1.1 Impact of hypothyroidism

As in other vertebrates, THs are needed for proper development and maturation of the avian gonads. Data on early gonadal development are scarce but temporary

exposure of both female and male chicks to thyroid inhibitors for several weeks affects later reproductive development and performance [review (McNabb, 2007)]. Studies in adult birds are more abundant. Induction of hypothyroidism by methimazole in male Japanese quail decreased plasma luteinizing hormone and testosterone levels as well as testis weight, and disturbed or even completely stopped spermatogenesis (Kirby et al., 1996; Weng et al., 2007). Multiple studies have shown that egg laying is affected by thyroid status: thyroid inhibition in adult hens resulted in a decrease or even complete cessation of egg laying in galliform birds [reviews (Decuypere et al., 1991; McNabb, 2007)] although some differences were found between species. Japanese quail hens stopped laying when treated with methimazole as soon as the dose was sufficient to decrease circulating TH levels, so they did not produce eggs deficient in THs (Wilson and McNabb, 1997). In contrast, chicken hens decreased laying rate but continued to produce eggs with reduced TH content when their own circulating TH levels were decreased by long-term treatment with a moderate dose of methimazole (Van Herck et al., 2013).

31.5.3.1.2 Impact of hyperthyroidism

While severe hypothyroidism clearly is deleterious for egg production, induction of hyperthyroidism in chicken by T_3 treatment also had adverse effects and resulted in a reduction or stoppage of egg laying (Verheyen et al., 1986; Sechman, 2013), suggesting that the link between THs and ovarian function may be complex. Granulosa and theca layers of chicken ovarian follicles express TRα, TRβ0, as well as the integrin receptor αvβ3, indicating that THs may have both genomic and nongenomic actions in the ovary. In vitro studies demonstrated a direct impact of T_3 on ovarian steroidogenesis and suggested that they participate in the processes during the selection of white follicles into preovulatory hierarchy, as well as during growth, maturation, and ovulation of the yellow hierarchical follicles (Sechman, 2013). Next to T_3, also addition of 3,5-T_2 had an effect on the production of progesterone in the granulosa layer of chicken preovulatory follicles, acting either alone or in combination with LH (Sechman et al., 2011).

Although most of the laboratory studies relating to thyroid effects on reproduction have been done on precocial galliform birds, studies of neuroendocrine control of reproduction in wild birds and studies of wild birds exposed to thyroid-disrupting environmental chemicals indicate the need for adequate thyroid function in altricial or semi-altricial species as well [review (McNabb, 2007)]. However, for most of these species, the coupling of reproduction with seasonality is an important interfering factor since changes in light, temperature, food, etc., are known to influence thyroid function.

31.5.3.2 Role in seasonal reproduction and molt

31.5.3.2.1 Effects on gonadal growth and regression

In temperate and cold climate zones, many birds use photoperiodic changes to regulate their reproduction in order to match optimal environmental conditions. A model was proposed and tested in American tree sparrows, showing that THs are implicated in photoperiodic testicular growth at the start of the breeding season, in cessation of reproduction despite continuing long-day lengths (photorefractoriness) and in postnuptial molt. Although it was shown that the model applies to both males and females (Wilson and Reinert, 1996, 1999), most researchers continued to work on male birds to investigate the role of THs in seasonal reproduction.

Over the years, studies combining thyroidectomy and TH supplementation have often produced contradictory results in different species and resulted in contrasting views on the need or not of THs for testicular recrudescence and for induction of photorefractoriness [review (Dawson et al., 2001)]. Starting in 2003, a series of studies has gradually elucidated the molecular mechanism underlying the stimulatory effect of THs on photoperiodic testicular growth using Japanese quail. Transfer of birds from nonbreeding short-day conditions to breeding long-day conditions induced production and secretion of TSH in the pars tuberalis. This TSH, different from the TSH secreted by the pars distalis and with minimal bioactivity on the thyroid gland, stimulated the expression of *DIO2* while inhibiting the expression of *DIO3* in the tanycytes lining the ventrolateral walls of the third ventricle. The resulting rise in local T_3 availability induced rapid changes in the morphology of the glial endfeet surrounding the gonadotropin-releasing hormone (GnRH) nerve terminals, increasing GnRH secretion into the portal capillaries of the median eminence and hence activating the pituitary-gonadal axis [review (Nakayama and Yoshimura, 2018) and Chapter 43]. In contrast to this light-dependent central action of T_3, testicular regression at the end of the breeding season may be due to stimulation of the HPT-axis by lowering temperatures. The resulting increase in circulating T_3 may subsequently trigger apoptosis and accelerate testicular regression (Ikegami et al., 2015). Whether this combination of central and peripheral effects of TH on testis is identical in passerine birds living in the wild remains to be elucidated,

since both similarities and differences have been reported [e.g., (Bentley et al., 2013; Perez et al., 2018)].

31.5.3.2.2 Effects on molting

THs have long been known to be important in postnuptial molt in both wild and domestic birds and alterations in plasma THs occur in conjunction with natural molts [review (Kuenzel, 2003) and Chapter 46)]. Inhibition of reproductive activity (including cessation of egg laying) and molt occur concurrently in seasonally reproducing wild birds, and in commercial poultry practice THs and/or starvation have been used to induce molt. Interestingly, although T_3 had some effects, T_4 proved to be the most active hormone to speed up molting in force-molted hens in both chicken and turkey (Verheyen et al., 1986; Queen et al., 1997). This is in line with a study in thyroidectomized American tree sparrows showing that T_4 and not T_3 was able to induce photorefractoriness and postnuptial molt (Mishra et al., 2004). In contrast, both hormones restored normal patterns of prenuptial molt in thyroidectomized Gambel's white-crowned sparrows (Perez et al., 2018) suggesting that different and possibly indirect effects are involved.

31.6 Environmental influences on thyroid function

Changes in the environment have an impact on the avian thyroid and external factors such as temperature, light, and food availability are important modulators of thyroid function. Many of these changes are mediated through the HPT axis, but they may also be induced at the peripheral level, e.g., by changes in TH metabolism. Moreover, some effects may be indirect resulting from interaction with other hormones.

31.6.1 Impact of food availability

The impact of food availability is a perfect example to illustrate this complexity. Similar to other vertebrates, both food restriction and starvation reduce circulating T_3 concentrations and increase circulating rT_3 concentrations in birds (Klandorf and Harvey, 1985; Cherel et al., 1988; Abdel-Fattah et al., 1991; Totzke et al., 1999). The primary cause of the decrease in circulating T_3 is a rapid upregulation of hepatic *DIO3* expression and hence increased T_3 degradation by D3-dependent inner ring deiodination, while D1 activity is not affected (Van der Geyten et al., 1999; Gyorffy et al., 2009). The effect of energy restriction on circulating T_4 levels seems to be more variable. Partial energy restriction and complete fasting were repeatedly shown to induce a rise in plasma T_4 in chicken (Klandorf and Harvey, 1985; Van der Geyten et al., 1999; Gyorffy et al., 2009), while food restriction in quail and complete fasting in king penguin and herring gulls led to a decrease in plasma T_4 (Cherel et al., 1988; Totzke et al., 1999; Ronning et al., 2009). The rise in plasma T_4 in fasted chicken occurred in spite of a concomitant drop in plasma TSH. Further research suggested that this drop was the result of a reduced hypothalamic stimulation of the thyrotrophs due to a fasting-induced increase in circulating CORT (Geris et al., 1999). Comparison of all data available from birds as well as other vertebrates indicates that both the length and the severity of energy restriction may influence the balance between the effects on the HPT axis and peripheral TH metabolism and hence the net result on plasma T_4.

31.6.2 Impact of environmental temperature

As THs are needed for thermoregulation (see Section 31.5.2.2), changes in environmental temperature induce changes in thyroid function. Circulating levels of T_3 were found to be higher in cold than in warm conditions in many species, including quail, chicken, barn owl, and Eurasian tree sparrows (Bobek et al., 1980; Rudas and Pethes, 1986; Klein et al., 2006; Zheng et al., 2008). Again, the impact on thyroid function occurs both at the central and peripheral level. Cold stress increased pituitary cAMP-dependent protein kinase activity in cockerels (Chiasson and Carr, 1985) and thyroidal iodide uptake in goslings (Poczopko and Uliasz, 1975) while neural deafferentiation of the hypothalamus abolished the thyroidal response to cold in quail (Herbute et al., 1984) indicating that cold activates the HPT axis. Direct effects at the peripheral level were shown by experiments in thyroidectomized or hypophysectomized chickens where cold exposure directly influenced TH deiodination leading to an increase in T_3 availability (Rudas and Pethes, 1986). Overall, these changes provide increased T_3 availability in association with the metabolic increases required for homeothermy at cold ambient temperatures. Changes in plasma T_4 concentrations are often slower, more variable, and relatively mild (Kühn and Nouwen, 1978; Rudas and Pethes, 1986; Hangalapura et al., 2004; Klein et al., 2006). In general, hot temperatures have the opposite effect, i.e., they depress thyroid function [review (Sharp and Klandorf, 1985)].

31.6.3 Impact of chemical pollutants

In addition to natural environmental events, endocrine disrupting chemicals in the environment influence thyroid function of birds exposed to such chemicals. The impact of endocrine disruptors on birds is covered in more detail in Chapter 50 and only a few examples are included here.

Perchlorate compounds, which have been used as experimental goitrogens, are environmental contaminants in many regions, so they affect thyroid function in animals exposed through drinking water or food sources.

The primary effect of the perchlorate ion is to competitively inhibit thyroidal iodide uptake by NIS, creating iodine deficiency and the consequent effects on thyroid function. Most of what is known about perchlorate effects in birds comes from laboratory studies in quail, showing induction of hypothyroidism with thyroid gland hypertrophy and hyperplasia and reduced T_4 content, decreased plasma T_4 and T_3 levels and increased expression of *DIO2* in liver but not in brain (McNabb et al., 2004; Gentles et al., 2005; Chen et al., 2009).

Polychlorinated biphenyls (PCBs) are industrial chemicals that have been released in large amounts into the environment. Bioaccumulation of PCBs in fish-eating herring gulls around the contaminated Great lakes resulted in population declines and thyroid disruption [review (Fox, 1993)]. Although PCB manufacture was banned in the United States in 1977, studies of thyroid function in gull embryos collected in 1998−2000 suggested that embryonic thyroid disruption, from the persistent environmental PCBs, continued at contaminated sites (McNabb and Fox, 2003). More recent studies have explored how PCBs and their hydroxylated/sulfated metabolites affect thyroid function through multiple mechanisms. They were shown to interfere with TH synthesis [e.g., (Techer et al., 2016)], TH binding to distributor proteins [e.g, (Ucan-Marin et al., 2010)], peripheral TH metabolism and clearance [e.g., (Beck et al., 2006; Webb and McNabb, 2008)], and TH binding to TRs [e.g., (Miyazaki et al., 2004; Ren et al., 2019)].

Other categories of industrial compounds that have received attention in recent years are those used as flame retardants (e.g., polybrominated diphenyl ethers) as well as those employed as nonstick coatings for cookware (perfluoroalkyl compounds) and bisphenol A, which is used in plastics and food can liners. These materials are widespread, persistent contaminants that are present in wild birds and have been shown to alter thyroid function. Brominated and chlorinated organic flame retardants have been shown to interfere with thyroid function in a wide variety of species [review (Guigueno and Fernie, 2017)]. Similar to PCBs, interaction occurs at different levels following either environmental or experimental exposure [e.g., (Farhat et al., 2013; Jacobsen et al., 2017; Marteinson et al., 2017; Techer et al., 2018)].

Important in the context of endocrine disruptors is the fact that free living birds are continuously exposed to a mixture of contaminants and that the adverse effect of these mixtures on thyroid function may be even more detrimental than the sum of the individual compounds (Mughal et al., 2018). It is also important to take into account that most of these compounds are deposited in the eggs and as such transferred to the developing embryos, which are the most vulnerable stages.

Gene symbol of proteins (ionic transporters, shell matrix proteins) are described in Tables 32.1 and 32.2.

1,25(OH)2D3,25-dihydroxyvitamin D_3or 25(OH)D 25 hydroxyvitamin D_3 Metabolites of vitamin D.

32.1 Introduction

Birds are oviparous and produce a cleidoic egg with its internal environment almost totally isolated from the exterior. This reproductive cell is composed of an oocyte surrounded by nutritional reserves. The unfertilized chicken egg is consumed worldwide because of its low price and high-nutritional value. It contains a large diversity of nutrients (protein, energy, vitamins, and minerals) that are largely sufficient for the human diet with the exception of calcium and vitamin C (Rehault-Godbert et al., 2019). Eggs also possess an ideal profile of balanced amino acids and contain large amounts of unsaturated fatty acids. The egg is similar between different species of birds: a yolk surrounded by an egg white, eggshell membranes (ESMs), and the eggshell. The egg is a package containing all components needed for the development of the embryo, with a variety of protective systems against physical and microbial attacks. The egg white contains numerous antimicrobial proteins and the eggshell protects the contents of the egg from mechanical insults. In addition, shell porosity regulates the exchange of water and gases during extrauterine development of the chick embryo; moreover, the eggshell is also a calcium reserve that supports embryonic bone development. The shell mineral structure is one of the most impressive terrestrial adaptations in amniotes, which allows embryonic development in the desiccating nonaquatic environment. Shell mineralization takes place in the lumen of the uterus, which secretes an acellular milieu, the uterine fluid that contains all necessary ionic and organic precursors. Its particularities, as compared to bone or teeth, are the material [calcium carbonate ($CaCO_3$) instead of calcium phosphate] and the absence of cell-directed assembly during mineralization. The ESMs play a crucial role by controlling the initial mineralization, which occurs upon organic cores on its outer surface.

In the laying chickens, eggshell formation takes place daily in the uterus and is one of the most rapid biomineralization processes known. To provide about 6 g of shell as $CaCO_3$, the hen exports each day 2.4 g of Ca corresponding to 10% of her total body calcium (Sauveur and de Reviers, 1988; Nys and Guyot, 2011) and in 1 year of egg production, the modern pedigree hen exports more than her body weight as eggshell. The intensity and discontinuity of Ca secretion challenges calcium homeostasis in hens; however, birds develop physiological adaptations in the intestine, bone, and uterus upon sexual maturity. Moreover, there is a daily cycle in these tissues during shell formation that provides the necessary Ca and bicarbonate. Two weeks before the onset of egg production, hens establish a calcium "reservoir"—the medullary bone, display a largely increased intestinal Ca retention and develop the secondary reproductive organ, the oviduct. The spatiotemporally regulated process of egg formation takes place in specialized segments of the oviduct following yolk ovulation (Figure 32.1): secretion of the vitelline membrane components in the infundibulum, secretion of albumen in the magnum, ESM deposition in the isthmus, and eggshell mineralization in the uterus (Sauveur and de Reviers, 1988; Nys and Guyot, 2011). The uterus secretes large amounts of Ca^{2+} and HCO_3^- ions to form the shell (Hurwitz, 1989a; Nys, 1993; Bar, 2009). This daily export of calcium causes a decrease in plasma calcium, which stimulates, through Ca^{2+}-sensing receptors (CaSRs), the synthesis and secretion of calcium-regulating hormones: mainly parathyroid hormone (PTH) and 1,25-dihydroxyvitamin D_3, which together influence Ca flux by acting on bone resorption and intestinal absorption (Wasserman, 2004; Christakos, 2014, 2019). Numerous classical physiological studies have explored the regulation of uterine ionic transfer, without demonstration of a direct effect of these hormones upon avian Ca metabolism (Bar, 2008, 2009; Nys and Le Roy, 2018). However, during the past 20 years, transcriptomic and proteomic in vivo analyses have provided detailed information on the proteins involved in the mechanisms of ion supply and of shell mineralization. The chicken constitutes an excellent model because the spatial and temporal sequence of egg formation is well known, and the oviduct provides experimental access to tissues that are specific to particular functions.

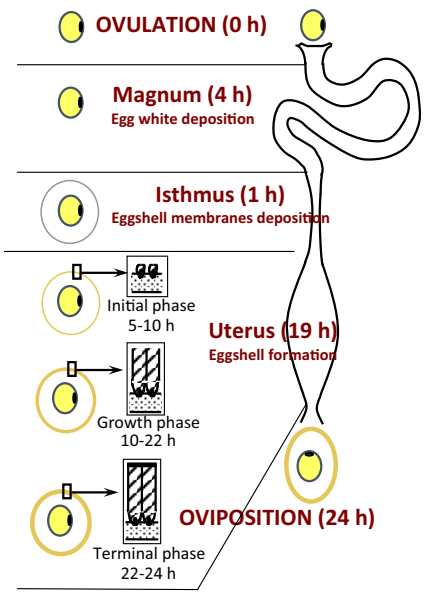

FIGURE 32.1 Spatiotemporal formation of the egg. Schematic drawing of the egg passage through the oviduct, timing and stage of shell formation.

Indeed, the components of each egg compartment are produced sequentially (Sauveur and De Reviers, 1988; Nys and Guyot, 2011). The liver synthesizes the egg yolk components that are exported to the ovary. Following ovulation, the largest ovarian follicle releases a mature ovum into the oviduct. Specialized parts of the oviduct successively synthesize and secrete: the constituents of the outer vitelline membrane which surround the yolk, the egg white, the shell membranes, and the eggshell. This temporal sequence is controlled by the daily cycle of steroid and pituitary hormones. In hens, it is possible to compare the expression of genes between specific segments of the oviduct at well-defined stages of egg formation in order to obtain insight into genes involved in specific functions associated with the formation of an egg component. Comparison of proteomic profiles of egg compartments or uterine fluid sampled at well-defined periods of egg formation also permit the identification of proteins involved in mechanisms of ionic transport, eggshell mineralization, and their regulation. These approaches have revealed in detail the mechanisms of Ca transfer at the intestinal and uterus level, identification of novel mechanisms of uterine Ca secretion (vesicular transport), as well as, identification of the matrix proteins involved in the control of eggshell mineralization. This novel information will be presented in this chapter. Transcriptomic and proteomic approaches also allow exploration of the regulation of these processes or highlight novel hormone pathways, such as fibroblast growth factor 23 (FGF23) acting on phosphate metabolism. Such studies are mainly qualitative but have allowed a myriad of protein candidates involved in ionic transport and shell mineralization to be identified. More quantitative and functional analyses are needed to hierarchize the candidates and to understand different mechanisms involved in shell formation. This chapter aims to update information in these areas and to underline the novel knowledge that has accrued on the proteins involved in providing and in building the shell material; however, there needs to be a better understanding of their physiological regulation.

32.2 Structure, composition, and formation of the eggshell

32.2.1 Structure and composition

The shell structure is similar for different species of birds and shares the same mineral component, namely the trigonal phase of $CaCO_3$ known as calcite, which is the most stable $CaCO_3$ polymorph at room temperature (Hamilton; 1986; Solomon, 1991; Nys et al., 1999; Hincke et al., 2012). In the shell ultrastructure, up to six layers can be distinguished (Figure 32.2). The inner part of the eggshell comprises two shell membranes consisting of interlacing protein fibers. The mineral portion is anchored on organic rich structures, the mammillary bodies, located at the surface of the outer shell membrane fibers. These structures have a strong calcium binding capacity and act as nucleation sites for calcite crystal formation during the initial stages of eggshell mineralization (Fernandez et al., 2001). Calcite crystals grow radiating away from mammillary bodies and forming inverted cones (mammillary layer) that fuse at their bases and continue growing outward to form a compact zone called the palisade layer. The palisades consist of juxtaposed irregular columnar units of calcite crystals that became larger toward the eggshell surface, with diameters ranging between 60 and 80 microns. The palisade layer is around 200 µm thick in chicken eggs, corresponding to about two-thirds of the eggshell thickness and has the largest contribution to eggshell mechanical properties. It is completed by a thin vertical crystal layer where the crystallites are aligned perpendicular to the shell surface which can be visualized in thin sections of eggshell viewed under an optical microscopy with crossed polarizing filters (Figures 32.3 and 32.4).

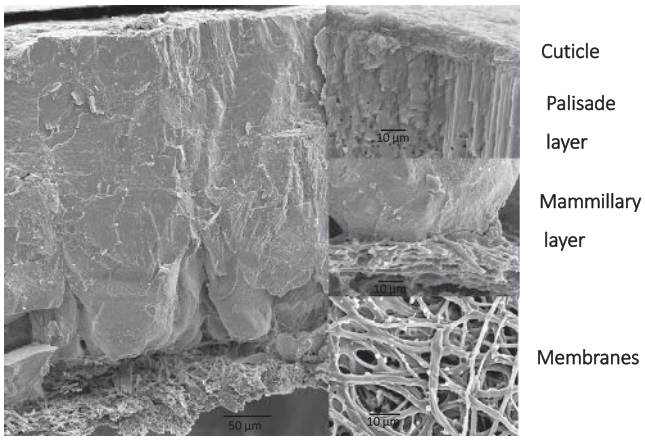

FIGURE 32.2 Left: Scanning electron micrograph (SEM) (shell thickness is 300 µm)) of a cross-fractured hen eggshell showing the different layers. Right: SEM of mammillary layer, palisade layer, and upper part of the shell (Nys et al., 2001).

The main ultrastructural characteristics (columnar structure) and mineralogical composition (calcite) of the eggshell are constant, across all avian species, but there is a notable variability in the eggshell microstructure characteristics (size, shape, and orientation of the crystals of calcite) between species and even within the same specie depending on different factors (Panheleux et al., 1999; Ahmed et al., 2005; Rodriguez-Navarro et al., 2007).

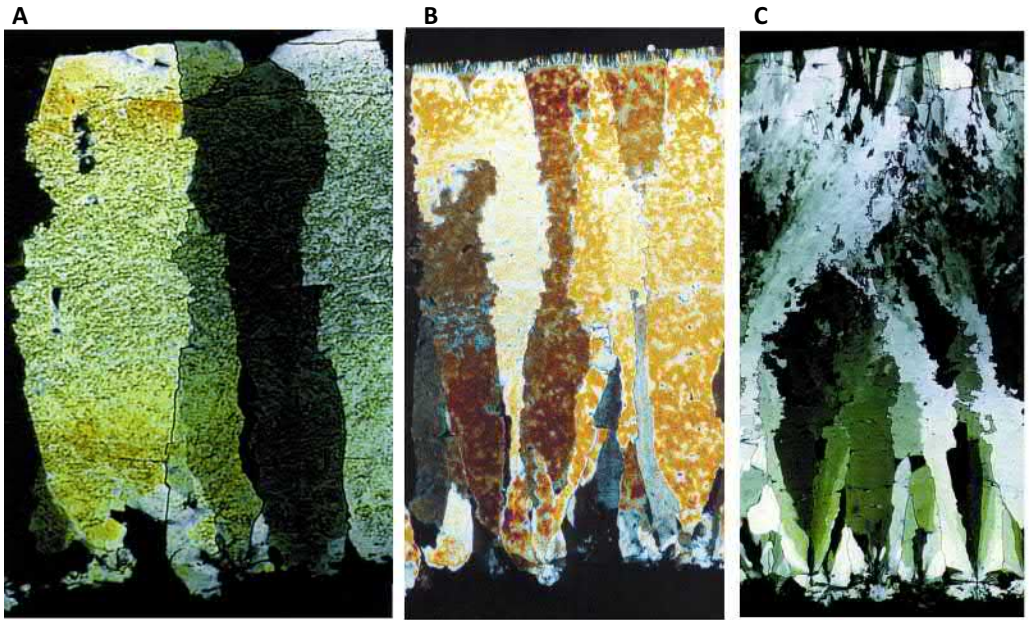

FIGURE 32.3 Cross-section of eggshell viewed in cross-polarized light photomicrographs showing the orientation of calcite crystals in the eggshells from hen (A), turkey (B), and guinea fowl (C). Note the presence of the thin vertical crystal layer at the top of the turkey shell (B) and the presence of interlaced calcite crystals in the upper palisade layer of the guinea fowl shell (C). *By courtesy of Juan Manuel Garcia-Ruiz, Laboratorio de Estudios Cristalograficos, Instituto Andaluz de Ciencias de la Tierra, Granada, Spain; Panheleux et al. (1999).*

The eggshell ultrastructure and microstructure are responsible for the exceptional mechanical properties of eggshell (in chickens, the egg breaking strength is 35N for a mean thickness of 0.33 mm). Changes in these characteristics have a strong effect on eggshell mechanical properties. A remarkable example is the Guinea fowl eggshell (Panheleux et al., 1999; Le Roy et al., 2019). Its inner part is made of calcite crystal units arranged vertically as in chickens. However, the outer zone has a more complex microstructural arrangement made of very smaller intricately interlaced calcite crystals with varying orientation (Figure 32.3). These characteristics of the Guinea fowl eggshell confer upon its superior mechanical properties compared to the eggs of other birds.

The cuticle, an organic layer, is deposited on the surface of the eggshell; it contains a large proportion (2/3) of the superficial pigments (Nys et al., 1991). The inner cuticle contains a thin layer of hydroxyapatite crystals (Dennis et al., 1996). About 10,000 respiratory pores penetrate the hen eggshell (200 pores/cm^2), which are plugged by the cuticle. They allow and control the exchange of water and metabolic gases during the extrauterine development of the chick embryo while impeding bacterial penetration through the shell and preventing contamination of the egg contents.

The ESMs are composed of disulfide-rich protein fibers (~10% cysteine) that are extensively cross-linked by irreversible lysine-derived crosslinks of desmosine and isodesmosine. Collagen was suggested to be present because of identification of hydroxylysine, the observation of digestion of ESMs by collagenase, and finally by immunochemistry using antibodies against type I, V, and X collagen (Wong et al., 1984; Arias et al., 1997; Wang et al., 2002). However, the amino acid composition of the shell membranes largely differs from that of collagenous tissues, suggesting that collagen is not predominant. In fact, a combination of proteomics and transcriptomics approaches have revealed that a major ESM component is a cysteine-rich eggshell matrix protein (abbreviated CREMP), whose sequence displays similarity to spore coat protein SP75 of cellular slime molds (Kodali et al., 2011). The structural proteins CREMP, collagen X, and fibrillin-1 are highly overexpressed in the white isthmus segment of the oviduct, which is responsible for the synthesis and secretion of the ESM constituents. CREMP contains around 14% cysteine, in contrast to collagen X (α-1) which is only 0.2% cysteine, suggesting that CREMP could account for the relatively high-cysteine content of eggshell (Du et al., 2015). Proteomics investigations suggest that the most abundant ESM proteins are CREMP, collagen X, lysyl oxidase−like 2 (LOXL2) and lysozyme, with the remaining approximately 25% constituted by more than 500 proteins (Ahmed et al., 2017, 2019a, 2019b).

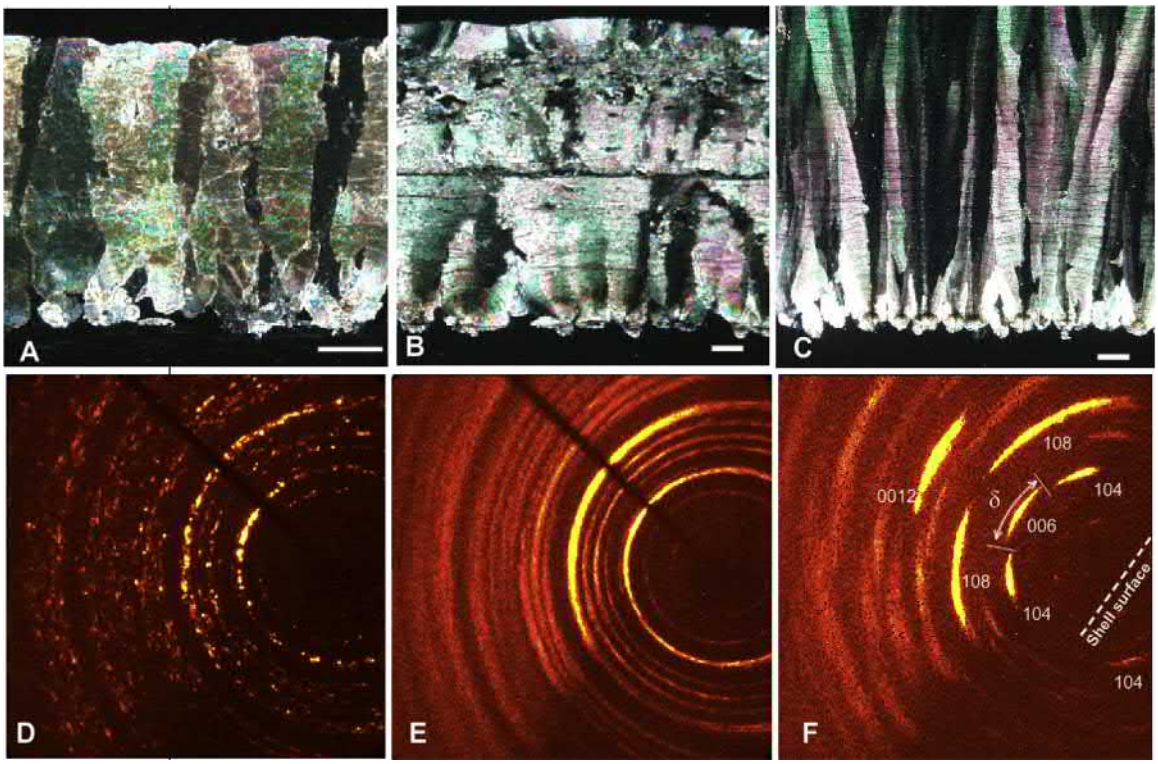

FIGURE 32.4 Upper part: Cross-section of eggshell viewed in cross-polarized light. Photomicrographs showing the orientation of calcite crystals in the eggshells from hen (A, larger randomly oriented crystals), emu (B, randomly oriented microcrystals), and ostrich (C, preferred orientation). Lower part: 2D-XRD patterns of eggshell of hen (D), emu (E), and ostrich (F) analyzing crystal orientation and size (Rodriguez-Navarro et al., 2002).

32.2.2 Kinetics and site of shell membranes and shell formation

ESM fibers are synthesized and secreted by glandular cells of the white isthmus 4 h after yolk ovulation (Nys et al., 1999, 2004). The organic components of mammillae (nucleation sites) and the first crystals are laid down on the external shell membranes in the distal red isthmus 5 h after ovulation. The progressive hydration of the egg albumen swells the forming egg, creating its ovoid shape and allowing close contact with the uterine wall about 10 h after ovulation. Active secretion of calcium, carbonate, and organic precursors over the following 12−14 h contribute to the rapid and linear deposition of the shell mineral, which ends with cuticle secretion about 1.5 h before oviposition (egg expulsion). Eggshell formation is the longest step of egg formation as it lasts about 20 h if the initial phase of shell nucleation is included; it is initiated at 4.5 h after ovulation and ends 1.5 h before oviposition. Shell formation occurs in three periods, the nucleation phase (5−10 h after ovulation), the rapid deposition of shell material (10−22 h after ovulation), and the termination of mineralization (21−23 h after ovulation).

32.3 Mineral supply: a challenge for calcium metabolism

No calcium storage occurs in the uterus before the initiation of shell formation (Sauveur and de Reviers, 1988; Nys et al., 1999). Calcium is directly provided by the ionic blood calcium. The amount needed to form a shell (2 g of Ca in chicken) is very large and the pool of blood ionic calcium in hens laying more than 320 eggs/year must be provided at a rate equivalent to its renewal every 12 min. The laying chicken exports, during 1 year of egg production, more than her body weight as eggshell. Calcium is initially provided by the hen's diet. During eggshell calcification, about two thirds of the Ca deposited in the uterus is directly supplied by the hen's diet, while one-third (30−40%) is mobilized from bone. Bone calcium mobilization is necessary because there is a desynchronization between food intake during the day and egg formation, which mainly takes place during the night. Provision of high-dietary level of Ca (3.5%), in the form of large particles of $CaCO_3$, provides sufficient intestinal Ca during the night to reduce the degree of bone mobilization for shell formation. Conversely, a hen fed a diet which is low in Ca

will mobilize up to 58% of the bone calcium. This cycle of daily resorption of bone is facilitated in hens by the presence of medullary bone. Two weeks before the onset of egg production, immature hens develop a novel and easily mobilized calcium "reservoir," the medullary bone. In addition, sexually mature laying hens largely increase their capacity to absorb Ca in the intestine under the control of the active metabolite of vitamin D (Hurwitz, 1989a; Nys, 1993; Bar, 2008; Nys and Le Roy, 2018) resulting in a threefold increase in intestinal Ca retention. The hourly kinetics of intestinal calcium absorption throughout the day is also of great importance because of the lack of overlap between the period of uterine deposition of calcium for shell during the night and the period of dietary calcium intake during the day. Hens show a specific appetite for calcium a few hours before the period of calcification, i.e., a few hours before lights off (Mongin and Sauveur, 1979). Diet and Ca-particles, when available, are stored in the crop. Dilatation of the crop elicits an increased acid secretion (Ruoff and Sewing, 1971; Lee et al., 1988). This specific appetite for calcium in hens therefore favors the storage and solubilization of the dietary calcium throughout the night especially when available as coarse particles, which partially compensates for the gap in time between dietary calcium intake and its requirement for shell formation. The timely provision of coarse calcium particles in this way also limits the hen's need to mobilize calcium from the bone reserve and therefore also decreases the associated elimination of phosphorus (Whitehead, 2004).

The shell contains 60% of carbonate originating from the blood CO_2, which penetrates the uterine glandular cells by simple diffusion through the plasma membrane (Hodges and Lörcher, 1967). Carbonic anhydrase 2 (CA2) catalyzes the reversible hydration of intracellular CO_2 to HCO_3^-. Bicarbonate is also supplied at a low level from plasma by the Na^+/HCO_3^- cotransporters (SLC4A4, A5, and A10) (Jonchère et al., 2012; Brionne et al., 2014). The carbonic anhydrase (CA) present in the uterine tubular gland cells is crucial for production of bicarbonate which is secreted into the uterine fluid through the HCO_3^-/Cl^- exchanger SLC26A9. Another less expressed CA, CA4, is also found in the uterine cells, its active site being localized in the extracellular space (Zhu and Sly, 1990). The precipitation of $CaCO_3$ in the uterine lumen provides H^+ ions, which are reabsorbed by the uterine cells. H^+ ions are exported via membrane Ca^{++} pumps, the vacuolar (H+)-ATPase (VAT) pump, and an H^+/Cl^- exchanger (Jonchère et al., 2012; Brionne et al., 2014). These pumps and exchangers control the pH balance and therefore contribute to maintenance of acid-base equilibrium in hens. The metabolic acidosis due to acidification of uterine fluid and plasma during shell formation is corrected in hens by respiratory hyperventilation and by an increased renal excretion of hydrogen (Mongin, 1978).

32.4 Hormones involved in calcium metabolism of laying hens: vitamin D, parathyroid hormone, calcitonin, and fibroblast growth factor-23

Regulation of the extracellular Ca^{2+} concentration is continuously challenged in hens by their large Ca requirement for shell formation; however, hens efficiently maintain Ca homeostasis by implementing the classical feedback mechanisms present in all vertebrates. These involve the intestines, bone, and kidney, and utilize three main calcium regulating hormones [PTH, calcitonin (CT), and 1,25-dihydroxy vitamin D3 ($1,25(OH)_2D_3$)]. FGF23 is a bone-derived hormone, which controls phosphorus homeostasis by suppressing phosphate reabsorption and vitamin D hormone synthesis in the kidney(Quarles, 2012). This mechanism has been recently revealed in birds, and the evidence demonstrating its influence on Ca metabolism are discussed in this section. These calcium-regulating hormones were initially studied in mice and human, revealing detailed information for these species. Their roles show numerous similarities with those in birds even if their actions and sensitivities are different from mammals (Dacke et al., 2015). The sex steroid hormones (estrogen and testosterone) influence Ca metabolism indirectly in hens at sexual maturity by initiating the formation of medullary bone and by increasing the appetite for Ca; however, there is no evidence of their control of Ca homeostasis. Similarly, the uterus is the major contributor to the elevated need for Ca; however, surprisingly this main organ of shell formation does not seem to be influenced by the Ca-regulating hormones even if the ionic transporters show numerous similarities at the uterine and intestinal levels (Bar, 2009; Nys and Le Roy, 2018). Other putative Ca and bone-regulating factors might influence Ca metabolism. Dacke et al. (2015) described the avian-specific actions of prostaglandins, calcitonin gene-related peptides (CGRPs), and amylin in pathways that are different from those in mammals. However, this aspect will not be discussed further in this review.

32.4.1 Regulation of vitamin D metabolites in hens

Vitamin D is essential for maintaining egg production and shell quality in hens. Its regulation in hens has been reviewed by many authors, including Hurwitz (1989), Nys (1993), Bar (2008, 2009), Christakos et al. (2014, 2019), and Nys and Le Roy (2018). One particularity of birds compared to mammals is the higher biological activity of vitamin D_3 relative to vitamin D_2 (ergocalciferol) because of the lower affinity of avian plasma vitamin D binding

proteins (DBPs) for vitamin D_2 compared to D_3 derivatives (DeLuca et al., 1988). Both vitamin D metabolism and regulation show large similarities in mammals and birds, but the magnitude of the fluctuations in hens relative to mammals is considerably larger. Vitamin D_3 is partly synthesized from 7-dehydrocholesterol in the skin in response to UV light, but is mainly provided by diet in commercial hens (Bar, 2008; Nys, 2017). The minimum daily requirement in hens was established at 7.5 µg/kg diet (corresponding to a requirement of about 1 µg/day/hen), according to earlier studies (Whitehead, 1986; Barroeta et al., 2012). The current recommendations are higher for hens producing more than 330 eggs in a laying year (50 µg/kg diet; 6 µg/bird/day) (Weber, 2009), which has a positive effect on bone strength and egg production (Barroeta et al., 2012).

Vitamin D_3 is initially hydroxylated in liver microsomes and mitochondria to form 25-hydroxyvitamin D (25(OH)D_3) (Bar, 2008; Christakos et al., 2014, 2019). This first hydroxylation is poorly regulated in contrast to the second hydroxylation step which occurs in the kidney to form the 1,25$(OH)_2D_3$ metabolite. Therefore, the plasma levels of 25(OH)D_3, which circulate as a complex with vitamin DBPs, mainly reflect the dietary supply of vitamin D_3. Its plasma level is however not directly proportional to the dietary supply of vitamin D_3 and circulating 25(OH)D_3 tends to plateau. Its biological activity is slightly higher in birds than the nonhydroxylated form, possibly as a consequence of better intestinal absorption.

A longitudinal study describing the changes in plasma DBPs and 1,25$(OH)_2D_3$ throughout embryonic development, followed by rearing of pullets (immature hens and males) until the onset of egg production at week 15−16, is shown in Figure 32.5 (Nys et al., 1986a). Vitamin 1,25$(OH)_2D_3$ is secreted first at embryonic day 13 (Moriuchi and Deluca, 1974), then its blood levels and that of DBP increase at hatching, possibly as a consequence of liver maturation. An additional increase occurs at sexual maturity under the influence of estrogens, as demonstrated by the increased 1,25$(OH)_2D_3$ induced by treatment of immature pullets with progesterone, testosterone, or estradiol (Montecuccoli et al., 1977; Baksi et Kenny, 1977; Nys et al., 1986a). The interruption of egg production induced by nutritional deficiencies is accompanied by decreases in the secretion of sex steroids and reduced concentrations of DBP and 1,25$(OH)_2D_3$. The resumption of egg production coincides with stimulation of 1,25$(OH)_2D_3$ plasma levels

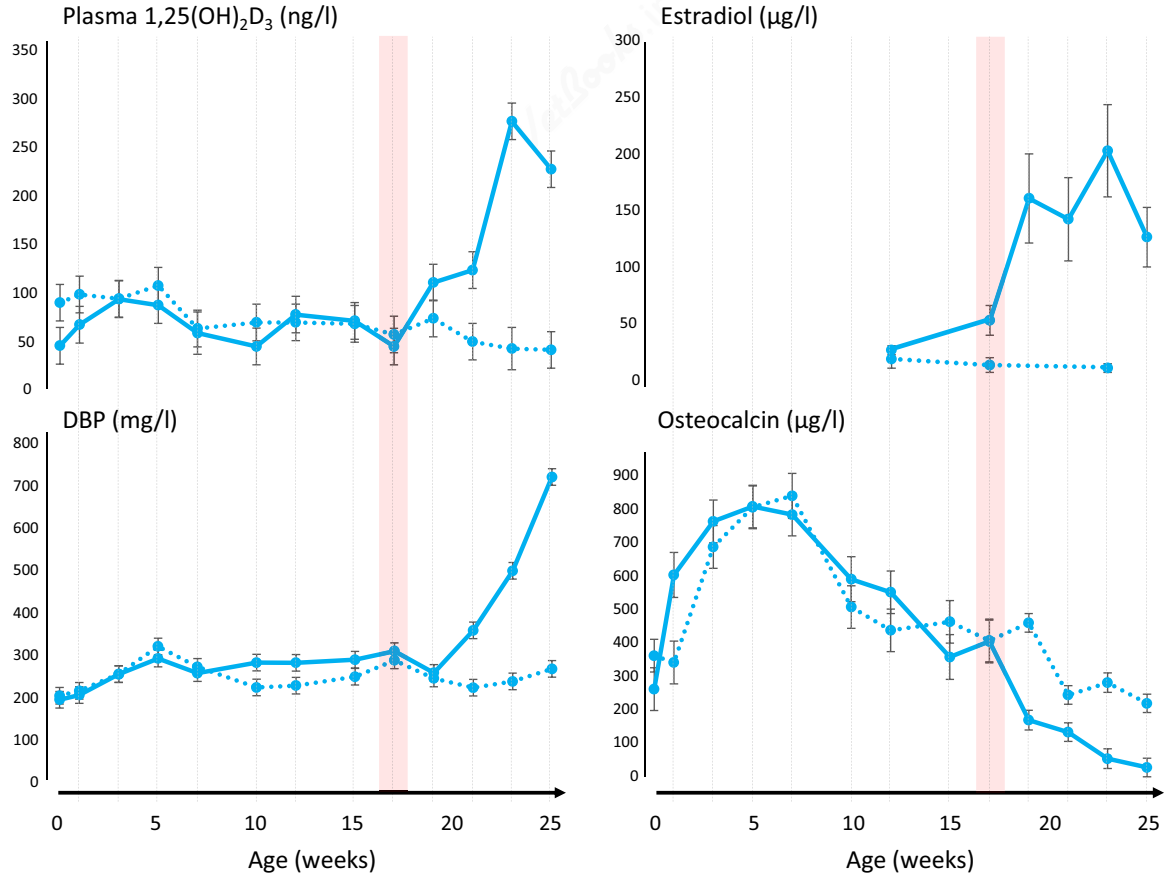

FIGURE 32.5 Evolution of plasma 1,25$(OH)_2D_3$, vitamin D-binding protein, estrogens, and osteocalcin concentrations during the growth of female (*continuous line*) and male (*dotted line*) chickens from birth to age of 25 weeks. The light orange band indicates the period of sexual maturity (Nys, 1993).

(Nys et al., 1986a, 1986b). Renal production of $24,25(OH)_2D_3$ is seven- to ninefold higher than that of $1,25(OH)_2D_3$ in immature pullets (Montecuccoli et al., 1977). However, at the onset of laying, hens activate kidney 25-hydroxycholecalciferol 1α-hydroxylase which elicits a large increase in plasma concentrations of $1,25(OH)_2D_3$ (Figure 32.5) and in intestinal $1,25(OH)_2D_3$, in contrast to $25(OH)D_3$ 24-hydroxylase (Spanos et al., 1976; Castillo et al., 1979). Daily eggshell formation coincides with slightly higher blood levels of $1,25(OH)_2D_3$. Its levels are around 100 pmol/L in immature pullets, rising to more than 200 pmol/L in hens laying shell-less eggs; however, this doubles in hens laying hard-shell eggs (Nys et al., 1986a). The stimulation of $1,25(OH)_2D_3$ depends on two types of regulation. The first is associated with sexual maturation, while the second results from changes in Ca metabolism induced by calcium exportation for eggshell formation. These observations are in agreement with numerous studies, as reviewed by many authors (Bar, 2008; Dacke et al., 2015, Nys and Le Roy, 2018). The increased $1,25(OH)_2D_3$ circulating levels in laying hens, compared to immature pullets, is due to stimulation by estrogens and, at a lower magnitude, by testosterone (Montecuccoli et al., 1977; Castillo et al., 1979; Baksi et Kenny, 1977). Estrogens act directly on the kidney production of $1,25(OH)_2D_3$ as shown in vitro (Baksi and Kenny, 1977; Tanaka et al., 1978), but with a lower magnitude than in vivo. Estrogens might act indirectly through the induced calcium deficiency (Bar and Hurwitz, 1979) due to the formation of medullary bone under the combined effect of sex steroids (Bar et al., 1978; Dacke et al., 2015). However, hens laying eggs with a soft shell due to artificial premature egg expulsion, and fed a high-dietary calcium diet, developed hypercalcemia during the entire laying cycle, while still exhibiting a relatively high level of plasma $1,25(OH)_2D_3$ (Figure 32.6). Sex steroids, therefore, can favor a high secretion of $1,25(OH)_2D_3$, even when PTH secretion is abolished and medullary bone is poorly mobilized. The largest stimulation in kidney production of $1,25(OH)_2D_3$ results from the hypocalcemia induced by shell formation at sexual maturity and to a lesser degree during the daily period of shell formation. Hypocalcemia causes increased secretion of PTH, which substantially increases the production of $1,25(OH)_2D_3$ in vivo (Garabedian et al., 1972) and in vitro (Trechsel et al., 1979). During the period of eggshell formation, the decrease in plasma ionized calcium occurs in hens laying hard-shelled eggs, but not in hens laying shell-less eggs (Figure 32.6). The hypocalcemia increases plasma PTH (van de Velde et al., 1984a; Singh et al., 1986; Yang et al., 2013; Kerschnitzki et al., 2014). Plasma hypocalcemia and PTH secretion are therefore the predominant factors stimulating $1,25(OH)_2D_3$ production, as demonstrated by the threefold increase of $1,25(OH)_2D_3$ induced in hypocalcemic hens fed a low-calcium diet (1% dietary

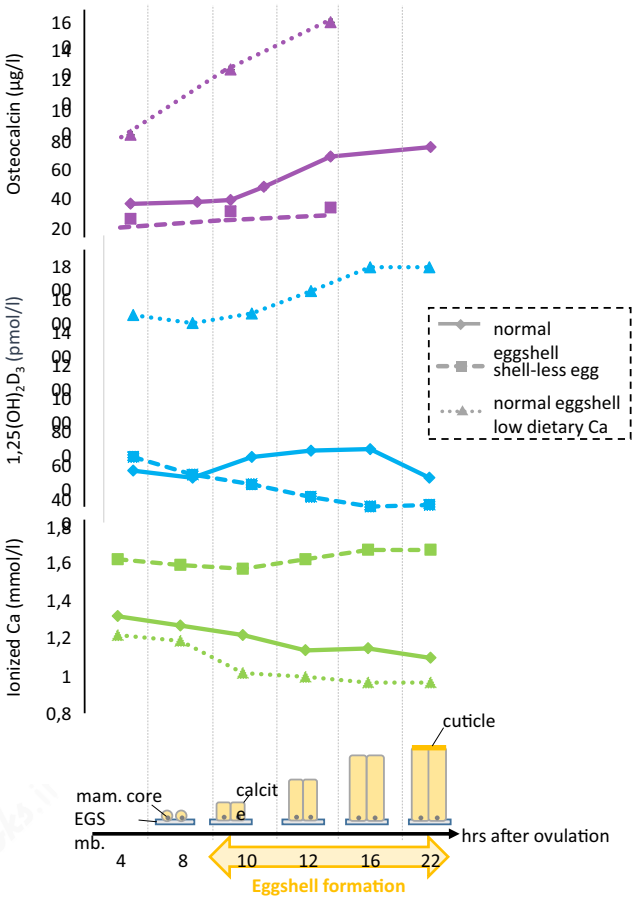

FIGURE 32.6 Plasma levels of osteocalcin, ionized calcium, and $1,25(OH)_2D_3$ throughout the ovulatory cycle. Eggshell formation takes place from 10 to 22 h after ovulation. Normal eggshell corresponds to hens laying hard-shelled eggs and fed 3.5% dietary calcium. Shell-less eggs were obtained by premature expulsion of the eggs before shell formation for a period of 4 days in hens fed 3.5% calcium. The low-dietary calcium corresponded to hens fed 1% dietary calcium and laying hard-shell eggs. EGS mb., eggshell membranes; mam. core, mammillary core (Nys, 1993; Nys and Le Roy, 2018).

calcium), compared with laying hens fed a normal calcium diet. Additional factors are thought to stimulate in vitro kidney production of $1,25(OH)_2D_3$, such as prolactin (Spanos et al., 1979), CT, and growth hormone, but are probably minor regulators of $1,25(OH)_2D_3$ in vivo in mature hens (Bar, 2008; Dacke et al., 2015).

More recently, knockout experiments in mice have revealed a novel circulating factor involved in phosphate and calcium metabolism. Fibroblast Growth Factor-23 (FGF23) is a bone-derived hormone that suppresses phosphate reabsorption and vitamin D hormone synthesis in the kidney (Quarles, 2012; Erben, 2018). Experimental approaches in mice have revealed the physiological importance of FGF23 in inhibiting renal 1α-hydroxylase (CYP27B1) transcription, which is the key enzyme for $1,25(OH)_2D_3$ synthesis (Shimada et al., 2004). FGF23 decreases serum levels of inorganic phosphate by inhibiting

renal phosphate reabsorption and calcitriol production and is suspected to have a large physiological role in phosphate homeostasis. Phosphate concentrations are less tightly regulated than serum ionized calcium levels, but are maintained in a very limited range thanks to PTH and active vitamin D. Recent evidence suggests a similar regulation of phosphate and calcium metabolism by FGF23 in laying hens.

32.4.2 Role of fibroblast growth factor-23 in regulation in calcium and phosphorus metabolism

FGF23 (phosphatonin) is a 32 kDa glycoprotein mainly produced in bone by osteoblasts and osteocytes stimulated by hyperphosphatemia, as reviewed in Erben (2018). High-dietary phosphorus stimulates FGF23 production in humans (Ferrari et al., 2005; Antoniucci et al., 2006). Its role in the control of phosphate (P) homeostasis was revealed when excessive FGF23 was discovered to be the factor responsible for inherited hypophosphatemic rickets in young children (White et al., 2000). FGF23 belongs to the family of endocrine FGFs and requires the transmembrane co-receptors α- and β-Klotho for high-affinity binding to the ubiquitously expressed FGF receptors (FGFR1-4) in target cells (Urakawa et al., 2006; Goetz et al., 2007). Among the four different FGFRs, FGF receptor-1c (FGFR1c) is probably the most important FGFR for FGF23 signaling, at least under physiological conditions (Urakawa et al., 2006). αKlotho enhances the binding affinity of FGFR1c to FGF23 by a factor of approximately 20 (Goetz et al., 2012). In humans, diseases characterized by excessive blood concentrations of intact FGF23 lead to renal phosphate wasting and inappropriately low circulating $1,25(OH)_2D_3$ levels in patients with normal kidney function (Martin et al., 2012). In the absence of FGF23 or its co-receptor α-Klotho, the endocrine control of 1α-hydroxylase transcription fails, leading to inappropriately high expression and activity of this enzyme. Hypercalcemia, hyperphosphatemia, and impaired bone mineralization are observed in α-Klotho and FGF23 deficient mice (Yoshida et al., 2002; Shimada et al., 2004). In addition, FGF23 might stimulate the expression of the 24-hydroxylase (CYP24A1) which hydrolyses $1,25(OH)_2D_3$ to the inactive 1,24, $25(OH)_2D_3$ (Liu and Quarles, 2007).

In mammals, FGF23 reduces renal phosphate reabsorption by inhibiting the activity of type IIa and type IIc phosphate transporters, which are responsible for reabsorption of phosphate from the glomerular filtrate (Gattineni et al., 2009). FGF23 promotes renal phosphate excretion by inhibiting cellular phosphate reuptake from the urine in proximal renal tubules through a cascade involving the α-Klotho/FGFR1c receptor complex. FGF23 induces the phosphorylation of the scaffolding protein Na^+/H^+ exchange regulatory cofactor (NHERF)-1 which in turn leads to degradation of the sodium-phosphate cotransporters NaPi-2a and NaPi-2c (Andrukhova et al., 2012). In addition, in distal convoluted tubules, FGF23 increases reabsorption of calcium and sodium by increasing the apical membrane abundance of the epithelial calcium channel, the transient receptor potential vanilloid-5 (TRPV5) and of the sodium-chloride cotransporter NCC (Erben, 2018). In chicken, its function on phosphate homeostasis was initially revealed by the use of antibodies against FGF23. Immunosuppression of FGF23 greatly improved phosphate utilization by young chicks, by inhibiting the stimulation of renal excretion by FGF23 (Bobbeck et al., 2012). Similarly, laying hens immunized to produce anti-FGF23 antibodies had reduced phosphate excretion (Ren et al., 2017) and improved eggshell quality (Ren et al., 2018). In hens, FGF23 expression in the liver is increased at sexual maturity (Gloux et al., 2019) and during the period of shell formation in the medullary bone (Hadley et al., 2016).

In hens and in chicken of different ages, FGF23 mRNA was expressed at higher levels in liver than other tissues evaluated, including calvaria, femur, tibia, medullary bone, brain, spleen, duodenum, jejunum, ileum, heart, and kidney; however, the highest expression of α-Klotho was found in kidney. It was also expressed in tibia but at a lower level. High-dietary phosphorus stimulates its expression in bone but not in liver (Wang et al., 2018).

Synthesis of FGF23 by medullary bone was confirmed by Gloux et al. (2019). They observed an overexpression of FGF23 in aged hens compared to young hens, which was associated with lower plasma levels of $1,25(OH)_2D_3$. In addition, FGF23 is overexpressed during the period of shell formation in younger hens when phosphoremia is elevated, in agreement with Hadley et al. (2016), but this change in FGF23 production was not observed in older hens. On the other hand, the ligands of FGF23 at the kidney level, FGFR2 and FGFR3, do not vary throughout the daily period of egg formation or with age of hens (Gloux et al., 2019). It is noteworthy that parathyroid cells in humans express both αKlotho and FGFRs, but the effect of FGF23 on the parathyroid gland (PTG) remains controversial (Goetz et al., 2012) and has not been yet explored in hens. In hens, the recommendation for dietary phosphorus has been largely decreased compared to 30 years ago because high levels negatively affect eggshell quality by an unknown process. FGF23 which is stimulated by high-dietary phosphorus and reduces the production of $1,25(OH)_2D_3$ might explain this negative impact of phosphorus on shell quality as suggested by the negative correlation between shell quality and plasma levels of phosphorus during the period of shell calcification (Sauveur and Mongin, 1983).

FGF23 might have physiologically functions on human bone mineralization, as suggested by its powerful inhibitory

effect on transcription of tissue nonspecific alkaline phosphatase (TNAP) mRNA in bone cells in a Klotho-independent manner (Murali et al., 2016). TNAP is essential for the regulation of bone mineralization by cleaving the mineralization inhibitor pyrophosphate, which is secreted by osteoblasts, to prevent premature mineralization of osteoid (Addison et al., 2007). Locally produced FGF23 may also serve as a physiological inhibitor of bone mineralization by downregulating TNAP expression. This possibility has not been yet explored in birds.

32.4.3 Parathyroid hormone and related peptides

32.4.3.1 Chemistry, secretion, and function of parathyroid hormone

The principal role of PTH is to regulate blood calcium concentration and to maintain calcium homeostasis. This system has been reviewed by many authors in humans and mice (Jüppner et al., 2000; Potts, 2005; Guerreiro et al., 2007), and in hens (Hurwitz, 1989b; Dacke, 2000; Dacke et al., 2015). Parathyroidectomy in birds leads to hypocalcemia, tetany, and death (Kenny, 1986), and reciprocally, PTH injections into birds increases plasma Ca levels (Kenny and Dacke, 1974), this effect being larger in laying birds. Changes in plasma Ca^{2+} concentrations are detected by the CaSR, which is expressed by the PTG chief cells that also store and secrete PTH (Hurwitz, 1989b). Increases in plasma Ca^{2+} levels lead to increased expression of the CaSR gene. Its expression in the PTG appears therefore to be inversely associated with changes in plasma Ca^{2+} (Yarden et al., 2000). However, it remains stable throughout the laying cycle in hens (Gloux et al., 2020a). CaSR is also expressed in bone and kidney (Courbebaisse and Soubervielle, 2011), and contributes to the physiological responses of these organs to maintain Ca homeostasis. Two (chicken) to four (Japanese quail) PTGs are present in birds, near the thyroids (Dacke et al., 2015). Sequences of mammalian forms of PTH and chicken PTH share structural homology and overlap in function (signal using the same G protein-linked receptor) (Potts, 2005). All mammalian PTH molecules consist of a single chain polypeptide with 84 amino acids and a molecular weight of approximately 9400 Da (Potts, 2005). The amino acid sequence deduced from the DNA sequence showed that chicken prepro-PTH mRNA encoded a 119 amino acid precursor and an 88 amino acid hormone (Lim et al., 1991). The sequence of chicken PTH shows significant differences in comparison with its mammalian homologs; for example, avian PTH contains two deletions in the hydrophobic middle portion of the sequence and an additional 22 amino acids near the C-terminus, which replaces the stretch of nine amino acids, residues 62 to 70, in the mammalian hormones (Potts, 2005). The amino terminal region of PTH is the minimum sequence necessary and sufficient for regulation of mineral ion homeostasis and shows high-sequence conservation among all vertebrate species (Jüppner et al., 2000). This 1−34 sequence is also present in the PTH-related peptide (PTHrP) and in a third PTH-like peptide (PTH-L) identified in chicken (Guerreiro et al., 2007; Pinheiro et al., 2010). These three peptides share the highly conserved N-terminal region, which controls Ca homeostasis and skeletal development. PTHrP and PTH-L shows a widespread and complex tissue distribution in vertebrates, which suggests their involvement in paracrine regulation (Pinheiro et al., 2010). Their role in non-mammalian vertebrates has not been fully explored.

The actions of PTH on mineral ion homeostasis in bone and kidney is mediated by a single receptor, the PTH-PTHrp receptor (PTHR1), which belongs to a distinct family of G protein-coupled receptors, as revealed by cloning in several species (Juppner et al., 2000; Potts 2005). This family of B receptors have a long amino terminal extracellular domain that is critical for binding peptide ligands such as PTH. The cloning of the receptor and studies of structure−activity relations with the PTH ligand and receptor has allowed the cellular biology of PTH action in various tissues to be explored (Jüppner et al., 2000; Potts, 2005; Courbebaisse and Soubervielle, 2011).

32.4.3.2 Regulation by parathyroid hormone of Calcium metabolism

The primary physiological role of PTH and its related proteins is to maintain in the short term the circulatory levels of ionic calcium. Hypocalcemia is detected by the PTGs and induces PTH secretion (Garabedian et al., 1972). When calcium is needed (calcium-deficient diet, vitamin D insufficiency, or eggshell formation), calcium is rapidly mobilized from bone, in particular medullary bone in laying birds, in response to increased PTH secretion. In addition, PTH stimulates calcium absorption over the longer term by increasing the synthesis of $1,25(OH)_2D$ in the kidney though activation of the 25-hydroxycholecalciferol-1−hydroxylase (Fraser and Kodicek, 1973). PTH also promotes phosphate excretion by blocking its reabsorption, leading to excretion of the phosphate excess liberated by bone resorption and reduces the excretion of urinary calcium by increasing renal calcium reabsorption at distal tubular sites in the kidney.

In bone, PTH has multiple catabolic and anabolic effects that affect the skeleton (Teitelbaum, 2000; Parra-Torres et al., 2013; Dacke et al., 2015). A number of cell lines of osteoblasts and stromal cells, utilizing specialized tissue culture systems, have evolved to study the interaction between different cell types and their role in bone formation and bone resorption (Potts, 2005). Through its abundant

receptors on osteoblasts, in contrast to osteoclasts, PTH has a variety of actions that are directly involved in promoting bone formation; however, physiologically, its most important role is to stimulate osteoclast differentiation and development and ultimately increase bone resorption. It has been shown in vitro that the maturation of macrophages into osteoclasts requires the presence of marrow stromal cells or their osteoblast progeny (Teitelbaum, 2000). Osteoclast differentiation is indirectly induced by osteoblasts that express the membrane-bound receptor for activation of nuclear factor kappa B (NF-kB) (RANK) ligand (RANKL) and macrophage colony-stimulating factor (M-CSF) (Teitelbaum, 2000). M-CSF binds to its receptor, c-Fms, on early osteoclast precursors, and provides signals required for their survival and proliferation. A direct contact between RANKL-expressing osteoblasts and RANK-possessing osteoclasts, and their progenitors, is essential for osteoclastogenesis during bone development (Yasuda et al., 1998). RANKL is also expressed in osteocytes at levels several-fold higher than in osteoblasts; therefore, osteocytes also control RANK-expressing osteoclasts during bone remodeling (Nakashima et al., 2012). This process is also regulated by a secreted decoy receptor of RANKL, osteoprotegerin (OPG), which functions as a paracrine inhibitor of osteoclast formation by competing with RANK for RANKL (Yasuda et al., 1998). Studies with avian systems confirm the critical role of RANK, RANKL, and OPG in birds (Dacke et al., 2015). Human recombinant RANKL has been shown to stimulate the resorptive activity of osteoclasts isolated from embryonic chick tibia (Boissy et al., 2001) and from bone marrow of Muscovy ducks (Gu et al., 2009). In hens, the hypercalcemic action of PTH is rapid (<30 min), firstly by inhibition of plasma Ca^{2+} clearance, followed by altering cell spread area in avian osteoclasts and by inducing the osteoclasts to form ruffled borders (Dacke et al., 2015). This effect was observed in vitro in osteoclasts located within hen medullary bone (Sugiyama and Kusuhara, 1994). Mechanisms of bone resorption by osteoclasts are similar in mammals and birds; a proton pump-ATPase and an Na^+, K^+-ATPase function in the ruffled border, and a CA and a Ca^{2+}-ATPase are located on the osteoclast plasma membrane. In laying hens, circulating PTH is implicated in the regulation of bone resorption, as evidenced by higher levels of circulating PTH during the period of shell formation, as demonstrated by a cytochemical bioassay (van de Velde et al., 1984a; Singh et al., 1986). This bioassay reflects activity of the 1−34 sequence, whatever its origin (PTH, PTHrP, or PTH-L), but was not observed in a recent study (Ren et al., 2019). However, an increased expression of PTH mRNA was also observed in the PTG during this active phase of eggshell formation (Gloux et al., 2020a). More detailed information on the role of PTH in other tissues including kidney, intestine, uterus, and smooth muscle have been reviewed by Dacke et al. (2015).

32.4.4 Calcitonin and calcitonin gene-related peptides

CT is a 32-amino acid polypeptide hormone secreted by the parafollicular cells (C-cells) of the thyroid gland in mammals and by the ultimobranchial tissue in avian and other nonmammalian species (Felsenfeld and Barton, 2015; Dacke et al., 2015; Xie et al., 2020). In humans, CT is released when plasma Ca^{2+} levels increase, and protects against the development of hypercalcemia. The secretion of CT is modified by the CaSR, as observed for PTH, but, while activation of the CaSR suppresses PTH secretion, it stimulates CT secretion. Both hormones also act on bone and kidney through receptors of the class II subclass of G-protein-coupled receptors. CTR expression is observed in the kidney, mature osteoclasts, and other tissues, and it interacts with receptor modifying proteins to form an active complex (Xie et al., 2020). CT administration decreases the magnitude of hypercalcemia during calcium loading in humans (Felsenfeld and Barton, 2015); however, birds are refractory to CT administration (Dacke et al., 2015). This hypocalcemic effect in mammals is attributed to inhibition of bone resorption by reducing osteoclast activity and to suppression of calcium release from the bone. In addition, CT increases renal production of 1,25D in the convoluted proximal tubule (Felsenfeld and Barton, 2015). Reciprocally, CT gene transcription is suppressed by $1,25(0H)_2D_3$. There is therefore evidence that CT administration in human is effective; however, since its discovery more than 50 years ago, there is no evidence that any deficiency or excess of CT observed in various human pathologies results in skeletal abnormalities. Calcium metabolism and bone mineral density are not affected in patients with medullary thyroid carcinoma with a chronically increased level of endogenous CT, or in thyroidectomized individuals with undetectable circulating CT (Xie et al., 2020). A precise role for CT remains elusive in humans and its function in nonmammalian vertebrates is even less understood (Felsenfeld and Barton., 2015). However, others still consider that under calcium stress conditions, CT might play a vital role in protecting the skeleton (Xie et al., 2020) because CT suppresses the bone disruption process in CT-deficient mice, as compared to wild-type mice. Dacke et al. (2015) reviewed some evidence in birds showing that in vitro CT can affect osteoclasts from Ca-deficient chicks. Cultured medullary bone osteoclasts from these birds respond to CT administration by a reduction in cell spread area, and by inhibiting the bone-resorptive activity or by suppressing ruffled borders. However, there is also experimental evidence that might explain why CT is not efficient in vivo to

correct hypercalcemia in birds. Dacke et al. (2015) concluded that CT plays a minor role in regulating Ca metabolism in birds. The difference between effects of CT on bone cells in vitro and in vivo in human, as well as the large variation in response between different species, brings into question the role of CT in Ca metabolism, particularly in birds.

Additional CGRPs, including CGRPs (alpha CGRP and beta CGRP), amylin, adrenomedullin, and intermedin, also contribute to bone regulation. In vitro and in vivo studies concluded that there were no inhibitory effects on osteoclasts and bone resorption and observed positive effects on osteoblasts and bone formation in mice and human. More information on their putative functions in mammals can be found in recent reviews (Naot et al., 2019; Xie et al., 2020). In birds, the roles of CGRP and amylin have been described by Dacke et al. (2015). CGRP is a 37 amino acid neuropeptide derived from the same gene as CT (amylin superfamily) and is expressed in many tissues of the central nervous system, including neurons innervating bone. CGRP might interact with osteoclastic CT receptors suggesting a paracrine role in modulation of bone turnover. A few studies show that CGRP in vivo elicits hypercalcemic and hypophosphatemic responses in chicks (Dacke et al., 2015), but very little experimental work has been carried out in birds and CGRP involvement in regulation of Ca metabolism remains hypothetical.

32.5 Intestinal absorption of calcium

32.5.1 Mechanisms of intestinal calcium absorption

Body calcium is ultimately derived from the diet, and intestinal absorption is therefore critical for calcium balance. Intestinal calcium uptake occurs in mammals through two defined mechanisms, a nonsaturable paracellular transport pathway, which results from passive diffusion and an active transcellular pathway (Courbebaisse and Soubervielle, 2011; Ghishan and Kiela, 2012; Christakos et al., 2014, 2019). High-dietary intake of calcium enables absorption by passive transport, but in humans, the dietary supply of calcium content is in the low−normal range, and the active transcellular pathway is required. This process occurs in the proximal part of the intestine (duodenum and jejunum) which shows a greater capability for calcium absorption than the distal segment. However, net calcium absorption might still be predominant in the ileal segment by passive absorption (up to 80%) due to the long-transit duration (Wasserman, 2004). Similarly, in birds, the intestinal absorption of calcium is controlled by these two distinct transport processes (Hurwitz, 1989a; Bar, 2009; Nys and Le Roy, 2018). In chicks and hens, the proximal intestine shows a high efficiency to absorb calcium, as demonstrated by direct measurement of Ca absorption using Yttrium-91 or Ca-45 (Hurwitz and Bar, 1966; Bar, 2009). The duodenum has a higher capacity for Ca absorption than the jejunum, but the transit duration is longer in the jejunum due to its greater length. In birds, most of the calcium is therefore absorbed before it reaches the lower ileum, as a result of the higher efficiency of the proximal intestine in absorbing Ca^{2+}, and of the lower ileal electrochemical potential difference (Bar, 2009). The high magnitude of calcium absorption (threefold greater in mature hens than in immature pullets), the huge increase in intestinal calbindin 28kD concentration in laying hens, the high correlation of calbindin with the capacity to absorb calcium, and the stimulation by vitamin D metabolites of key proteins involved in the transcellular pathway (Bar, 2009; Nys and Le Roy 2018), all underline the importance of the active cellular process in calcium absorption in hens. However, the paracellular pathway, which is stimulated by a favorable gradient of Ca^{2+} concentration between the intestinal and plasma compartments, might contribute to the large daily increase in Ca retention observed during the eggshell formation period (Hurwitz and Bar, 1965), as this is consistent with the higher levels of solubilized calcium in the intestinal lumen (Guinotte et al., 1995). The larger concentration of solubilized Ca in the intestinal content of the proximal intestine results firstly from the large intake of dietary calcium due to a specific appetite for calcium a few hours before shell formation (Mongin and Sauveur, 1974; Wilkinson et al., 2011), and secondly from the stimulation of acid secretion induced by dilatation of the crop a few hours before nightfall (Mongin, 1976). Inhibition of acid secretion by omeprazole (inhibitor of H^+, Na^+-ATPase) reduces net calcium intestinal retention by 20%, confirming the importance of the calcic gradient (Guinotte et al., 1995). The use of dietary calcium with a large particle size reinforces the supply of calcium for a longer period in the intestinal content, and reduced the gap between the intestinal supply of Ca and its uterine exportation for the eggshell formation, which mainly take place during the night. The use of large particles of dietary Ca is therefore very frequent in practical conditions and is well known for more than 50 years to improve shell strength (Nys, 2017). In conclusion, both passive and active processes in hens contribute to optimize the Ca retention needed for shell formation.

Both mechanisms of Ca absorption, the transcellular active transport and the paracellular nonsaturable passive pathway, are regulated by 1,25 dihydroxyvitamin D3 and have been biochemically characterized in mammals and birds (Christakos et al., 2014, 2019; Bar, 2008; Nys and Le Roy, 2018). The active transcellular calcium absorption involves the transfer of calcium across the luminal brush border membrane, through the cell interior and its extrusion from the basolateral membrane. In mammals

(Wasserman, 2004; Christakos et al., 2014, 2019), calcium entry occurs through the epithelial calcium-selective channel TRPV6 (transient receptor potential cation channel subfamily V member 6). It belongs to a super-family of cation channels (>30 different TRP subunit genes proteins in six subfamilies in mammals). TRP channels operate either as primary detectors of chemical and physical stimuli, as secondary transducers of ionotropic or metabotropic receptors, or as ion transport channels (Zheng, 2013; Alaimo and Rubert, 2019). Functional TRP channels, thought to be composed as homo- or heterotetramers, are opened or closed by conformational changes in the channel protein (Holzer, 2011). TRPV5 and TRPV6 are the most Ca^{2+}-selective members of the TRP ion channel family and play an important role in intestinal or kidney Ca^{2+} transfer in mammals (Holzer, 2011). TRPV6 is however predominantly expressed in intestinal epithelial cells while TRPV5 is more present in the kidney (Nijenhuis et al., 2005; Ko et al., 2009). TRPV6 has been identified by some authors (Yang et al., 2011; Jonchere et al., 2010, 2012; Huber et al., 2015; Li et al., 2018) in the intestine of the laying hen, but was not detected by others (Proszkowiec-Weglarz and Angel, 2013; Juanchich et al., 2018; Proszkowiec-Weglarz et al., 2019; Gloux et al., 2019). An immunoreactive TRPV6 protein was however revealed in the chicken small intestine by Western blotting (Huber et al., 2015). Additional TRPVs (TRPV2 but not TRPV5), TRPM7, and TRPC1 genes are expressed in the various part of the intestine of laying hens (Li et al., 2018; Gloux et al., 2019). A summary of ionic transporters in hen intestine is presented in Figure 32.7, and a list of putative ionic transporters in the intestine are reported in Table 32.1.

Following its entry, calcium accumulates within several minutes in the subapical brush border (Fullmer and Wasserman, 1987; Chandra et al., 1990). Cytosolic calbindin (9K in mammals, 28 kD in chicken) binds calcium with high affinity and facilitates the transcytosolic diffusion of calcium from the subapical zone to the basal membrane as reviewed by numerous authors (Wasserman, 2004; Ghishan and Kiela, 2012; Christakos et al., 2014, 2019; Hurwitz and Bar, 1989; Bar, 2009; Nys and Le Roy, 2018). Calbindins are present at high levels in all tissues that transfer large amount of Ca, including intestine and uterus (Wasserman and Taylor, 1966; Corradino et al., 1968). Its presence is considered to be a biomarker for regulated Ca transfer, since calbindin concentration is well correlated with the capacity of a tissue to transfer Ca. Ca may also be sequestered by the endoplasmic reticulum (ER) to prevent increased levels of intracellular calcium in the enterocyte (Christakos et al., 2014). Genes of the ITPR family, which are involved in Ca^{2+} extrusion from the ER, are expressed and modulated by sexual maturity in laying hens (Jonchere et al., 2012; Gloux et al., 2019). The intestinal plasma

membrane ATPase (ATP2B1 also called PMCA1b), along with the Na^+/Ca^{2+} exchangers (SLC8A1 or NCX1), performs the final step in transcellular Ca_2 absorption, extruding Ca^{2+} from the cell interior to the interstitial space at the basolateral membrane (Stafford et al., 2017). PMCA1 (ATP2B1) is the only isoform present in enterocytes throughout the human or mouse intestine and its expression is higher proximally in the duodenum than in the jejunum or ileum (Alexander et al., 2015); expression levels are positively correlated with both intestinal Ca^{2+} absorption and bone mineral density in mice (Replogle et al., 2014). PMCA1b is also the predominant isomer expressed in the chicken intestine (Melancon and DeLuca, 1970; Bar, 2009; Jonchere et al., 2012; Brionne et al., 2014).

The Na^+/Ca^{2+} exchange mechanism (NCX, SLC8A) is the alternative transporting system involved in the "uphill" extrusion of Ca^{2+} across the basolateral membrane of the epithelial cell, toward the plasma (Bar, 2009; Liao et al., 2019). The NCX family contains three separate gene products exhibiting differential expression; NCX1 (SLC8A1) is mainly expressed in all organs of the digestive system, while NCX2 and NCX3 are expressed in the nervous system and skeletal muscle (Liao et al., 2019). Na^+/Ca^{2+} exchange activity is increased in response to calcium deficiency in chick enterocytes (Centeno et al., 2004). In laying hens, both NCX1 (SLC8A1) and NCX3 (SLC8A3) are expressed in the duodenum at a level quite similar to that of the uterus (Jonchere et al., 2012). The relative expression of both genes cannot be compared in this transcriptomic approach, but by analogy with mammals, it is likely that NCX1 predominates, and that PCMA is more active than NCX1 to extrude Ca^{2+}.
