The paracellular pathway occurs between adjacent enterocytes (Figure 32.7). The most apical region of the intercellular junction is the tight junction (TJ). The barrier function and the permeability characteristics of epithelial cell sheets covering different organs are defined by the properties of the TJ and their paracellular channels (Gunzel and Yu, 2013; Alexander et al., 2014). TJs are predominantly formed by claudins, a family of four-transmembrane proteins with 27 members in human and mouse (Van Itallie and Anderson, 2014; Zeisel et al., 2019). The physiological properties of TJs allow selective transport of solutes and water between compartments, which mainly depends on the specific subtypes of claudins that they contain. These membrane proteins function as paracellular cation channels. Overexpression of claudin 2 (CLDN2) or CLDN12 enhances Ca transfer through intestinal epithelial cells in vitro (Fujita et al., 2008). TJs contain numerous additional proteins, among them transmembrane proteins including the junctional adhesion molecule (JAM), occludin (OCLN), and tricellulin. In addition, some cytoplasmic plaque proteins (Zonula occludens, ZO-1, 2, and 3, also called TJ proteins −1, 2, and 3) are framework-forming proteins that connect transmembrane proteins with the actin cytoskeleton (Van Itallie and Anderson, 2014; Zihni et al., 2016; Zeisel et al., 2019). In laying hens, expression of CLDN1, 2, 10, and 12, of TJP 1, 2, and 3, of OCLN, and of JAM2 are observed in duodenum, jejunum, and ileum (Gloux et al., 2019, 2020a). Only expression of CLDN2 and 10, OCLN, and JAM2 are affected by age or intestinal location. Expression of CLDN2 and TJP-1, 2, 3 (ZO1, 2, 3) is higher in intestine of mature hens compared to that of immature pullets (Gloux et al., 2019). Expression of CLDN2 and TJP3 is also slightly increased during the period of shell calcification (Gloux et al., 2020). Expression of both these genes and of OCLN is decreased in aged hens compared to young ones (Gloux et al., 2020). These observations confirm the relative importance of the transcellular to the paracellular Ca uptake pathway in laying hens.

32.5.2 Regulation of Calcium absorption in laying hens

Vitamin D and its metabolites, mainly $1,25(OH)_2D_3$, are the key factors regulating intestinal Ca^{2+} absorption in mammals and birds (Bouillon et al., 2003; Wasserman, 2004; Bouillon and Suda, 2014; Christakos et al., 2014, 2019; Diaz de Barbosa et al., 2015; Hurwitz, 1989a; Bar, 2008; Nys and Le Roy, 2018). In hens, sexual maturity and the egg production period coincide with a large increase in renal production and plasma $1,25(OH)_2D_3$. This large increase in levels of $1,25(OH)_2D_3$ is responsible for the large stimulation in net absorption of calcium (Bar et., 1978; Hurwitz, 1989a: Nys, 1993; Bar, 2008; Nys and Le Roy, 2018; Gloux et al., 2019). The active form of vitamin D binds to the intracellular receptor vitamin D receptor (VDR), which also interacts with retinoic X receptor (RXR), to form a VDR-RXR complex for binding with a specific vitamin D receptor element (VDRE) sequence of the targeted genes in the gene-promoter region; this stimulates the synthesis of mRNAs coding for several proteins (Schräder et 1993; Dong et al., 2010; Bar, 2008). The coupled $1,25(OH)_2D_3$ + VDR has been purified from the chicken intestine (Pike and Haussler, 1979) and is expressed in all intestinal segments (Gloux et al., 2019, 2020a), although less expressed in aged hens (Gloux et al., 2020b). This stimulates the permeation of calcium ions across the apical surface of enterocytes, as well as its cytosolic transport and extrusion from the cell (Wasserman et al., 1992). VDREs were identified in the promoters of genes encoding TRPV (Weber et al., 2001), calbindins (Christakos et al., 2014; Nys and Le Roy, 2018), and PMCAs (Glendenning et al., 2000).

TRPV6 expression is stimulated by low-dietary calcium and by $1,25(OH)_2D_3$ in mammals (Nijenhuis et al., 2005). TRPV6 is expressed at a lower level in the duodenum than in uterus (Jonchère et al., 2012). However, more recent

studies question the role of TRPV6 as they were unable to find any expression in the intestine (Gloux et al., 2019, 2020). However, changes in expression of other calcium TRP channels are observed in hens: TRPM7 and TRPC1 expression increase with age (Gloux et al., 2019), that of TRPV2 varies with intestinal localization and in response to Ca diet (Gloux et al., 2020), and expression of TRPM7 and TRPV2 is down-regulated in old hens compared to young ones (Gloux et al., 2020b); these observations suggest a possible involvement of these additional Ca channels in enterocyte Ca entry in hens.

Calbindins were intensively studied for their dependence on 1,25-$(OH)_2D_3$ (Wasserman et al., 1992; Wasserman, 2004; Christakos et al., 2014, 2019; Bar, 2009). In chickens, calbindin 28kD has been extensively investigated because of its high levels observed in epithelia transporting large amounts of calcium. The epithelial capacity to transfer calcium is highly correlated with calbindin content (Wasserman et al., 1966; Bar and Hurwitz, 1979). In vitamin D deficient chicks, CALB1 mRNA is barely detectable in the intestine (Theofan et al., 1986; Mayel-Afshar et al., 1988) and is increased approximately 10-fold after injection of $1,25(OH)_2D_3$. Calcium is rapidly (5 to 20 min) transferred from the intestinal lumen to the epithelium through the apical surface of enterocytes and accumulates at the subjacent apical zone when vitamin D is deficient. When supplied with vitamin D, calcium is transferred from the subapical region to the basal zone of the cells via calbindin (Chandra et al., 1990). Duodenal calbindin levels are correlated with changes in $1,25(OH)_2D_3$ plasma levels, whether induced by restrictions of dietary Ca^{2+} or by exogenous supply of vitamin D derivatives in young chicks (Wasserman and Taylor, 1966; Bar et al., 1990), or when egg production is induced or interrupted (Bar et al., 1978; Nys et al., 1992a; Sugiyama et al., 2007). In chickens, increased concentrations of plasma $1,25(OH)_2D_3$, increases in intestinal absorption of calcium and increases in concentration of intestinal CALB1 and its mRNA are all observed to occur at two time points: at the onset of laying after the hen becomes sexually mature, and at the time of the formation of the first eggshell (Bar et al., 1978; Nys et al., 1992a; Striem and Bar, 1991). When immature birds are not deficient in vitamin D, administration of estrogen and testosterone stimulates the synthesis of intestinal calbindin (Nys et al., 1992a; Striem and Bar, 1991). However, the largest increase in calbindin levels is associated with the onset of egg and shell formation. Induction of the production of shell-less eggs by premature expulsion of the egg for a few days decreases the intestinal level of calbindin by 50%, while resumption of shell formation stimulates levels of calbindin protein and its mRNA abundance (Nys et al., 1992a). The decreased calbindin level and mRNA expression does not occur in the few hours following egg expulsion but after a few days in the intestine in contrast to

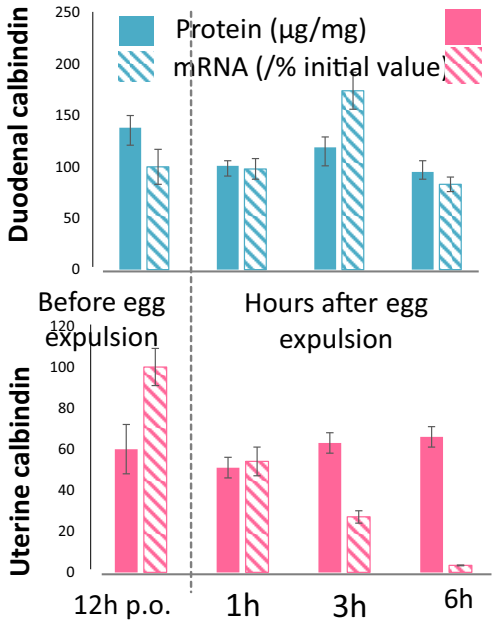

FIGURE 32.8 Level of expression and concentration of duodenal and uterine calbindin in hens during the initial phase of shell mineralization of the shell and 1, 5, and 6 h after experimental expulsion of the egg to suppress the shell formation Nys et al., 1992a.

uterus (Figure 32.8). Arrest of egg production in molted hens also reduces the intestinal concentration of calbindin (Bar et al., 1992). These changes in calbindin levels are synchronized with those of plasma $1,25(OH)_2D_3$. However, hourly changes in plasma $1,25(OH)_2D_3$ observed during the daily cycle of egg formation, or alterations induced by suppression of shell formation by egg expulsion, have no influence on mRNA expression of intestinal calbindin nor on the concentration of the protein (Nys et al., 1992a; Gloux et al., 2020a).

Extrusion of calcium from the enterocyte through the PMCA1 is also vitamin D dependent. PMCA1 (ATP2B1) expression is stimulated by the metabolite 1,25-$(OH)_2D_3$ in mice and chickens (Lee et al., 2015) or by factors influencing its metabolism in chicks (Wasserman et al., 1992). The PMCA pump (ATP2B1) is expressed at a higher level in the duodenum compared to the uterus during the active phase of calcium secretion (Jonchère et al., 2012). In hens, ATPase plasma membrane Ca^{2+} transporting 1 (ATP2B1) and ATPase plasma membrane Ca^{2+} transporting 2 (ATP2B2) are expressed in all intestinal segments at different ages; however, only ATP2B2 expression is greatly enhanced after sexual maturity in the duodenum, jejunum, and ileum (Gloux et al., 2019). PMCA1 (ATP2B1) was slightly increased during the daily period of shell formation in young hens, but not in older birds (Gloux et al., 2020a, 2020b). However, the Ca^{2+}-ATPase activity when measured globally was similar in the duodenum of hens calcifying an egg compared to hens laying shell-less eggs

(Nys and de Laage, 1984). The role of sex steroids in the regulation of duodenal PMCA1 is confirmed by stimulation of its expression by estrogens, and by the observation that ovariectomized rats and mice display reduced PMCA1 mRNA (Dong et al., 2014; Van Cromphaut et al., 2003). Moreover, an estrogen response element (EREF) is present in the ATP2B1-2 gene, in addition to a VDRE (Nys and Le Roy, 2018). No information is available on the regulation in birds of intestinal Na^{+}/Ca^{2+} exchangers (NCX1).

It has been suggested that vitamin D might also stimulate paracellular calcium absorption, as observed in mammals (Wasserman, 2004; Christakos et al., 2014). In hens, the paracellular pathway is of importance due to the large dietary consumption of Ca. Recent experimental evidence confirms this hypothesis. The expression of CLDN2 and of three TJ protein mRNAs (TJP 1,2,3 corresponding to ZO 1,2,3) in duodenum were observed to increase with age of the hen (12−23 wks) and to be highest in mature hens (Gloux et al., 2019). CLDN2 expression also increases in the jejunum between 17 and 23 wks of age and was slightly higher during the final period of shell formation (Gloux et al., 2020a). In contrast, CLDN10 decreased and exhibited a higher level of expression in ileum at sexual maturity (Gloux et al., 2019). In aged hens, the expression of CLDN2 and of the anchoring protein (TJP3) were downregulated, as was the VDR gene, suggesting a decreased efficiency in paracellular Ca transfer with increased age (Gloux et al., 2020b). Expression of other candidates involved in the paracellular pathway, claudin 1 and 12, JAM and OCLN, were not affected by sexual maturity nor by age of the hens (Gloux et al., 2020b).

In conclusion, numerous ionic transporters have been now identified in the hen intestine, but no hierarchy has yet been established on the relative roles of these candidates, within a family or between families of a particular ionic transporter (channel, pump, or exchanger). The role of vitamin D metabolites on expression of TRPV, calbindin and PMCA for the transcellular pathway and of some CLDNs and TJPs for the paracellular transfer is demonstrated in hens but remains to be characterized for additional proteins involved in calcium absorption.

32.6 Medullary bone

32.6.1 Structure and composition

One of the most relevant physiological adaptations that female birds have developed to facilitate an adequate supply of calcium for eggshell mineralization is the development of medullary bone, which can be more easily resorbed to release calcium (Dacke et al., 1993, 2015; Nys and Le Roy, 2018). Medullary bone (Figure 32.9) is a special type of bone formed within the marrow cavities of long bones of female birds during reproduction (Bloom et al., 1941, 1958; Van de Velde, 1984b, 1985; Whitehead, 2004; Kerschnitzki et al., 2014; Rodrõguez-Navarro et al., 2018). The formation of medullary bone starts about 2 weeks before laying of the first egg at sexual maturity and is associated with higher levels of plasma estrogen and vitamin D active metabolite (Figure 32.5). High-estrogen levels produce a dramatic change in bone biology, causing osteoblast function to switch from producing cortical and trabecular bone to forming medullary bone (Hudson et al., 1993; Whitehead, 2004). Medullary bone partially fills the marrow space (endosteal cavities) of long bones (tibia, humerus, femur), causing a 20% increase in skeletal weight before the commencement of egg laying. However, during the laying period, osteoclasts continue to resorb cortical and trabecular bone, resulting in a progressive reduction of the amount of structural bone and increased bone porosity (Figure 32.10). The loss of structural bone is associated with a higher accumulation of medullary bone, therefore the total amount of bone is maintained at a nearly constant level. Nevertheless, the loss of cortical bone induces a general weakening of the skeleton over the intensive laying period, causing hens to suffer a high incidence of bone deformation and fractures (especially in the keel); this is a mayor welfare problem that also has an important economic impact on egg producers (Fleming et al., 2006). The medullary bone is deposited by osteoblasts and represents about 11.7% of total bone calcium. It is a nonstructural type of woven bone consisting of a system of bone spicules that grow out from endosteal surfaces and may completely fill the marrow spaces (Dacke et al., 1993). Thus, medullary bone has no major mechanical function and is distinct from the cancelous bone, which is concentrated toward the metaphysis/epiphysis and has a mechanical functionality dependent upon the integrity of the intact long bone structure.

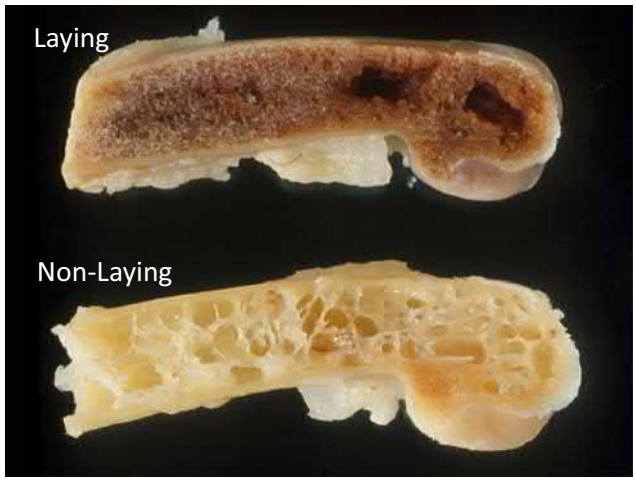

FIGURE 32.9 Images showing the presence of medullary bone in hens by comparing transverse section of the tibia of nonlaying and laying hens. *Image courtesy of the Roslin Institute & R(D)SVS, University of Edinburgh, Scotland.*

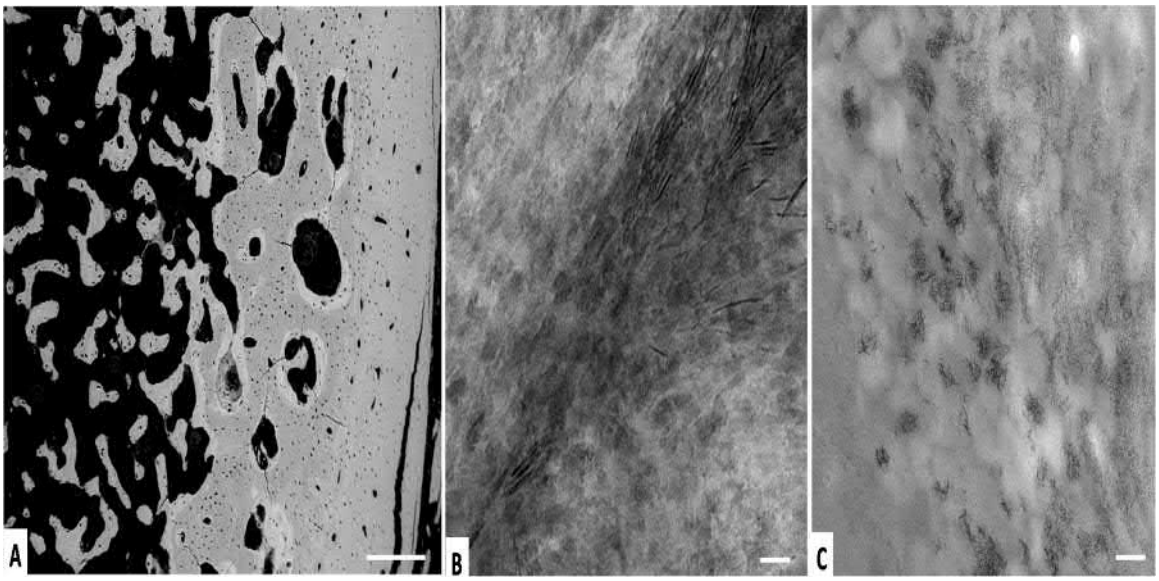

FIGURE 32.10 (A) Scanning electron microscope image of the tibia cross-section showing cortical bone (right) with large resorption centers and medullary bone (left) formed by isolated mineral trabecula. (B) Transmission electron microscopy (TEM) image of cortical bone showing oriented apatite crystals mineralizing a collagen matrix. (C) TEM image of medullary bone showing bundles of randomly oriented apatite crystals mineralizing a non-collagen matrix. Scale bars: (A) 100 μm; (B–C) 200 nm (Dominguez-Gasca et al., 2019).

Cortical bone is constituted by aligned collagen fibrils mineralized by apatite crystals oriented with their c-axis parallel to the fibrils. In contrast, medullary bone is less organized. It is formed by isolated mineral spicules or trabecula. The spicules contain osteocytes and are surrounded by a large number of osteoblasts and osteoclasts. Internally, these spicules contain collagen fibers that run in all directions. Apatite crystals of very small size cover the collagen fibrils and mineralize an extracellular organic matrix in the interfibrillar space consisting mainly of non-collagenous proteins, glycoproteins, and proteoglycans (Ascenzi et al., 1963; Bonucci and Gheraldi, 1975). This mineralization consists of ribbon-shaped apatite crystals distributed in separated bundles or foci that resemble the early stages of embryonic bone mineralization (Figure 32.10).

The mineral part of medullary bone is made of nano-crystalline carbonate-apatite (calcium phosphate), similar to cortical bone (Ascenzi et al., 1963). However, it also contains a small fraction of calcite ($CaCO_3$) as a separated mineral phase (Lörcher and Newesely, 1969). The presence of other more soluble and reactive mineral phases such as calcite and possibly noncrystalline mineral phases (amorphous $CaCO_3$ or calcium phosphate) could explain the extremely high reactivity of this form of labile bone and its main functionality as a source of calcium for the rapid calcification of the eggshell. Its solubility is at least 30-fold greater than that of cortical bone (Dominguez-Gasca et al., 2019). The high solubility of medullary bone mineral is due to its greater surface area, lower crystallinity, greater carbonate content, and organic matrix composition. The high-mineral solubility, together with its intense vascularization and spicule concentration of bone cells, explains why medullary bone can be metabolized at a much higher rate than cortical bone. While cortical bone turnover can take several months, medullary bone is turned over in only three days (Van de Velde, 1984b, 1985). Moreover, the composition of its organic matrix is believed to favor the rapid mineralization/demineralization of medullary bone.

Medullary bone cell activities are synchronized with the 24-hour egg-laying cycle (Figure 32.11). During eggshell calcification, there is an intense osteoclastic resorption of medullary bone, followed by an intense osteoblastic activity that forms new medullary bone before the beginning of the next cycle of eggshell formation (Van de Velde, 1984b, 1985). In laying hens, the medullary bone is in continuous activity throughout every stage of the egg-laying period, although osteoclast activity increases during calcification of the shell. Medullary bone serves as a calcium reservoir for eggshell calcification when calcium from the diet is exhausted (during the night) (Dacke et al., 1993; Van de Velde, 1985; Whitehead, 2004). It can be mobilized to provide 40% of the required calcium to the eggshell daily, or up to 60% when hens are fed a low-calcium diet. Taylor and Moore (1954) showed that hens on a calcium deficient diet can mobilize up to 38% of skeletal calcium before egg laying ceases. Regarding its mechanical properties, even though it is less dense and structurally weaker than cortical bone, medullary bone still contributes significantly to the overall strength of bone

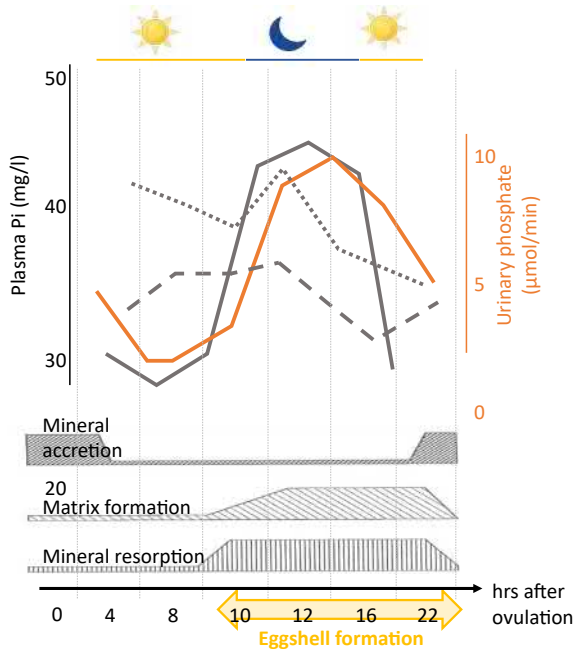

FIGURE 32.11 Plasma levels of inorganic phosphorus and urinary excretion of phosphorus during the laying cycle or in cokerel (dashes). Shell formation occurred 10–22 h after yolk ovulation in the oviduct. Laying hens were fed 3.5% dietary calcium, as fine (continuous line)or coarse particles of calcium carbonate (dotted line). Urinary calcium was sampled in hens fed fine particle calcium (3.5%). During the night (no food intake), the hen mobilize more Ca from the bone when fed fine particle compared to coarse one (Nys and Le Roy, 2018).

(Fleming et al. al., 2006; Rodrõguez-Navarro et al., 2018). In fact, the amount of medullary bone mineral has a large genetic correlation with tibia bone breaking strength (Dunn et al., in press, 2020). Additionally, the large amount of medullary bone that accumulates near the endosteal bone surfaces can also protect cortical bone against osteoclast resorption.

32.6.2 Regulation of medullary bone formation and resorption

32.6.2.1 Induction and maintenance of medullary bone by sex steroid hormones

Avian medullary bone probably represents the most estrogen-sensitive of all known vertebrate bone types, as gonadal steroids are absolutely essential for the induction and maintenance of medullary bone in egg-laying birds (Simkiss, 1967; Whitehead, 2004; 2015; Squire et al., 2017). In laying hens, the secretion of androgens and estrogens increases at sexual maturity. These gonadal hormones have a synergistic action on medullary bone formation, which can also be induced in male birds by estrogen treatment (Whitehead, 2004; Simkiss, 1967; Squire et al., 2017). Estrogens induce differentiation of endosteal cells to form osteoblasts and decrease the number of osteoclasts and their activity on the endosteal surface (Ascenzi et al., 1963; Miller and Bowman, 1981). Estrogen receptors are present in medullary bone osteoblasts (Ohashi et al., 1991) and osteoclasts (Oursler et al., 1993). In laying hens fed a calcium deficient diet, the medullary bone shows a large increase in the osteoblast population, the osteoclasts being substituted by osteoblasts on the trabecular surface (Zambonin-Zallone and Mueller, 1969). In addition, the percentage of medullary bone in the skeleton increases because of the depletion of cortical bone, which reveals the priority for medullary bone in reproductive hens (Dacke et al., 2015). However, the balance between the two types of bone and severity of bone loss depends on the duration of a calcium and vitamin D deficiency; clearly a reduction in dietary calcium and vitamin D has negative effects on bone mineralization (Dacke et al., 2015).

Bone is a metabolically active calcified tissue in a constant state of remodeling. Bone mineralization/demineralization is regulated by a complicated array of feedback processes under the control of specialized hormones related to calcium homeostasis (PTH, vitamin D). It has been well established that vitamin D contributes to bone mineralization in mammals (Pike et al., 2014; Christakos, 2014, 2019), partially by the activation of osteoblastic activity and also by the induction of bone protein synthesis. Vitamin D is clearly a key element for bone mineralization in growing chickens, but also in hens, even if medullary bone formation appears to be a priority relative to cortical bone in sexually mature hens. Vitamin D will globally contribute to the supply of calcium and phosphorus to facilitate bone mineralization, and more specifically, it will stimulate the synthesis of certain bone matrix proteins, as demonstrated for osteocalcin and osteopontin (OPN). Osteocalcin (OC) (bone γ-carboxy-glutamic acid protein) is the most abundant noncollagenous protein associated with the mineralized matrix of bone (Price, 1985). It has the ability to bind calcium, and it shows adsorption affinity for hydroxyapatite (Hauschka et al., 1989). This noncollagenous protein also plays a role in bone resorption because of its implication in the differentiation of osteoclasts (Ishida and Amano, 2004). OPN (SPP1) is a glycosylated, highly phosphorylated protein initially identified in bone and also present in eggshell (Chien et al., 2008; Hincke et al., 2008). In bone, SPP1 is considered to influence the migration and maturation of osteoclast precursors, the attachment of osteoclasts to the mineral phase of the bone, and osteoclast activity. $1,25(OH)_2D_3$ stimulates OC (Lian and Stein, 1992) and OPN (Noda et al., 1990) synthesis in osteoblast cell culture by binding to specific vitamin D-response promoter elements to enhance their gene transcription. However, OC synthesis, in contrast to calbindin, is modulated by, rather than dependent upon, vitamin D since there is substantial OC synthesis in vitamin D-deficient chicks. It has been shown that medullary bone

contains multiple isoforms of bone sialoprotein (BSP), OPN, osteonectin, OC, and dentin matrix protein-1 (Wang et al., 2005). Another particularity of medullary bone compared to cortical bone is the presence of large amounts of a keratan sulfate (KS) proteoglycan (KSPG). The core protein of KSPG is BSP (Hadley et al., 2016), which plays a key role in bone mineralization and remodeling (Staines et al., 2012). It was shown previously that KS is the major proteoglycan in medullary bone rather than chondroitin sulfate (Fisher and Schraer, 1980; Hunter and Schraer, 1983). Therefore, Hadley et al. (2016) have proposed that plasma levels of KS are a specific biomarker for medullary bone metabolism and have demonstrated that it indeed fluctuates in synchrony with the egg-laying cycle.

In hens, matrix formation within medullary bone can be induced by sex steroids regardless of the vitamin D status of chicks, but its mineralization is observed only when vitamin D3 is administered together with the gonadal steroids (Takahashi et al., 1983). It is likely that vitamin D is a key element which favors osteoblast activity in both cortical and medullary bone; however, the balance between both tissues is modulated by sex steroids, possibly indirectly, through their effects on the general parameters of bone physiology(vasculature and larger exchange surface area) (van de Velde et al., 1984b; Dacke et al., 2015). In addition, it has been demonstrated that estrogens stimulate OC secretion in response to $1,25(OH)_2D_3$ in osteoblast-like cells by increasing VDR expression, which supports the involvement of vitamin D in medullary bone formation. OC is predominantly synthesized by osteoblasts, is partially released into the circulation and has a rapid turnover (Figures 32.5 and 32.6) (Nys et al., 1986; Nys, 1993). It therefore reflects osteoblast synthesis and provides an index of bone turnover in humans (Delmas, 1992). Its plasma variation has been explored in hens in various physiological situations associated with large changes in plasma $1,25(OH)_2D_3$ (Figures 32.5 and 32.6). Unexpectedly, in immature pullets treated with gonadal steroids or in laying hens, plasma OC is lower than that of immature pullets, in contrast to the higher levels of plasma $1,25(OH)_2D_3$ (Figure 32.5). In hens, daily changes in plasma OC levels, however, parallel those in plasma $1,25(OH)_2D_3$ when inducing variation in bone activity by feeding hens with low-calcium diet or by suppressing shell formation in hens fed normal high-calcium diet (Figure 32.6). It increases during the period of shell formation in hens fed a low-calcium diet with a very high level of $1,25(OH)_2D_3$ and decreases in hens laying shell-less eggs possessing lower plasma $1,25(OH)_2D_3$ levels Nys (1993). It is further stimulated in hens fed a low-calcium diet when bone is highly implicated in shell formation. Plasma OC corresponds to the period of bone matrix synthesis, but also coincides with the period of most active bone resorption (van de Velde et al., 1984b). Therefore, hen plasma OC levels reflect osteoblastic activity only during the daily laying cycle but not during the long-term changes that occur with sexual maturity. These observations might be because of large mobilization of OC in the tissue during intensive bone formation, it being trapped in bone and no longer secreted in the plasma. It is of interest to note that estrogens stimulate OC secretion in response to $1,25(OH)_2D_3$ in osteoblast-like cells by increasing VDR expression.

32.6.2.2 Role of parathyroid hormone in daily mobilization of medullary bone

In hens, medullary bone is considered to be a labile calcium reservoir because of the daily osteoblast/osteoclast remodeling which supplies calcium for shell formation during the period when no dietary calcium is available (Hurwitz, 1965; Dacke et al., 2015; Whitehead, 2004). Eggshell formation takes place mainly during the night, when the hens have to mobilize calcium from bone since dietary calcium has been exhausted. Thus, medullary bone serves as a calcium reservoir for eggshell calcification and buffers the supply of calcium in response to its cyclical requirement. Use of large $CaCO_3$ particles, which slows down intestinal calcium solubilization and provides a higher calcium intestinal supply throughout the night, reduces bone mobilization (Figure 32.11). This nutritional approach is intensively used in practical conditions for improving eggshell quality (strength and thickness). The large resorption of medullary bone during the period of shell formation is clearly demonstrated by the huge increase in plasma phosphorus and its excretion in urine observed in hens from 10 to 22 h postovulation (Figure 32.11; Prashad and Edwards, 1973), which coincides with the period of shell deposition Wideman et al. (1987). These changes are abolished when hens are laying shell-less eggs. van de Velde et al. (1984a) reported that bone resorption was increased ninefold during shell formation due to an increase in active osteoclasts and in the resorbing surface per active osteoclast (Figure 32.11). At the same time, osteoblasts deposited some matrix protein, contributing to bone accretion that was also activated twofold to renew the medullary bone. There is a lot of evidence demonstrating that this diurnal regulation of bone resorption is under the control of PTH (van de Velde et al., 1984a; Kerschnitzki et al., 2014; Dacke et al., 2015). PTH secretion is increased during the period of shell formation (van de Velde et al., 1984a; Singh et al., 1986; Kerschnitzki et al., 2014) because of lower ionized calcium in the plasma. PTH stimulates bone resorption acutely, as described in the previous section describing the role of PTH in birds. It is noteworthy that FGF23 (phosphatonin) is expressed in medullary bone, in synchrony with the egg-laying cycle (Hadley et al., 2016; Gloux et al., 2019). This phosphatemic hormone is produced by osteocytes and plays a key

role in maintaining phosphate homeostasis, as described in the section of this review that discusses the role of hormones in Ca metabolism in hens.

32.7 Uterine secretions of Calcium

32.7.1 Mechanisms of ionic transfers

Eggshell formation takes place in the uterine segment of the oviduct (shell gland). Daily shell formation is associated with a massive transfer of calcium and bicarbonate into the lumen of the uterus during a short period (12hrs). In chickens, the mean rate of accumulation of $CaCO_3$ is 0.33 g/h between the period 10 to 22 h following ovulation and entry of the yolk into the oviduct (Eastin and Spaziani, 1978a; Nys and Guyot, 2011) this results in deposition of more than 6g of shell mineral. Calcium transfer follows a favorable positive (blood/uterine fluid) electrical potential difference (Pearson and Goldner, 1973, 1974; Bar, 2008), but is against a large and unfavorable Ca^{2+} gradient, since the level of ionized calcium in plasma (1.2 mM) is lower than its concentration in the uterine fluid (6 to 10 mM—depending on the stage of eggshell calcification) (Arad et al., 1989; Nys et al., 1991). The transcellular Ca^{2+} transport system has some similarities with mechanisms of Ca absorption in the intestine, even if the fluxes are inversed (Table 32.1). Calcium entry occurs in three steps (Figure 32.12), as reviewed by numerous authors (Hurwitz, 1989a; Nys et al., 1999; Bar, 2009): (1) passive entry of Ca^{2+} from plasma into the uterine cells via Ca channels; (2) its transfer through the cytosol bound to the Ca-binding protein, calbindin 28k; and (3) its extrusion by a calcium pump and Na/Ca exchanger. Many transcellular transporters of additional ionic species (HCO_3, Na^+, K^+, Cl^-, H^+) participate in the process of calcium secretion and in the maintenance of cellular ionic homeostasis (Eastin, W.C. and Spaziani, E., 1978a, 1978b; Jonchere et al., 2012; Brionne et al., 2014; Sah et al., 2018; Zhang et al., 2020), as observed at the intestinal level (Bar, 2009; Gloux et al., 2019). However, the additional contribution of a paracellular pathway for Ca is probably minor, even if this issue remains controversial for the uterus (Bar, 2009; Nys and Le Roy, 2018). Ca^{2+} secretion in the uterine lumen of hens shows particular features. Firstly, it has been

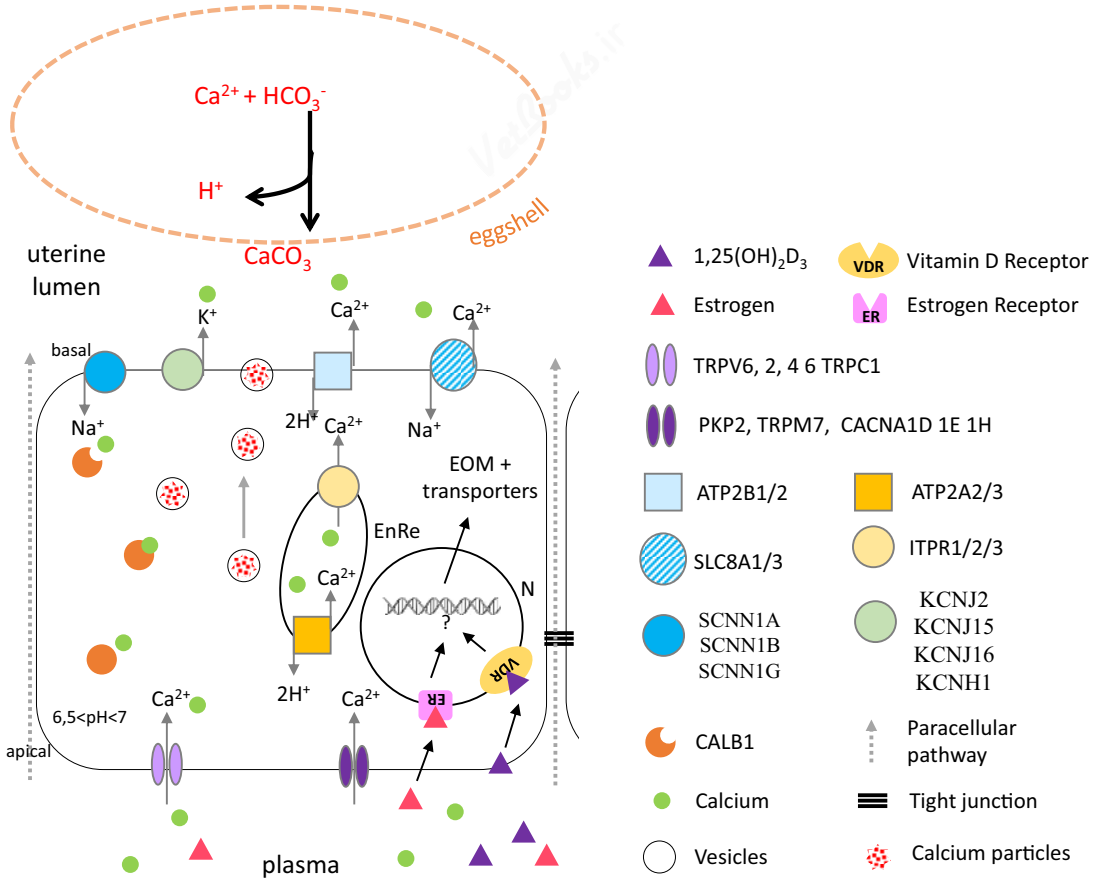

FIGURE 32.12 General model describing uterine ion transporters through the uterine cells of the laying hen. All symbols are defined in the legend part (right). *EnRe*, endoplasmic reticulum; EOM, extracellular organic matrix; *N*, nucleus. *Data are compiled from Jonchere et al. (2012); Brionne et al. (2014); Nys and Le Roy (2018).*

recently demonstrated that some of the transcellular Ca transfer into the uterine fluid occurs by secretion of extracellular vesicles (EVs) (100−400 nm) containing stabilized amorphous calcium carbonate (ACC) (Stapane et al., 2020). Secondly, the daily uterine secretion of calcium is discontinuous as the uterus expresses a high capacity to transfer Ca and bicarbonate only during the period of active shell formation (10 to 22 h postovulation, p.o. (Eastin and Spaziani, 1978a). The supply of Ca^{2+} and HCO_3^- is therefore, firstly, synchronized with the previous ovulation by unknown factors activated by the ovary or associated with ovulation, and secondly, is reinforced by the mechanical dilatation of the uterine wall elicited by the egg when it becomes fully hydrated (plumping). Mechanical stimulus is necessary, but insufficient, to elicit Ca secretion, as demonstrated by introduction of a surrogate wax egg in the oviduct. Calcification will occur only if the introduction of the artificial egg in the upper oviduct is synchronized with ovulation (Eastin, W.C. and Spaziani, E., 1978a; Nys, 1987; Nys et al., 1999).

The mineral composition of uterine fluid undergoes large changes throughout shell formation (Mongin and Sauveur, 1970; Arad et al., 1989; Nys et al., 1991). Sodium (140−80 mM) and chloride (70−45 mM) concentrations are high at the onset of shell calcification (8 h p.o.), but progressively decrease until shell calcification is complete (18 h, p.o.). The final levels of these ions are two to three folds lower than those of plasma. On the other hand, potassium levels show an inverse change, being higher at the end of calcification (12 to 60 mM). The pH decreases from 7.6 to 7.1 during shell calcification. Ca (6 to 10 mM) and bicarbonate (60 to 100 mM) levels in uterine fluid almost double during this process. Sodium is therefore reabsorbed in parallel with chloride during calcification, while the potassium flux is in the opposite direction (Sauveur and Mongin, 1971; Eastin and Spaziani, 1978b). The composition of the uterine fluid reflects absorption of sodium and chloride, while secretion of potassium, calcium, and bicarbonate occur against their electrochemical gradients. Active transport has been clearly demonstrated for Ca and Na in this process. The unidirectional fluxes of sodium are much greater than the net flux reflecting a balance between secretion of sodium linked to movement of chloride and water through the paracellular pathway. The active transport of sodium by the Na/K-ATPase, and the role of the Na/Ca exchanger have been demonstrated using specific inhibitors (Pearson and Goldner, 1974; Eastin and Spaziani, 1978b). The unfavorable gradient of Ca^{2+} concentration between plasma and uterine fluid, the discontinuity of calcium secretion and large fluctuation of the capacity of uterine Ca secretion according to the physiological stage support the predominance of an active transcellular secretion of calcium and the very limited contribution of passive Ca transport via the paracellular pathway. Bar (2009) suggested a possible contribution of the paracellular pathway due to the positive polarity of plasma with respect to mucosa, but this process contributes rather to the secretion of water, K, Na, and chloride to control osmolarity, which is stable and slightly lower than in plasma (290 vs. 320 mosm/mL in plasma) (Nys et al., 1999). The active transcellular transfer of calcium, bicarbonate, and sodium occurs mainly via the uterine glandular cells, as confirmed by the presence of calbindin 28 kD (Lippiello and Wasserman, 1975; Fullmer et al., 1976; Wasserman et al., 1991), Na/K-ATPase and CA in these cells (Pearson and Goldner, 1973; Bernstein et al., 1968); however, the vesicular secretion of ACC in the uterine fluid instead originates from the uterine epithelial cells (Stapane et al., 2020). The importance of the transcellular pathway is confirmed by the direct correlation between the calbindin mucosal concentration and the efficiency of Ca^{2+} transfer in uterus under numerous experimental conditions (Wasserman, 2004; Bar, 2009; Nys and Le Roy, 2018). This relationship is specific to the uterus and is not observed in other parts of the oviduct. Both uterine glandular and epithelial cells transfer large amounts of calcium into the uterine lumen against the concentration gradient, while preserving low-intracellular calcium levels (<2 μM). Ca^{2+} is not stored in the uterus before eggshell calcification and comes from blood plasma, the total circulating calcium being regularly renewed every 12 min. It has been demonstrated that bicarbonate is derived from CO_2 diffusion and its hydration by CA (Lörcher et al., 1970; Eastin and Spaziani, 1978a). Early physiological studies were described by an initial model of Ca secretion, with three steps: entrance into the cell by passive diffusion through Ca channels, trapping of Ca by calbindin, and then extrusion by the Ca-ATPase and Na/Ca exchange, with a role for movement of other ions (Na, K, and Cl) (Sauveur and Mongin, 1971; Nys et al., 1999). However, transcriptomic studies carried out during the past 15 years comparing various parts of the oviduct or tissues transporting large amounts of Ca (Jonchere et al., 2010, 2012; Brionne et al., 2014), or analyzing changes induced in RNA expression by physiological factors (Marie et al., 2015a, b; Sun et al., 2016; Sah et al., 2018; Khan et al., 2019; Zhang et al., 2019, 2020), have revealed upregulation and expression of a large number of ion transporters involved in uterine calcium secretion (Figure 32.12; Table 32.1), in addition to new processes such as the vesicular secretion of ACC (Stapane et al., 2020). These findings are mainly qualitative and not quantitative, but they allow hypotheses to be developed on the mechanisms of Ca secretion and other ion transfers in order to maintain cellular homeostasis. It remains, however, difficult to establish a definitive hierarchy between the putative candidates for a particular ion transfer or to evaluate the respective contribution of the different processes contributing to the supply of Ca and bicarbonate

for shell formation. All this information has been used to update the model describing the mechanisms of Ca secretion and for combined ion transport (Figure 32.12).

32.7.1.1 Transcellular transfer of Calcium and bicarbonate

The entrance of Ca into the glandular epithelial cells involves TRPV Ca^{2+} channels. In initial studies, the TRPV Ca^{2+} channel was identified as TRPV6 by microarray analysis or by Western blotting (Yang et al., 2013; Jonchere et al., 2012); however, more recent studies using RNA-seq approaches were unable to confirm TRPV6, but rather suggested TRPV2 or 3 (Brionne et al., 2014), TRPV4 (Zhang et al., 2019), the purinergic receptor P2X 7 (P2RX7), or calcium homeostasis modulator 5 (*FAM26E*) (Le Roy N., Gautron J., Nys Y., personal communication) as putative candidates. Further data are clearly needed to identify the Ca channels responsible of Ca entry into the glandular cells. In contrast, there is numerous convincing experimental evidences demonstrating that calbindin is involved in the intracellular transfer of Ca, as reviewed by Bar (2009) or Nys and Le Roy (2018). The ER also contributes to maintenance of low-intracellular calcium levels via ATP-dependent calcium pumps (ATP2A2 and 3), while and inositol trisphosphate receptors type 1, 2, and 3 (ITPR1, 2, 3) contribute to Ca release from the ER. These ER genes are over expressed during eggshell calcification (Brionne et al., 2014; Sah et al., 2018). The otopetrin gene (Otop2) is expressed in the uterus (Khan et al., 2019) and may also participate to the transepithelial transport of Ca^{2+} across the uterus by regulating intracellular calcium (Sah et al., 2018). Calcium is then extruded from the glandular cells by plasma membrane Ca^{2+} pumps (ATP2B1 and ATP2B2) and Ca^{2+}/Na^{+} exchangers (SLC8A1 and SLC8A3) (Jonchere et al., 2012; Brionne et al., 2014; Sah et al., 2018) (Figure 32.12, Table 32.1).

Blood carbon dioxide (CO_2) penetrates the uterine glandular cells by simple diffusion through the plasma membrane (Hodges and Lôrcher, 1967) and is the main source of bicarbonate. CA2 catalyzes the reversible hydration of intracellular CO_2 to HCO_3^-. However, it is also supplied at a low level from plasma by the Na^{+}/HCO_3^- cotransporters (SLC4A4, SLC4A5, and SLC4A10). Bicarbonate ions are finally secreted into the uterine fluid via the HCO_3^-/Cl^- exchanger SLC26A9 (Jonchere et al., 2012; Brionne et al., 2014). Bicarbonate from the uterine fluid can also be produced by the membrane-bound CA4, which has its active site in the extracellular space (Zhu and Sly, 1990). Expression of CA9 is also observed in the uterus, but at very low levels (Khan et al., 2019).

In parallel with the transfer of Ca and bicarbonate, cellular homeostasis is maintained by the reabsorption of sodium and chloride from the uterine fluid and secretion of potassium. Na^+ uptake from the uterine fluid is carried out by Na^{+}/Ca^{2+} exchangers (SLC8A1, 3) and by amiloride-sensitive Na^+ channels (SCNN1A, B, G) at the apical membrane. Sodium ion is extruded from the cell at the basolateral membrane against the electrochemical gradient by the Na^{+}/K^{+} ATPase, with concomitant uptake of K^+ (ATP1A1, B1) (Jonchere et al., 2012; Brionne et al., 2014). This is in addition to the $Ca^{2+/}Na^{+}$ exchangers (SLC8A1 and 3) and Na^{+}/HCO_3^- cotransporters previously described for Ca extrusion and bicarbonate entry, respectively. K entry into the cell is associated with Na (ATP1A1, B1) and associated NKAIN1, which interacts with the subunit of the Na^{+}/K^{+} ATPase (ATP1B1). The passive diffusion of K^+ into the uterine lumen through the apical membrane is facilitated by the high concentration of intracellular potassium in cells, with involvement of two voltage-dependent ion channels (KCNJ2, KCNJ16) and a large conductance calcium activated potassium channel (KCNMA1), as revealed by their high expression during eggshell calcification (Jonchere et al., 2012; Brionne et al., 2014). Chloride ions in the uterine fluid enter the cell by the HCO3-/Cl-exchanger SLC26A9 and by Cl-channels (CLCN2, CFTR), and might be extruded by the Cl-/H+ exchanger (CLCN5), in addition to the Na+ -K+ -2Cl- and K+ -Cl-cotransporters (SLC12Ax). During eggshell formation, a progressive acidification of uterine fluid and glandular cells occurs, due to production of two protons for each CO_3^{2-} (Nys et al., 1999). The V-type H^+-ATPase (VAT) (ATP6V1B2) exports protons to the plasma with hydrolysis of ATP, as suggested by its high expression during shell formation (Jonchere et al., 2012). Another VAT subunit, the H+ transporting lysosomal 42 kDa, V1 subunit C2 (ATP6V1C2) might also be involved (Brionne et al., 2014). The VAT complex is probably located in the basolateral membrane, as protons are secreted toward the plasma, which shows some acidification during the period of shell formation. This metabolic acidosis is partially compensated by hyperventilation by the hen and by an increased renal H^+ excretion (Mongin, 1978).

It is noteworthy that intestinal and uterine mechanisms of ionic transfer show some similarities, although they correspond to absorption or secretion of Ca with respect to the intestinal and uterine lumen, respectively. However, the regulation of Ca transfer largely differs between these tissues, being directly dependent upon the active metabolite of vitamin D in the intestine, in contrast to the uterus, where such regulation has not yet been demonstrated.

32.7.1.2 Vesicular secretion of calcium

Recently, uterine vesicular transport of $CaCO_3$ as ACC has been shown to deliver ACC to the site of eggshell mineralization in hens (Stapane et al., 2019, 2020). Evaluation of $CaCO_3$ vesicular transport in chicken uterus was initiated

following the observation of high levels of vesicular protein markers (EDIL3 and MFGE8) in eggshell and in uterine fluid during shell formation (Marie et al., 2015a), as inspired by the demonstration of amorphous $CaCO_3$ in invertebrates that produce a $CaCO_3$ shell (Addadi et al., 2006). ACC is a metastable polymorph of $CaCO_3$, which can deliver ions required for rapid physiological biomineralization. It was initially demonstrated in molluscan or echinoderm species that the incipient $CaCO_3$ crystal formation occurs intracellularly as a membrane-enclosed ACC phase that contributes to the calcification of $CaCO_3$ biominerals (Beniash et al., 1997; Politi et al., 2008; Addadi et al., 2003; Gomez- Morales et al., 2015). In the calcifying chicken eggshell, ACC has been demonstrated with a calcite short-range order favoring the transformation of ACC to calcite, which is the sole crystalline form of the eggshell mineral (Rodriguez-Navarro et al., 2015). ACC is a highly reactive transitional phase for the formation of $CaCO_3$ biominerals and can be stabilized by specialized molecules (Aizenberg et al., 1996). Vesicles stabilize and transport ACC to the mineralization front as shown in sea urchin (Politi et al., 2008) mollusks (Addadi et al., 2006) and corals (Bahn et al., 2017)

In hen uterus, transmission electron microscopy (TEM) observations demonstrated the presence of intracellular vesicles (100−500 nm) in the cytoplasm of the epithelial ciliated cells (Figure 32.13) (Stapane et al., 2020). Vesicles accumulate at the apical plasma membrane and bud to secrete EVs which were revealed in uterine fluid adjacent to the apical region of uterine cells (Stapane et al., 2020). The presence of $CaCO_3$ as ACC in the vesicles was confirmed by electron energy loss spectroscopy and by energy-dispersive X-ray spectroscopic. Electron diffraction on EVs extracted from uterine fluid indicated that the $CaCO_3$ inside vesicles was amorphous, similar to the ACC previously identified at the initial stage of eggshell formation (Rodriguez-Navarro et al., 2015). This observation was further explored by studying the presence of major EV proteins using transcriptomics, proteomics, and immunochemistry to decipher the origin and mechanisms of vesicle formation and function.

Three annexins (Anxa 1, 2, and 8) are expressed at high levels in the uterus at the onset of shell formation (Stapane et al., 2020), in agreement with previous proteomics studies (Mann, 2006; Jonchere et al., 2012; Marie et al., 2015b), and were revealed in the epithelium (Anxa 1, 8) and tubular glands (Anxa 8) by immunochemistry. Annexins are Ca channels proposed to contribute to uptake of Ca for intravesicular ACC formation. EDIL3 is overexpressed in the uterus and is specific to the uterine fluid EV fraction (Stapane et al., 2019, 2020). This protein possesses an EGF-like calcium-binding domain and is hypothesized to guide EVs to the mineralization front. Carbonic anhydrase 4 (CA4) is present in the epithelial cells and in EVs and is highly expressed at the early stage of shell formation. CA4 catalyzes the reversible hydration of CO_2 forming HCO_3 and might contribute to accumulation of ACC in vesicles.

A schematic representation of vesicular transport and molecular actors during eggshell mineralization is proposed (Figure 32.14). Annexins would promote calcium entry into EVs, whereas CA4 catalyzes the hydration of CO_2 into bicarbonate ions. ACC accumulates inside EVs and is stabilized by specific proteins. EDIL3 and potentially MFGE8 would serve as guidance molecules to deliver vesicular ACC to the mineralization site. The quantitative contribution of the vesicular secretion of $CaCO_3$, relative to the secretion of each ion by the transcellular pathway, remains to be explored.

32.7.2 Regulation of uterine calcium transfer

32.7.2.1 Regulation of the timing of ion secretion

Organic and mineral precursors of eggshell are secreted daily in the uterine fluid with a specific temporal sequence. Secretion of Ca, bicarbonate, and vesicular $CaCO_3$ occurs at a low levels 6 to 10 h after ovulation in hens, and then with rapid kinetics (0.33 g/h) for the period corresponding to 10 to 22 h postovulation. During the first period, there is also a large secretion of water (plumping) which expands the egg contents within the ESMs and contributes to the ovoid shape of the egg, which generates mechanical strain upon the uterine wall at 10hrs postovulation (Sauveur and de Reviers, 1988; Nys and Guyot, 2011). This mechanical dilatation of the uterine wall is coupled to the secretion of ionic precursors of the shell mineral, as shown using in vivo perfusion of the uterus (Eastin and Spaziani, 1978a) in addition, upregulation of the Na^+/K^+-ATPase is observed. Overexpression of the calbindin (CALB1) gene is also highly synchronized with the active phase of ion secretion in the uterus, as demonstrated by upregulation of CALB1 during the eggshell formation period (Nys et al., 1989; Bar et al., 1992; Ieda et al., 1995), followed by its rapid down regulation after egg expulsion (Nys et al., 1992b). The period of shell formation and associated bicarbonate and calcium secretion is precisely synchronized with ovulation (Eastin and Spaziani, 1978a; Sauveur and de Reviers, 1988; Nys et al., 1999). Its initiation coincides with entrance of the egg into the uterus, whereas shell formation is arrested about 2 h before oviposition when the cuticle is deposited (Eastin and Spaziani, 1978a; Nys et al., 1991). An artificial intervention, either mechanical or pharmacological (using a prostaglandin inhibitor), which causes egg retention in the uterus, largely delays egg oviposition but does not elicit any additional deposition of shell (Nys, 1987; Bar et al., 1996). In addition, the combination of artificial retention with an expulsion of the egg at the expected time of oviposition shows that the eggshell was completed at 24 h. In contrast, it is possible to retain the egg in utero for 36 h by injecting progesterone 2−4 h after ovulation (Nys, 1987; Zhang et al., 2020). This treatment delays oviposition and also the arrest of shell mineralization, as shown by a 50% increase in eggshell weight; moreover, a partial shell without cuticle is formed when the retained egg is expulsed at 24 h (Nys, 1987). In addition, an artificial egg introduced in the upper part of the oviduct will be calcified only when its introduction is synchronized with the normal arrival of the yolk, 2−3 h after the natural ovulation (Nakada et al., 1976). These observations demonstrate that an active control of the timing of shell formation, initiation, and arrest of shell mineralization is associated with the process of ovulation. The largest mature follicule which is due to ovulate acquires the capacity to secrete large amount of progesterone which stimulates the hormonal secretion of luteinizing hormone by the posterior pituitary at the origin of ovulation (Johnson, 2000; Nys and Guyot, 2011). Experimental supply of progesterone will affect the interaction between pituitary gland and ovary. The putative regulator(s) of shell formation and uterine calcium secretion associated with the ovulatory cycle or follicular maturation remain to be identified.

32.7.2.2 Regulation of uterine ionic transporters

During the period of eggshell formation, hens export large amounts of calcium, bicarbonate, and carbonate into the uterine lumen, in coordination with other ions that contribute to cell homeostasis. Detailed mechanisms have been described in the previous section. Cytosolic calbindin 28k has been intensively used as a marker for Ca secretion because its epithelial levels during Ca absorption or secretion reflect their capacity to transfer Ca (Hurwitz, 1989a; Wasserman, 2004; Bar, 2008, 2009; Christakos, 2014, 2019; Nys and Le Roy, 2018). The regulation of CALB1 expression and Ca absorption in the intestine by the active metabolite of vitamin D has been clearly demonstrated; however, in contrast, numerous evidence shows that calbindin synthesis is not directly dependent on $1,25(OH)_2D_3$ levels in the hen uterus. Administration of exogenous $1,25(OH)_2D_3$ or increasing its endogenous levels by lowering dietary calcium in hens has no effect on calbindin concentration in the uterus (Bar et al., 1978, 1992; Nys and de Laage, 1984). Moreover, uterine calbindin is present in vitamin D deficient quail (Streim and Bar, 1991) and its levels increase following resumption of eggshell mineralization in parathyroidectomized hens (Nys et al., 1992). $1,25(OH)_2D_3$ might however facilitate calbindin synthesis as it stimulates calbindin production in vitro in uterine tissue from vitamin D deficient birds when added to the culture medium alone or in combination with estrogens (Corradino, 1993). The presence of the VDR in the uterus (Coty, 1980), its over expression during the period of shell calcification (Ieda et al., 1995; Bar et al., 1996), decreased expression when the egg is expelled (Bar et al., 1996) and observation of a putative VDRE in the calbindin gene (Christakos et al., 2014; Nys and Le Roy, 2018) and CA II (Quélo et al., 1994) also support a possible role for vitamin D; however, there is no evidence of a direct influence. The uterine calbindin concentration is large and CALB1 is one of the most highly expressed genes in the uterus during the process of eggshell formation (Nys et al., 1989; Striem and Bar, 1991; Bar et al., 1992); this decreases rapidly when shell formation is suppressed by artificial expulsion of the egg from the uterus (Figure 32.8). Calbindin falls to 50% and 3% of its initial expression levels at 1 and 6 h, respectively, after suppression of calcium secretion, which is in contrast to the stable level in the duodenum (Figure 32.8; Nys et al., 1992b). There is a good correlation between uterine calbindin levels and the amount of uterine calcium secreted for shell formation in mature laying hens or after arrest of egg production (Bar et al., 1984; Nys et al., 1989; Jonchere et al., 2012; Brionne et al., 2014)

The stimulation of uterine CALB1 expression occurs in two stages in mature laying hens. It is firstly stimulated by

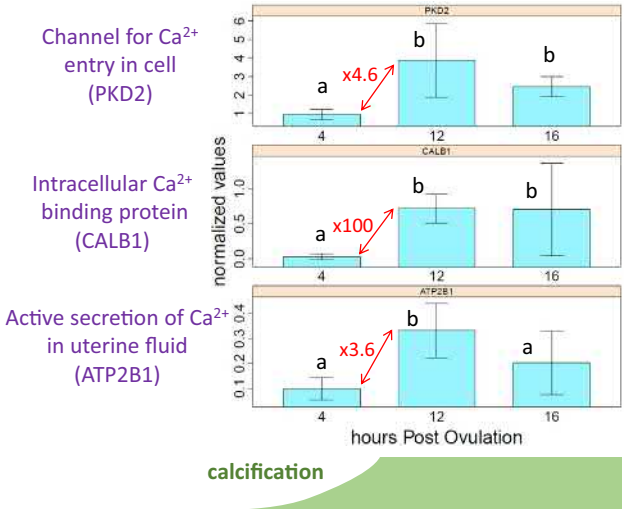

FIGURE 32.15 Overexpression of PKD2, CALB1, and ATP2B1 in hen uterus after re-induction of eggshell calcification in hens previously laying shell-less eggs due to premature expulsion Nys, Y., Gautron, J. and Brionne, A., personal communication.

sexual maturity, and secondly, during the calcification of the first shell (Figure 32.15); high calbindin levels are then maintained as long as the hen is laying. The greater estrogen secretion by the ovary at sexual maturity, and its high levels in mature hens, initially contribute to oviduct maturation and then to its maintenance in laying birds (Johnson, 2000; Nys and Guyot, 2011). Expression of CALB1 and levels of calbindin increase during sexual maturity (Wasserman and Taylor, 1968; Bar and Hurwitz, 1973; Navickis et al., 1979; Nys et al., 1989; Bar et al., 1990; 1992; Striem and Bar, 1991); this is specific to the uterus and does not occur in other segments of the oviduct (Jonchere et al., 2012). CALB1 levels are higher in laying hens, compared to immature pullets, but also compared to mature nonlaying birds (Bar et al., 1978; Striem and Bar, 1991) or in hens laying shell-less eggs with a normal ovulatory cycle (Nys et al.;, 1989; Nys et al., 1992). Uterine calbindin levels are stimulated by estrogen even if the pullets are deficient in vitamin D (Navickis et al., 1979; Bar et al., 1990; Corradino, 1993). Testosterone alone does not stimulate calbindin synthesis, but rather reinforces the estrogen effect; however, alone, it does not stimulate the increase in calbindin levels (Navickis et al., 1979). The estrogen receptor is localized in the glandular cells (Isola, 1990), as is calbindin (Jande et al., 1981).

The main increase in CALB1 expression and calbindin levels occurs during calcification of the first shell (Striem and Bar, 1991; Bar et al., 1992), or at resumption of shell formation in hens previously laying shell-less eggs (Figure 32.15; Nys et al., 1989). The high levels of calbindin in the uterus are maintained in laying hens by a daily increase in CALB1 expression during the period of shell formation (Nys et al., 1989; Bar et al., 1992; Ieda et al., 1995;

Jonchere et al., 2012; Brionne et al., 2014); however, the levels of the protein remain high in laying hens and are stable throughout the laying cycle because of its long half-live. Calbindin levels decrease after 48 h when shell formation is interrupted by egg expulsion or by an arrest of egg laying (Nys et al., 1989; Bar et al., 1992; Ieda et al., 1995) or molt (Yosefi et al., 2003). The induction of shell-less egg formation decreases expression and reduces levels of calbindin without affecting the plasma levels of sex steroids (Nys et al., 1986). We stress that $1,25(OH)_2D_3$ is not involved in the stimulation of calbindin at the uterus level in contrast to intestine. The entry of the egg into the uterus induces a mechanical stimulation to the uterus wall (distension) and has been shown to stimulate uterine calcium secretion (Eastin and Spaziani, 1978a) and expression of the Na^+/K^+-ATPase transporter (Lavelin et al., 2001), but not of CALB1 (Lavelin et al., 1998). The high synchronization between Ca entry and CALB1 upregulation in the uterus suggests that Ca might regulate CALB1 expression as has been shown in the kidney (Enomoto et al., 1992). This was experimentally confirmed in vitro (Corradino, 1993), using cultured uterus tissue from vitamin D deficient birds treated with estradiol to develop the oviduct. Administration of thapsigargin increases the entry of Ca and induces calbindin synthesis in the absence of estrogens or $1,25(OH)_2D_3$. Ca is a widely used second messenger system and fulfills numerous cell functions through complex intracellular Ca^{2+} signaling networks (Clapham, 2007; Barbado et al., 2009). The uterine effect might be mediated through the CaSR, which is expressed in calcitropic tissues such as the PTGs and kidneys in human, but also in other tissues not contributing to Ca homeostasis (Hannan et al., 2018). In hens, CaSR is found in kidney tubules and intestine, as well as in brain (Diaz et al., 1997); moreover, its expression in the parathyroid gland is stable throughout the laying cycle (Gloux et al., 2020). CaSR expression has not yet been detected in the uterus in studies exploring differential expression with physiological stimuli (Brionne et al., 2014), or associated with inferior/superior eggshell quality (Zhang et al., 2015), or correlation with hen age (Feng et al., 2020).

Regulation of other ion transporters has been less explored. Identification of the uterine ionic transporters was performed by measuring their differential expression when comparing uterus to another oviduct segment not secreting Ca, or by comparing uterine expression in the presence/absence of active calcification (Jonchére et al., 2012, Brionne et al., 2014; Sah et al., 2018; Khan et al., 2019) or different eggshell properties (Sun et al., 2016). These approaches have identified genes that are differentially expressed during Ca secretion. The ER Ca^{2+} pumps, PMCA pump (ATP2B1, 2), Na^+/Ca^{2+}/exchanger, Na channel, Na^+/K^+ exchanger, Na^+/HCO_3^- cotransporter, Na^+/K^+ ATPase, CA2, HCO_3^-/Cl^- exchanger, and vacuolar H^+ ATPase are all highly expressed in the active uterus compared to the magnum (Jonchere et al., 2012). Expression of genes involved in Ca transfer through the glandular cells of the uterus is also upregulated in hens during shell calcification compared to the hens in which shell formation has been suppressed by egg expulsion (Figure 32.15; Coty and Mc Conkey, 1982; Nys and de Laage, 1984; Jonchere et a., 2012; Brionne et al., 2014). The magnitude of the changes (two- to threefold) was however lower for the Ca channels PKD2 or TRPVs, ER pumps, PMCA (ATP2B1, Figure 32.15), Na^+/Ca^{2+}/exchanger, CA2, Na^+/HCO_3^- exchangers, Na^+/K^+ exchanger and K^+ voltage-gated channel, compared to CALB1 (16 fold). The expression of the calcium channel TRPV6 is higher during the period of calcification (Yang et al., 2013), as is that of ATP2A3 (Ca entry into the ER, CEMIP (release of Ca from the ER) and OTO2, 3 (vesicular transfer) (Khan et al., 2019). The presence of vesicular transfer of Ca has been suggested partly because of a high concentration in the eggshell of MFGE8 and EDIL3 protein (Marie et al., 2015a) and of an over expression of EDIL3 in the uterus in particular during the period of egg calcification (Stapane et al., 2019). Three Annexins (Anxa1, -2 and -3) are highly expressed in the uterus at the initial phase of shell formation (5 to 10 h postovulation) (Stepane et al., 2020). Some proteins are specific to the paracellular pathway such as claudins. However, claudins are not differentially expressed in the uterus in hens with or without a calcifying eggshell, and were not detected in transcriptomic studies (Jonchere et al., 2012; Brionne et al., 2014; Sah et al., 2018; Khan et al., 2019; Zhang et al., 2019). Therefore, shell formation clearly influences both Ca and bicarbonate transporters, but also other ionic transfers associated with regulation of cell homeostasis; however, the mechanisms of their regulation remain rather enigmatic. Mechanical dilation of the uterine wall induced by the presence of an egg can also upregulate some genes as shown for the expression of a few transporters such as Na^+/K^+-ATPase or other genes involved in shell formation (Lavelin et al., 1998, 2001). No studies have yet explored in vitro the influence of vitamin D or other hormones (steroids) on the synthesis of these ionic transporters. However, VDRE and the EREF are present in uterine transporter genes (Table 32.1, CALB1, ATP2A3, ITPR2-3, RYR2, ATP2B1-2-4, SLC8A1, SLC4A4-10, and CA2-7-9); moreover, calcium/cAMP response elements (CREB) are also observed in ATP2A2-3, ITPR1-2-3, RYR2, ATP2B1-2, SLC4A4-10, or CA2-7-9 (Nys and Le Roy, 2018). The involvement of these transporters to explain differences in shell quality due to genetic variability or the effect of hen age has been explored between groups laying eggs with different shell quality or by looking at genetic association with specific single nucleotide polymorphisms (SNPs) (Zhang et al., 2015; Feng et al., 2020). A number of genes possibly involved in Ca uterine transport (voltage-dependent L-type calcium channel subunit

alpha-1D, -1E, -1H (CACNA1D, 1E, 1H), PRKCB, and NCX1 (Na^+/Ca^{2+} exchanger, SLC8A1) were overexpressed in uterus of hens laying eggs with low-eggshell quality; in contrast, no differences were observed for the Na^+ channel (SCNN1A,1B, and 1G). Nonsynonymous SNP variations were found in the CACNA1E, CACNA1H, PRKCB, and NCX1 genes (Zhang et al., 2015). When comparing young and old hens, Feng and coworkers (Feng et al., 2020) also observed numerous differentially expressed genes among some uterine ionic transporters, including CACNA1C and CACNA1D, and SLC9A9; however, these approaches cannot reveal a change affecting numerous genes belonging to a specific process of Ca secretion.

32.8 Mineralization of the eggshell

32.8.1 Mechanisms of shell mineralization and the role of organic matrix

32.8.1.1 Eggshell temporal and spatial deposition

Avian eggshell is a porous bioceramic that is formed at body temperature in a confined and cell-free environmental space, the lumen of the uterus. Its formation is one of the fastest calcifying processes known in biology. The uterine fluid is supersaturated with respect to calcium and bicarbonate (about 70-fold relative to calcite solubility) and contains the organic precursors of the shell matrix (Gautron et al., 1997; Nys et al., 2004). The mature eggshell is made of $CaCO_3$ in the form of calcite and is formed in the absence of cell-directed assembly, in contrast to the cell-mediated mineralization of bone and teeth, which are composed of Ca phosphate. The eggshell is formed on a supporting meshwork of collagenous and noncollagenous membranes. Mineralization is initiated upon organic cores on the outer surface of the membrane fibers, which greatly influences the spacing of the mammillary cores and the subsequent mineral texture (Rodriguez-Navarro and Garcia-Ruiz, 2000; Dunn et al., 2012).

The first stage of eggshell formation is the initial phase (from 5 to 10 h after ovulation). When this phase begins, the eggshell weight is very low (0.18 g) compared to the final weight of the complete shell (about 6 g), and consists of the ESM fibers and their organic rich rounded surface structures (mammillary knobs). This corresponds to a "slow" phase, since 0.1 g of shell is deposited per hour and is divided into three events. Initially, eggshell mineralization is initiated with the deposition of flat disk-shaped ACC particles (Figure 32.16) that accumulate at specific organic-rich sites (mammillary knobs) on the ESM fibers that are rich in proteins and sulfated proteoglycans. These components are thought to promote the nucleation and stabilization of ACC with a calcite short-range order, which predetermines its conversion into calcite and the calcitic mineral composition of the mature eggshell (Figure 32.16; Rodriguez-Navarro et al., 2015). In the initial mineralization process, aggregates of calcite crystals grow radially from the nucleation sites to produce the mammillary cones. Calcite crystals from adjacent mammillary knobs continue growing until their adjacent bases merge as they compete for available space (competitive crystal growth) (Figure 32.17: Garcia-Ruiz and Rodríguez-Navarro, 1994; Rodriguez-Navarro and Garcia-Ruiz, 2000).

The second stage is the rapid-growth phase with a linear deposition of 0.33 g of calcite per hour. This phase is initiated when adjacent mammillary cones become fused (10 h postovulation), which then forms a continuous

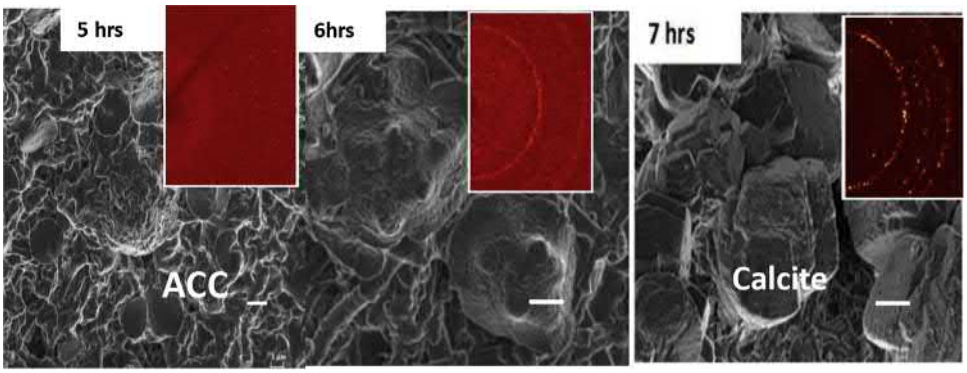

FIGURE 32.16 Scanning electron microscope microphotographs of forming eggshell collected at different stages of mineralization. At 5 h p.o., nonmineralized eggshell with organic-rich structures and appearance of mineralization by flat disk-shaped amorphous calcium carbonate particles nucleating on membrane fibers are observed. Inset: detail of a disk-shape particle showing an inner granular nanostructure. At 6 h, massive mineral deposits showing emerging calcite crystals. After 7 h, only large calcite crystals bounded by well-defined rhombohedral faces remain. Inserted in right corner: 2D-XRD patterns of eggshell membranes collected at 5 h p.o. showing no diffraction rings; at 6 h, there are weak and continuous rings produced by the incipient crystallization of nanosized calcite and at 7 h, some calcite crystals have grown and produce spotty rings whereas most of the nanocrystalline calcite has dissolved. Scale bars: (5 h) 1 μm. (6 and 7 h) 10 μm Rodríguez-Navarro et al. (2015).

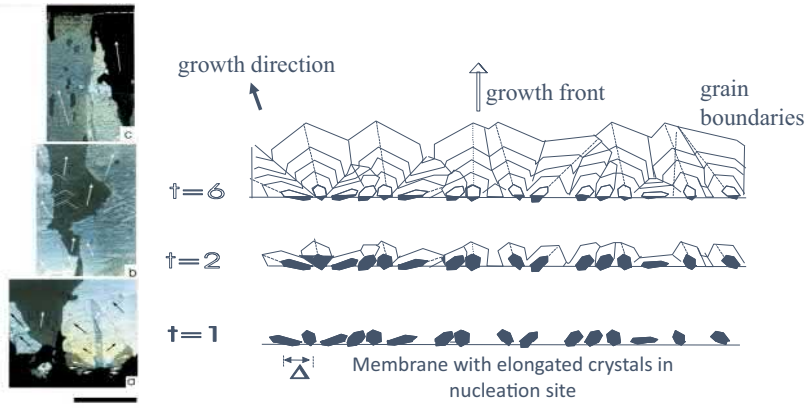

FIGURE 32.17 Left side: Cross-section of an eggshell viewed in cross-polarized light. *Arrows* indicate the orientation of the c axis of calcite crystals. Scale bar is 100 μm. (A). mammillary knobs, (B) mid palisade layer, (C) outer palisade. Right side: schematic illustration of competitive growth of crystals generating larger crystals with preferred orientation; Initially, crystals grow in all direction; eventually, only crystals growing perpendicular to the eggshell membranes will continue to grow due to competition for space between adjacent crystals Garcia-Ruiz and Rodríguez-Navarro (1994)

compact layer (palisade layer). This phase lasts 12h, corresponding to deposition of about 4 g of eggshell, which is organized as columnar calcite units with preferred orientation perpendicular to the eggshell surface. Calcite crystals with c-axis (fastest growth direction) oriented perpendicular to the shell surface continue growing outwards, blocking and burying other less favorably oriented crystals (Figure 32.17). Consequently, in the palisade layer, columnar calcite crystals increase progressively in size as they grow vertically and develop a preferred crystal orientation, with their c-axis oriented almost perpendicular to the egg surface (Sharp and Silyn-Roberts, 1984; Silyn-Robert and Sharp, 1986). This process of geometrical selection of calcite crystals is responsible for the characteristic columnar ultrastructure of avian eggshells crystal morphology and their exceptional mechanical properties, for example, the chicken eggshell (mean thickness of 0.33 mm) requires an average force of 35 N before fracture.

Finally, 2 h before oviposition, the terminal phase is characterized by the arrest of calcification and the deposition of a thin organic layer (cuticle), which constitutes a biofilm that covers the shell and plugs the respiratory pores to consequently restrict bacterial penetration through the shell.

32.8.1.2 Role of matrix proteins in the biomineralization process

Different avian species develop eggshells with specific microstructural characteristics (Figures 32.3 and 32.4; Silyn-Robert and Sharp, 1986; Panheleux et al., 1999; Dalbeck and Cusack., 2006; Rodriguez-Navarro et al., 2007). Eggshell microstructural characteristics are defined by the interaction of $CaCO_3$ with the organic matrix components during the nucleation and crystal growth phases. A particularity of the eggshell is the low amount of organic material which corresponds to 3.5% when the ESMs are included and to 2% of occluded proteins in the calcified region, in contrast to the matrix of dentin (20%), enamel (<5%), and bone (30%) (Feng, 2009; Neel et al., 2016). This organic matrix of the chicken eggshell plays a fundamental role in the manufacture of the shell and therefore in the establishment of its mechanical properties. Proteins and proteoglycans from the organic matrix stabilize the initial amorphous $CaCO_3$ and control its conversion into calcite crystals. They also inhibit the growth of the faces parallel to the c-axis of the calcite crystals that became elongated along the c-axis. This favors the growth of crystals with their c-axis that are roughly perpendicular to the egg surface during the competitive growth process (Garcia-Ruiz and Rodriguez-Navarro, 1994; Arias et al., 1993; Nys et al., 1999; 2004; Fernandez et al., 2004; Hincke et al., 2012). In vitro experiments, in situ observations and genetic association analysis has confirmed the active control of the eggshell mineralization by the organic matrix.

The first evidence implicating the matrix proteins in control of eggshell fabric/microstructure was the variation in concentration and protein species of the eggshell matrix components in the uterine fluid during the three sequential stages of shell formation, i.e., an initiation phase corresponding to the nucleation of calcite on ESMs (5 to 10 h postovulation in hens), the rapid crystal growth forming the main calcified shell (10 to 22 h postovulation) and finally, the dynamic arrest of shell calcification which occurs about 1.5 h before egg expulsion (Nys et al., 2001; Gautron et al., 1997). The composition of the uterine fluid progressively changes due to the secretion of specific proteins at different phases of eggshell formation (Figure 32.18; Gautron et al., 1997). The organic fraction contained in the shell has calcium-binding properties due to proteins (Abatangelo et al., 1978; Cortivo et al., 1982; Hincke et al., 1992), or

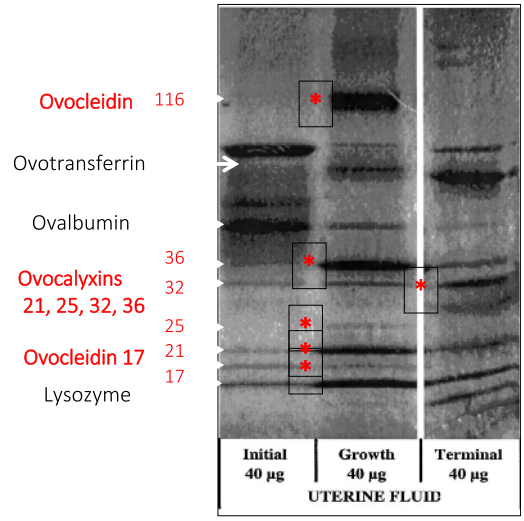

FIGURE 32.18 Electrophoretic profile (SDS-PAGE) of the uterine fluid collected at three stages of shell formation (initiation, period of rapid deposition, and termination of the hen eggshell). Molecular weights are indicated by arrows. Coomassie blue staining. Proteins involved in shell mineralization; Those in red are specific to the uterus. *Data from Gautron et al. (1997).*

proteoglycans with keratans or dermatan sulfates (Arias et al., 1992). Similarly, protein bands in uterine fluid have an affinity for calcium (Figure 32.18; Gautron et al., 1997).

In vitro experimental studies have demonstrated that components of uterine fluid favor the formation of the calcite polymorph, and influence the size, number, and morphology of crystals. The soluble organic fraction of the shell delays the precipitation of $CaCO_3$ in a dose-dependent manner (Arias et al., 1993; Gautron et al., 1996). An identical effect is observed with fractions rich in proteoglycans (Arias et al., 1992) and with macromolecules contained in the uterine fluid (Gautron et al., 1997). The synthetic crystals thus formed were collected to analyze polymorphic type and morphology. In the absence of organic constituents, the control crystals were composed of 55% calcite, and 45% of the two other polymorphs of $CaCO_3$ (vaterite and aragonite). Addition of uterine fluid increased the number of crystals produced, decreased their size, accelerated the initiation of mineralization, and favored the exclusive formation of calcite, which is the polymorphic type of $CaCO_3$ present on the shell, since the crystals formed in the presence of this fluid collected at the three stages are composed exclusively of calcite (Dominguez-Vera et al., 2000; Hernandez-Hernandez et al., 2008a). The morphology of calcite crystals was strongly modified by the presence of organic constituents extracted from the shell (Gautron et al., 1996; Hernandez-Hernandez et al., 2008b) and uterine fluid collected at the three stages of shell formation (Gautron et al., 1997; Hernandez-Hernandez et al., 2008b). The electrophoretic profile of the uterine fluid examined at the time of collection was compared with that obtained after the in vitro crystallization test (Gautron et al., 1997; Hernandez-Hernandez et al., 2008b). Numerous protein bands associated with $CaCO_3$ during precipitation and disappeared from the supernatant to be present in the precipitate containing $CaCO_3$.

The effects described above were obtained with a mixture of proteins present in the uterine fluid and shell extracts. They demonstrated that the organic matrix interacts with the mineral phase of the shell. The question quickly arose as to which constituent(s) of this matrix were involved in this mechanism of interaction between the mineral and organic phases. To answer this question, tests were conducted using proteins identified in the shell and protein fractions obtained by chromatographic separation of the organic matrix from the shell. Calcite crystals are strongly modified when formed in the presence of lysozyme, ovotransferrin, and ovocleidin-17 (Gautron et al., 2001b; Hincke et al., 2000; Jimenez-Lopez et al., 2003; Reyes-Grajeda et al., 2004; Dombre et al., 2017). Ansocalcin is a protein identified in the goose shell and is an ortholog of ovocleidin-17. It modified the crystallization of calcite crystals grown in vitro (Lakshminarayanan et al., 2002; Lakshminarayanan et al., 2003). Ovoglycan, which is a dermatan sulfate proteoglycan with ovocleidin-116 as its protein core, is polyanionic and acidic. It has a high affinity for calcium and therefore may modulate crystal growth during the formation of the palisade layer of the shell (Fernandez et al., 2001). Additional roles have been ascribed to other individual eggshell matrix proteins, such as ACC stabilization(Freeman et al., 2010). Calcium binds to ovalbumin, and this accumulation creates a nucleation center for mineralization (Schwahn et al., 2004). A schematic representation of $CaCO_3$ mineralization in the presence of ovalbumin has been proposed (Pipich et al., 2008). Calcium ions are bound to the protein by complexation through acidic groups leading to protein rearrangement. The calcium ions are the starting point for the subsequent formation of ACC nuclei, which then undergo a series of phase transitions to the stable crystalline polymorphs (Schwahn et al., 2004). The ability of ovalbumin to stabilize unstable $CaCO_3$ phases was further confirmed using in vitro experiments (Wang et al., 2009, 2010). Calcite crystals grown in vitro in the presence of lysozyme exhibited altered crystal morphology, although only at high concentrations (Hincke et al., 2000). Its role in the stabilization of ACC has been investigated but remains controversial. Lysozyme from eggshells of quail did not induced the precipitation of ACC under in vitro conditions (Lakshminarayanan et al., 2006). However, metastable ACC particles were obtained in vitro in the presence of chicken egg white lysozyme (Voinescu et al., 2007; Wang et al., 2009). Lysozyme considerably decreased the average diameter of the metastable ACC particles and promoted a network of associated particles, with the protein becoming

incorporated into the precipitate (Voinescu et al., 2007). In addition, lysozyme-ACC particles reorganized exclusively into crystalline calcite (Voinescu et al., 2007; Wang et al., 2009). Conversely, lysozyme was shown to be ineffective in the stabilization of ACC (Wolf et al., 2011). OPN is also a favorite candidate in the control of shell mineralization, since it modifies the morphology of calcite crystals and is correlated with eggshell hardness (Chien et al., 2008; Hincke et al., 2008; Freeman et al., 2010; Athanasiadou et al., 2018).

Many physical parameters (hydrophobicity, charge …) modify the adsorption or repulsion mechanisms of these proteins toward calcite and consequently alter the morphology of eggshell calcite crystals. These modifications affect the texture of the shell (size and orientation of the crystals) and therefore modify the mechanical properties of the shell. This hypothesis implies a variation in the quantity of specific proteins in the organic matrix according to the mechanical properties of the shell. The existence of this quantitative relationship between organic matrix proteins and shell strength has been demonstrated using shell samples that possess a range of mechanical properties such as breaking strength (Panheleux et al., 2000; Ahmed et al., 2005; Zhang et al., 2019).

The influence of eggshell matrix proteins on the ultrastructure of the shell and its mechanical properties is also supported by association studies between polymorphisms of genes encoding shell organic matrix proteins and different eggshell characteristics. Polymorphisms of specific shell proteins (ovalbumin, ovocleidin-116, and ovocalyxin-32) partially explain variation in specific eggshell properties (i.e., eggshell thickness, crystal size, crystal orientation, eggshell mechanical properties) (Dunn et al., 2009a, 2012; Rome and Le Roy 2016). Additionally, SNPs provide the potential to improve eggshell quality by optimizing beneficial eggshell microstructure traits through genetic assisted selection programs. These may lead to promising biological makers for genomic selection using a candidate gene approach. Indeed, a recent study recorded a total of 118 quantitative trait loci (QTLs), associated with shell strength (Rome and Le Roy, 2016). Among them, 24 are involved in fracture resistance (Sasaki et al., 2004; Dunn et al., 2009a; Jiang et al., 2010; Yao et al., 2010; Liu et al., 2011; Tuiskula-Haavisto et al., 2011) and 33 in shell stiffness (Dunn et al., 2009a; Takahashi et al., 2010; Tuiskula-Haavisto et al., 2011; Wolc et al., 2014). In addition, QTLs for characteristics such as breaking strength, shell stiffness, and shell morphological parameters were found on chromosome 2, 9, and Z of the hen (Ankra-Badu and Aggrey, 2005; Takahashi et al., 2009; Tuiskula-Haavisto et al., 2011). There are also notable changes in eggshell ultra- and microstructural properties that occur with increasing hen age (i.e., type of defects, mammillary density, size of calcite crystal units) (Rodriguez-Navarro et al., 2002; Robert et al., 2013; Park and Sohn 2018). Selection based on different haplotypes could improve the marked decrease in eggshell mechanical properties that occur in older hens. Indeed, the comparison of transcriptome of young and old hens revealed that some matrix involved in eggshell mineralization (ovalbumin, versican, and glypican 3) show differential expression (Feng et al., 2020)

The eggshell matrix proteome is currently well characterized for chicken eggs. Earlier biochemical studies, followed more recently by proteomics and transcriptomics approaches, have identified large numbers of occluded eggshell matrix proteins including those present at very low concentrations; altogether, more than 900 unique proteins have been identified in the eggshell including membranes and cuticle (Gautron et al., 2019; Gautron et al., 2020). Another integrated analysis of chicken eggshell matrix has enumerated a total of 69 phosphoproteins and 182 N-glycoproteins, for a total of 676 eggshell matrix proteins in the mineralized part (Mann et al., 2007; Yang et al., 2020). However, among Neoaves, only the zebra finch eggshell proteome has been characterized and exhibits 475 proteins (Mann, 2015). Additionally, the proteomes of a small number of closely related Neognathae species have been characterized (turkey, quail, duck, Guinea fowl), which contain 697, 622, 484, and 149 shell matrix proteins, respectively (Mann et al., 2007; Mann and Mann, 2013, 2015; Le Roy et al., 2019; Zhu et al., 2019; Marie et al., 2015a, b). These datasets must be expanded to cover a wide range of bird eggshells, with improved annotation, in order to clearly determine whether there is a minimal and essential eggshell proteome toolkit across all avian species.

As described earlier, matrix proteins play a decisive role in the establishment of the ultrastructure of the shell and its mechanical properties. In order to prioritize the most important proteins among this huge list of identified proteins, quantitative proteomics approaches have been conducted (Marie et al., 2015a, b). They have allowed characterization of the most abundant proteins at each of the crucial stages of mineralization, on the one hand, and to study their potential function by in silico approaches, on the other hand.

A first category of eggshell matrix proteins consists of proteins that direct the mineralization process through their ability to interact with the mineral (Figure 32.19). These proteins have a well-established role in the mineralization process, with functions that have been validated experimentally. Lysozyme, ovalbumin, and ovotransferrin are egg white proteins that are capable of interacting with the mineralized shell (Hincke, 1995; Hincke et al., 2000, Gautron et al., 2001; Dombre et al., 2017). OPN, ovocleidin-17, and EDIL3 are also in this category (Pines et al., 1995; Hincke et al., 1995; Hincke et al., 2008; Stapane et al., 2019, 2020).

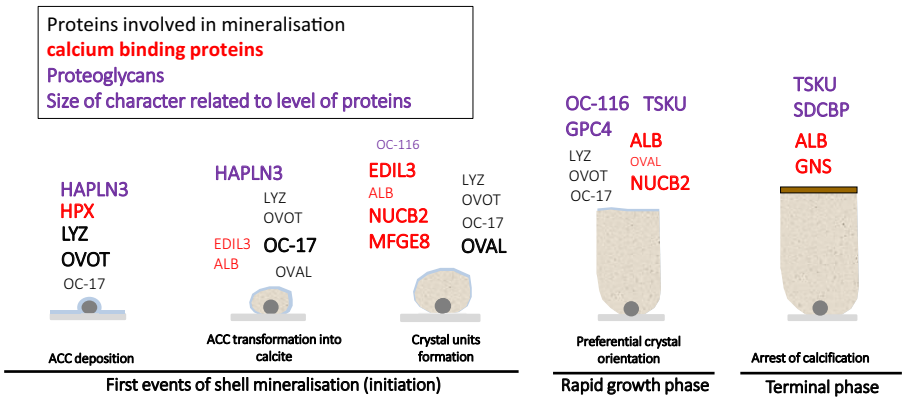

FIGURE 32.19 Schematic representation of the sequential events of mineralization and description of major matrix proteins at four time points of shell of mineralization. Size of characters is relative to their level in the eggshell extract (hierarchical ranking of the emPAI value) at individual stages. Overabundant proteins at each stage were determined using a spectral counting label free quantitative method and statistical analysis (ANOVA and HCA). *Adapted from Marie et al. (2015b).*

The second category of proteins consists of proteins regulating the activity of the proteins directing mineralization in the acellular uterine fluid. In this group, there are molecular chaperones such as clusterin that can form complexes with other proteins, and regulate their folding (Mann et al., 2003). Proteases or protease inhibitors are also identified in this group (Hincke et al., 2012; Dombre et al., 2017). They would have the role of regulating the degradation of active proteins or the activation of peptides with activity toward the mineralization process.

A great number of eggshell matrix proteins can be termed ubiquitous components, since they are also found in many other tissues and/or body fluids, and their specificity with respect to eggshell calcification is not obvious. Functionally relevant matrix constituents include OPN (SSP1) and ovocleidin-116 (OC-116, MEPE), which are phosphoglycoprotein members of the SIBLING family that are found in both bone and eggshell (Hincke et al., 2008; Hincke et al., 1999; Bardet et al., 2010). In addition, the shell matrix is constituted of proteins that originally were thought to be extremely specific to the distal oviduct of birds (isthmus and uterus) and to eggshell formation: in chicken, these have been characterized as ovocleidin 17 (OC-17), ovocalyxins 21, 25, 32, 36 (Hincke et al., 1995; Nys et al., 1999; Gautron et al., 2001; Nys et al., 2004; Gautron et al., 2007; Hincke et al., 2012). Proteomics studies of avian eggshells have identified OC-116 as the most abundant matrix protein in chicken, turkey, quail, and guinea fowl (Mann and Mann, 2013; Mann, 2015; Le Roy et al., 2019). OCX-36 is another abundant constituent of the chicken, turkey, quail, zebra finch, and Guinea fowl eggshell proteomes (Mann, 2015; Mann and Mann, 2013, 2015; Le Roy et al., 2019). OC-17 orthologs have been identified in eggshell from goose (ansocalcin), ostrich (struthiocalcin: SCA-1 and -2), emu (dromaiocalcin: DCA-1 and -2), rhea (rheacalcin: RCA-1 and -2) (Lakshminarayanan et al., 2002; Mann and Siedler, 2004; Mann and Siedler, 2006), and guinea fowl (OC-17-like and DCA-1-like) (Le Roy et al., 2019). In contrast to other eggshell matrix proteins implicated in mineralization (i.e., OCX-36, OC-116, OPN, and EDIL3), OC-17 and its orthologs appear to be both avian- and oviduct/eggshell−specific (Zhang et al., 2014). In contrast, OCX-32 protein cannot be generalized to all avian eggshells, since its absence from quail and turkey eggshell has been emphasized (Mann and Mann, 2013, 2015)

Ovocleidin 17 is the second most abundant matrix protein and modifies the morphology of calcite crystals grown in vitro (Reyes-Grajeda et al., 2004). Modeling of OC-17 suggests the involvement of this protein in the crystallization of calcite from ACC nanoparticles (Freeman et al., 2015). OPN is associated with parallel sheets of matrix in the highly mineralized palisade layer and with the {104} crystallographic faces of eggshell calcite, suggesting its role in regulating calcite crystal growth and orientation during the rapid phase of shell deposition which results in formation of the palisade layer (Chien et al., 2008). Quantitative proteomic analysis of the organic matrix proteins of the uterine fluid, where shell mineralization takes place, and of eggshell extracts, throughout the different steps of eggshell formation (ACC transformation in calcite, nucleation phase, rapid growth phase, and arrest of shell formation), reveals the presence of overabundant proteins at particular phases of the process (OC-17, OC-116, EDIL3, LOXL2, ovalbumin, ovotransferrin, lysozyme, etc …) and underlines the likely involvement of these proteins in the control of eggshell formation (Marie et al., 2015a, 2015b). In addition, significant associations between gene polymorphism and eggshell quality indicate the influence of organic matrix proteins on eggshell fabric. Ovalbumin gene polymorphism is associated with breaking strength, shell deformation, eggshell thickness, and crystal size; OC-116 with shell thickness, elastic modulus, and crystal orientation; OPN with fracture toughness; ovotransferrin

with crystal size; and OCX-32 with shell thickness and crystal orientation (Dunn et al., 2009, 2012). Nanoindentation and atomic force microscopy measurements verify OPN's influence on eggshell hardness and nanostructure, which in turn control the mechanical properties of the shell (Athanasiadou et al., 2018)

32.8.2 Regulation of eggshell matrix protein synthesis

There are numerous similarities between the regulation of ionic transporters and matrix proteins in the uterus, but specific information concerning matrix proteins remains limited. Sex steroids are implicated as shown by the increased expression of matrix proteins at hen sexual maturity of female birds compared to immature pullets (Dunn et al., 2009). Expression of OCX-21, OCX-36, OC-116 (Dunn et al., 2009), OPN (Pines et al., 1995), and OC-17 (Zhang et al., 2014) are upregulated at sexual maturity. OC-116 expression is also highly upregulated in laying compared to nonlaying hens (Brionne et al., 2014; Sah et al., 2018), and many other genes are over expressed in laying hens during the period of shell formation (Table 32.2). The upregulation of matrix proteins is associated with the development and differentiation of the oviduct induced by increased level of estrogens 2 weeks before the onset of egg production (Sauveur and de Reviers, 1988; Johnson, 2000; Nys and Guyot, 2011). The observation of an EREF family motif in some of the matrix protein genes (Table 32.2) also supports the role of estrogen in synthesis of these proteins. Secondly, a large stimulation of uterine matrix protein synthesis is linked to the process of eggshell formation, as shown by uterine expression in hens laying a hard-shelled egg compared to hens for which egg calcification has been experimentally suppressed (Jonchére et al., 2010; Brionne et al., 2014). Numerous matrix proteins (OCX-21, OCX-32, and OCX-36, OPN, OC-116, Table 32.2) are upregulated under these conditions, and the presence of a large secretion of sex steroids does not prevent the drop in matrix protein expression in hens laying a shell-less egg due to premature expulsion of the egg (Jonchere et al., 2010; Brionne et al., 2014). The induction of ovalbumin, lysozyme, and ovotransferrin expression by estrogen or progesterone has been demonstrated in the magnum (Chambon P. et al., 1984), but has not been explored in the isthmus and uterus segments. These proteins of the egg white do not seem to be upregulated by shell formation in the uterus, as their mRNAs were not differentially expressed in hens laying hard versus soft shell eggs. These changes at sexual maturity and in laying hens coincide with stimulation of $1,25(OH)_2D_3$ production and increases in its circulating plasma levels, but there is no direct evidence to implicate this metabolite in upregulation of matrix proteins, with the exception of a VDRE in certain genes (Nys and Le Roy, 2018, Table 32.2). The effect of this metabolite on expression of shell matrix proteins in vivo has not been studied yet. An exogenous supply of $1,25(OH)_2D_3$ in hens does not improve shell strength (Nys and de Laage, 1984; Bar et al., 1978; Bar et Striem, 1992). No study has yet been carried out in vitro or in vivo to explore the effect of its exogenous supply on expression of shell matrix proteins; only intracellular levels of calbindin have been assessed, which is not dependent on vitamin D in the uterus, as previously described. Another experimental approach to explore the regulation of matrix proteins is comparison of uterine gene expression between the inactive uterus (egg in magnum) with the active uterus (calcifying egg in uterus). These approaches (Jonchere et al., 2010, 2012; Brionne et al., 2014; Khan et al., 2019) reveal large differential expression in ionic transport but matrix proteins genes do not exhibit large differential gene expression between the two physiological stages (Table 32.2). Earlier studies using Western blot analysis suggested that OC-17, OC-116, OCX-32, and OPN are secreted only by the uterine segment of the oviduct, and are mainly present in the uterine fluid collected during active eggshell calcification (Hincke et al., 1995, 1999; Lavelin et al., 1998; Gautron et al., 2001). The overexpression of OPN gene (SPP1) but also that of glypican-4 were demonstrated to be induced by the mechanical strain of dilatation of the uterine wall induced by entry of the egg (Lavelin et al., 1998; Lavelin et al., 2002). However, it is not obvious to differentiate the mechanical stress from the process of eggshell mineral precursor secretion during calcification. It has been shown that Ca secretion is facilitated by dilatation but only during the period expected for shell formation (Eastin and Spaziani, 1978a). In addition, the profile of proteins in uterine fluid changes during the various phases of shell formation (Gautron et al., 1997) when the egg is present in the uterus, and this occurs without any change in mechanical stimuli. A proteomic study exploring the protein profile of uterine fluid and eggshell extract throughout the progressive mineralization of the shell, 5, 6, 7, and 19 h postovulation also revealed hourly variations in matrix protein concentrations during continuous mechanical strain associated with the presence of the egg in utero (Figure19) (Marie et al., 2015a, 2015b). This short-term temporal control of protein secretion during the phase of shell mineralization is confirmed by the observation of the specific localization of the eggshell matrix proteins in the different layers of the eggshell (Nys et al., 1999, 2004; Hincke et al., 2012). OCX-36 is upregulated during eggshell calcification and is predominantly localized in the inner part of the shell and in the inner shell membranes (Gautron et al., 2007). On the other hand, expression of OCX-32 is upregulated during the terminal phase of shell formation and is localized in the outer palisade layer, the vertical crystal layer, and the

TABLE 32.2 Major proteins involved in shell mineralization: description, gene expression, presence of vitamin D response element and estrogen response element.

cuticle of the eggshell (Gautron et al., 2001). These differences clearly suggest additional regulating factors than solely mechanical strain. Moreover, a major change in crystallography of the Guinea fowl shell occurs about 12 h postovulation and is associated with changes in the matrix composition (Le Roy et al., 2019). The process of eggshell formation is therefore associated with changes in the expression of eggshell matrix genes, which occurs at a short term (hourly variation) or at longer term (daily variation); however, the mechanisms of such regulation remain to be further defined. The presence of the calcium/cAMP responsive elements (CREB) in numerous eggshell matrix protein genes (Panheleux et al., 1999; Nys and Leroy, 2018) reinforces the hypothesis of a multifactorial regulation, which might also involve some paracrine factors.

Identifying and exploring the respective roles of regulatory factors for eggshell matrix proteins is challenging in hens because of the difficulties to study uterine tissue culture in vitro and to explore individual factors in vivo when numerous physiological factors need to be preserved in order to maintain egg laying and shell formation. However, novel approaches such as CRISPR-based gene invalidation might help to decipher the mechanism of shell formation (Kuscu et al., 2017). Molecular biology (high-throughput technologies), however, has been very useful to identify the actors; emergence of more quantitative evaluation should help to establish some hierarchy between the matrix proteins and to better understand the origin of shell defects induced by physiological factors such as hen age. The comparison of gene expression in young and old hen with lower eggshell quality has revealed a large number of differentially expressed genes, among them ovalbumin, versican, and glypican 3 (Feng et al., 2020). It will be of interest to apply this approach to compare uterine expression in aged hens to the same hens after molting, as the protein profile of eggshell extracts differs between the two groups (Ahmed et al., 2005). In conclusion, biomineralization of the shell is under the control of matrix proteins, the synthesis and secretion of which is under spatiotemporal regulation. A remaining challenge is to decipher the complex interaction between sex steroids, mechanical stimulus, vitamin D, and additional unknown factors.

Chapter 33

Adrenals

Rocco V. Carsia

Department of Cell Biology and Neuroscience, Rowan University School of Osteopathic Medicine, Stratford, NJ, United States

33.1 Anatomy

33.1.1 Gross anatomy, blood supply, and innervation

The paired adrenal glands are located anterior and medial to the cephalic lobes of the kidneys (Figure 33.1). They are generally flat and lie close together and are closely applied to the dorsal aorta and posterior vena cava (caudal vena cava; postcava). In the domestic chicken (*Gallus gallus*) and the African ostrich (*Struthio camelus*), the glands differ in shape in that the right gland is more triangular in shape and the left more oblong (Tang et al., 2009; Humayun et al., 2012; Moawad and Randa, 2017). The glands receive direct arterial blood supply from the cranial renal arteries and occasionally from the aorta. Each gland is drained by a single adrenal vein which enters the posterior (caudal) vena cava or its caudal bifurcation. In the chicken, each gland also receives one or two lymphatic vessels.

The gland is enclosed in a highly vascularized but extremely friable connective tissue capsule (Chester Jones and Phillips, 1986). Each gland generally has two postganglionic sympathetic ganglia (cranial and caudal), embedded within the pericapsular sheath or more deeply within the outer gland substance (discussed in Section 33.1.2.3).

33.1.2 Microanatomy

33.1.2.1 The chromaffin tissue

The adrenal gland of birds consists of what appears to be an intermingling of steroid-secreting cells (adrenocortical cells) and chromaffin (adrenomedullary) cells (Figure 33.2). The arrangement of the adrenocortical cells (Figure 33.2) is described later. The chromaffin cells are larger, polygonal cells arranged in nests or clusters surrounded by a thin basal lamina. A single nerve bundle innervates the cluster such that one neuronal terminal forms synapses with up to three chromaffin cells of the same type, i.e., norepinephrine (NE) or epinephrine (E) chromaffin cells (Unsicker, 1973). The consensus of studies suggests

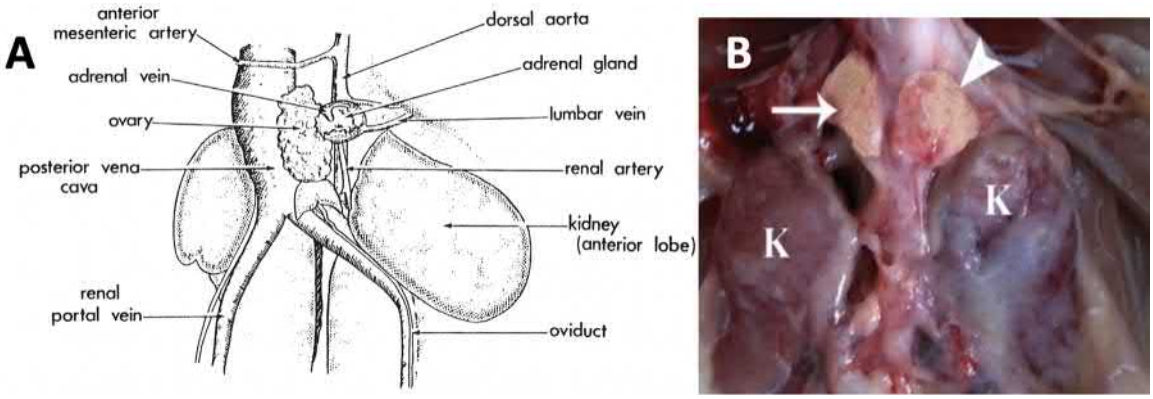

FIGURE 33.1 (A) The position of the left adrenal gland and its vascular supply in the female gull (*Larus argentatus*). (Preparation and drawing by I. Carthy and J. G. Phillips.) . (B) Ventral view of the adrenal glands of the domestic chicken (*Gallus gallus*). K, anterior lobes of the kidneys; *Arrow*, right adrenal gland; *Arrowhead*, left adrenal gland. Note the more triangular shape of the right adrenal gland. *Taken from (A) Holmes and Phillips (1976), (B) Moawad and Randa (2017).*

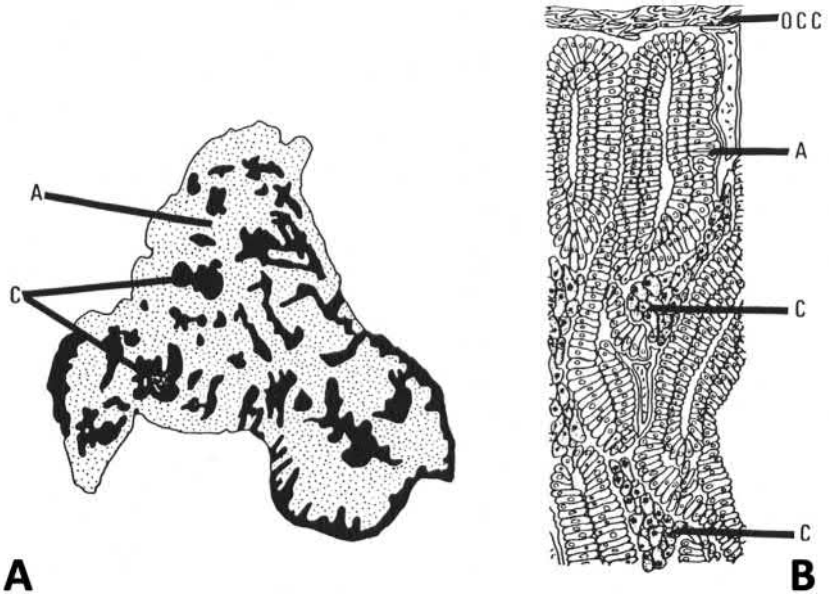

FIGURE 33.2 Microanatomy of a typical avian adrenal gland (Florida quail, *Colinus virginiatus floridanus*). (A) Distribution of chromaffin (C) and adrenocortical (A) tissues; (B) Structure of the looped cords of adrenocortical cells with intermingled chromaffin cell islets. The outer connective tissue (adrenal capsule) is also indicated (OCC). *Taken from Chester Jones and Phillips (1986).*

that the overall ratio of adrenocortical to chromaffin cells is about 1.5:1, and a similar ratio has been demonstrated in dispersed chicken adrenal cells (Carsia et al., 1985a).

The ratio of E- to NE-secreting chromaffin cells varies with species and age within a species. There is some suggestion that the ratio is smaller, i.e., greater proportion of NE cells, in orders with more primitive ancestry and greater in more recently evolved birds (Ghosh et al., 2001; Humayun et al., 2010). In the domestic chicken, about 70% of the chromaffin cells are E-secreting cells (Ohmori, 1998).

33.1.2.2 The adrenocortical tissue

The adrenocortical cells are arranged in cords consisting of a double row of adrenocortical cells oriented with their columnar axes perpendicular to the cord and with their basal side facing sinusoids (Holmes and Phillips, 1976). At the periphery of the gland, the cords form tighter loops, almost basket-like cells that in many species resemble the glomerular structure (zona glomerulosa) seen in mammals (Figure 33.2). More centrally the cords are long and interlacing.

The preponderance of histological, ultrastructural, and functional evidence indicates that birds have a modest segregation of adrenocortical cell subpopulations that resembles the zonation of the mammalian adrenal cortex (Bhattacharyya et al., 1972; Pierce et al., 1978; Holmes and Cronshaw, 1984, 1993). Histological preparations reveal at least two different zones of cells: a subcapsular zone (SCZ) and an inner zone (IZ). In the chicken, there is a fairly continuous subcapsular layer of essentially pure chromaffin cells outside the SCZ (Humayun et al., 2012; Moawad and Randa, 2017) (see Figures 33.3 and 33.4).

Adrenocortical cells of the SCZ are large and replete with lipid droplets. Like most steroid-secreting cells, they have the troika of organelles: stores of lipid, mainly in lipid droplets, varying amounts of smooth endoplasmic reticulum and mitochondria. The mitochondria bear regularly arranged tubular cristae, similar to mammalian zona glomerulosa cells. Functionally, the tissue secretes predominantly aldosterone in response to adrenocorticotropin (ACTH) and exclusively aldosterone in response to angiotensin II (Ang II) and is insensitive to ACTH withdrawal (adenohypophysectomy) (Klingbeil, 1985; Pierce et al., 1978; Holmes and Cronshaw, 1984, 1993).

Adrenocortical cells of the IZ are smaller, more elongated or columnar, contain fewer lipid droplets (Figures 33.3 and 33.4), have more abundant smooth endoplasmic reticulum and have mitochondria-bearing tubulovesicular cristae, similar to mammalian zona fasciculata cells. Functionally, the tissue secretes predominantly corticosterone in response to ACTH is refractory to Ang II and undergoes atrophy with ACTH withdrawal (adenohypophysectomy) with some cells converting to the SCZ-type (Klingbeil, 1985; Pierce et al., 1978; Holmes and Cronshaw, 1984, 1993).

The relationship of the SCZ with the IZ is not readily apparent due to the interspersed CC islets which at points "force" the IZ cords in and out of a plane of section and

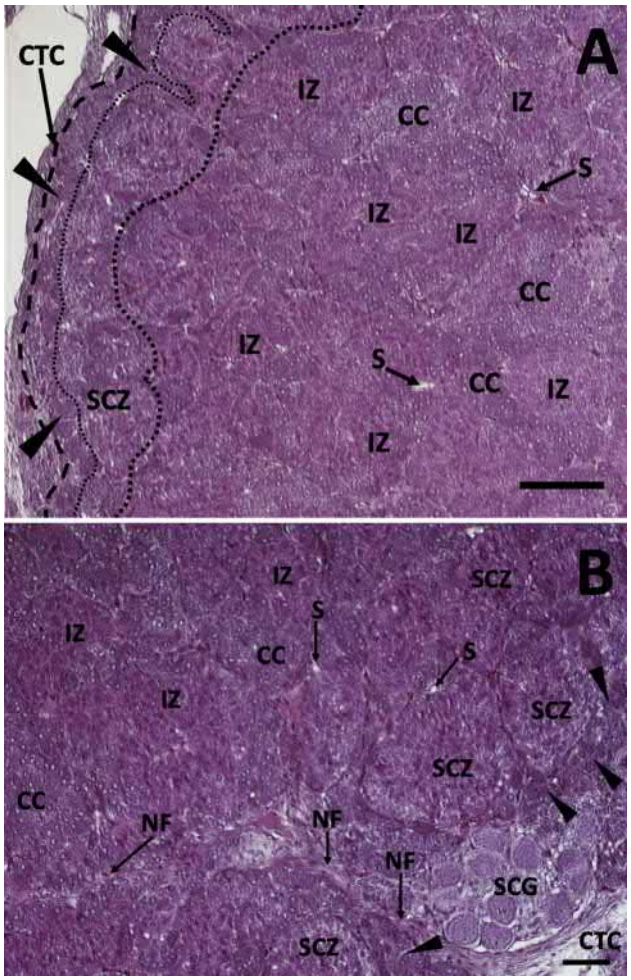

FIGURE 33.3 Light micrographs of portions of coronal sections through the right adrenal gland of the immature (2 weeks old) domestic chicken (*Gallus gallus*) (Moyer's broiler strain) (hematoxylin and eosin stain). (A) Note the zonation of the adrenal gland. There is an outer subcapsular zone (SCZ) consisting of basket-like cords of large, lipid-laden adrenocortical cells, with an outer layer of basophilic chromaffin cells (*arrowheads*) just under the connective tissue capsule (CTC). The inner zone (IZ) adrenocortical cells consists of tightly packed, eosinophilic cords with interspersed islets of lightly basophilic chromaffin-cell islets (CC). The nuclei of the chromaffin cells are conspicuously clear whereas those of the IZ cells are homogeneously granular and eosinophilic. Sinusoids (S) are seen between cords and chromaffin cell islets when cut in cross-section and also as narrow, blood-cell-containing channels squeezed between adrenocortical cords and chromaffin-cell islets. (B) Higher magnification of the SCZ and IZ adrenocortical cells and an embedded, subcapsular ganglion (SCG). The outer layer of basophilic chromaffin cells (*arrowheads*) is interrupted by the SCG and the streaming nerve fibers (NF) in relation to the SCG. Bars = 100 μM. *Histological preparations and micrographs provided by Renee M. Demarest, Ph.D., Department of Molecular Biology, Department of Cell Biology and Neuroscience, and the Histopathology Program of the Graduate School of Biomedical Sciences, Rowan University School of Osteopathic Medicine.*

disrupting a visible continuity. Nevertheless, it seems likely that the adrenocortical cords are formed by a continuously streaming lineage of cells: starting from putative capsular and/or subcapsular stem cell populations, or perhaps even within the SCZ, then moving to the more mature SCZ compartment , and then finally to the IZ. Cell-tracing and other molecular studies are currently underway to test this supposition (Chen-Che Jeff Huang, DVM, PhD; personal communication).

Additional evidence for a segregation or zonation of avian adrenocortical tissue comes from work with dispersed adrenocortical cells from the domestic turkey (*Meleagris gallopavo*) subjected to dietary Na^+ restriction and in which functionally distinct cell subpopulations were segregated based on density (Kocsis et al., 1995a). A population of high-density cells, the proportion of which was increased by the Na^+ restriction, showed a disproportionately enhanced aldosterone response to Ang II and K^+.

33.1.2.3 Extrinsic and intrinsic adrenal innervation

Preganglionic sympathetic fibers in thoracic and synsacral splanchnic nerves converge on the ganglia. However, the preponderance of the fibers (cholinergic) course through the ganglia without synapsing and penetrate the gland substance to innervate clusters of adrenal chromaffin cells. Indeed, preganglionic denervation leads to atrophy of the chromaffin tissue (Holmes and Phillips, 1976). Postganglionic sympathetic fibers emanating from the ganglia mainly innervate adrenal blood vessels (vasomotor), and the adrenergic type innervate the chromaffin cells (Ghosh et al., 2001).

The preponderance of ganglion cells is catecholaminergic, however, there appears to be noncatecholaminergic cells as well (Arcamone et al., 2006). Neuronal endings, ganglion cells, and the chromaffin cells elaborate a number of biogenic amines and neuropeptides, and the adrenal tissues exhibit a robust expression of cognate receptors. An incomplete list of biogenic amines and neuropeptides includes neuronal nitric oxide synthase (nNOS), vasoactive intestinal peptide (VIP), pituitary adenylyl cyclase-activating peptide (PACAP), neuropeptide tyrosine (NPY), galanine, atrial natriuretic peptide (ANP), substance P, and calcitonin gene-related peptide (CGRP). Moreover, the avian adrenal chromaffin cells have an intrinsic corticotropin-releasing hormone (CRH)/melanocortin system and the requisite cognate receptors (Takeuchi and Takahashi, 1998, 1999; Takeuchi et al., 1998, 1999, 2000; De Groef et al., 2004; Mirabella et al., 2004). Current thinking is that the intrinsic and extrinsic neuronal endings, the embedded ganglia, the scattered intraglandular ganglion cells, and the chromaffin cells form the intraadrenal regulation. Furthermore, this intraadrenal system is replete with neurotrophic factors and their cognate receptors (Arcamone et al., 2006). Indeed, many of the factors listed above have been shown to affect

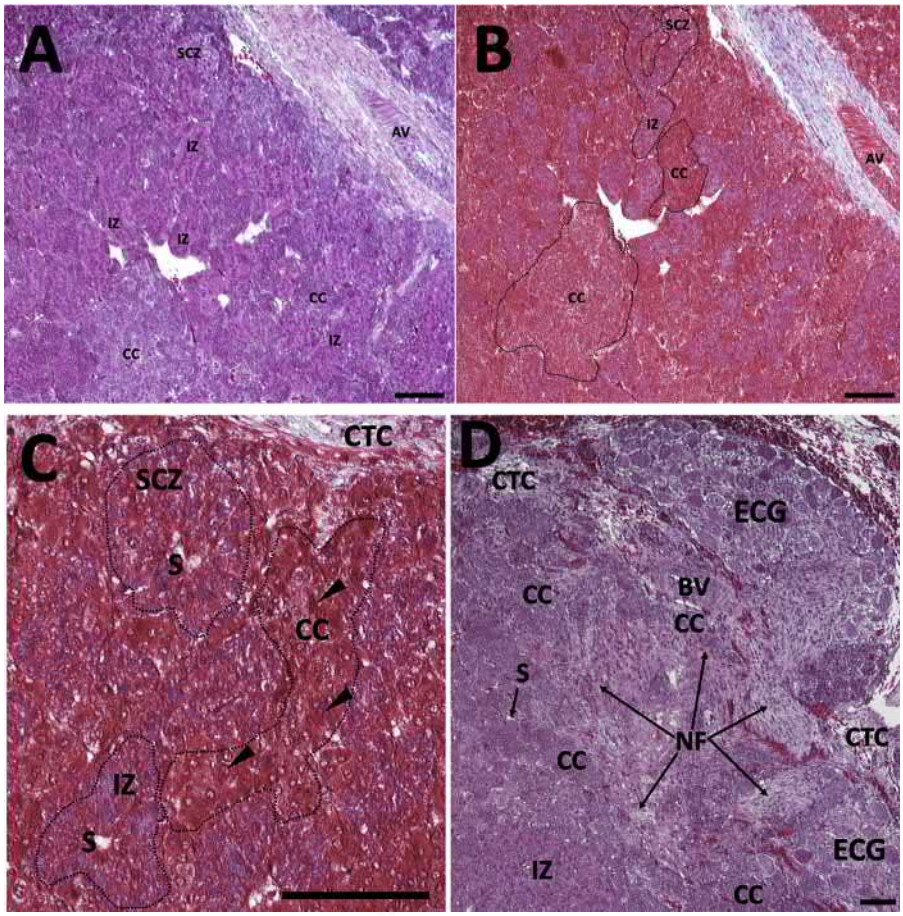

FIGURE 33.4 Light micrographs of portions of sections through the adrenal glands of the immature (2 weeks old) domestic chicken (*Gallus gallus*) (Moyer's broiler strain). (A and B) Coronal sections of the right adrenal gland to include the central adrenal vein (AV). (A) Section stained with hematoxylin and eosin and showing features mentioned in Figure 33.3; *CC*, chromaffin-cell islet; *IZ*, inner zone adrenocortical cells; *SCZ*, subcapsular zone adrenocortical cells. (B) Consecutive section prepared with Masson's trichrome stain. Adrenocortical cell cords show blueish nuclear and perinuclear staining, whereas chromaffin cells show varying intensity of reddish staining. A frequent observation is the continuity of the SCZ with the IZ (*outlined*). Note that the larger CC islet (*outlined*) has many central cells staining with less intensity compared with the CC islet (*outlined*) contiguous with surrounding IZ cords. (C) Higher power of a section demonstrating the differential staining with the Masson's trichrome stain between adrenocortical cell cords (SCZ and IZ outlined) and interspersed CC islets (*outlined*). *Arrowheads* point to some intensely staining chromaffin cells, likely epinephrine-secreting cells, whereas the paler-staining cells are likely norepinephrine-secreting cells. *CTC*, connective tissue capsule. (D) Parasagittal section through left adrenal gland stained with hematoxylin and eosin. Two extracapsular ganglia (ECG) are shown with large neurons, ~70 μM, with different staining intensities, probably a reflection of different functions. The ECG and nerve fibers (NF) coursing in relation to the interior of the ganglia and also penetrating into the gland disrupt the connective tissue capsule (CTC). Conspicuously absent in immediate relation to the ganglia are adrenocortical cell cords. CC islets are in close relationship to the ECG. *BV*, blood vessel. Note that in several sections the sinusoids (*S*) are conspicuous. Bars = 100 μM. *Histological preparations and micrographs provided by Renee M. Demarest, Ph.D., Department of Molecular Biology, Department of Cell Biology and Neuroscience, and the Histopathology Program of the Graduate School of Biomedical Sciences, Rowan University School of Osteopathic Medicine.*

steroid and catecholamine secretion in vitro. However, it is obvious that the role of this regulation appears to be modest, given the drastic effects of hypophysectomy (Carsia et al., 1985c). The main role of the intraadrenal regulation may be to remodel the adrenal tissues, that is, to alter the proportions of chromaffin and steroid-secreting cell subtypes to meet changing physiological needs dictated by life-history-cycle/stage requirements and long-term stress events. A proposed scheme of such an intra-adrenal regulation is shown in Figure 33.5.

33.2 Adrenocortical hormones

33.2.1 Corticosteroid secretory products

The glucocorticoid, corticosterone, is the principal corticosteroid released by the avian adrenal gland. The principle mineralocorticoid, aldosterone, is produced in considerably less quantity in the posthatch bird. In-vitro studies with anseriform and galliform adrenal tissues and dispersed adrenal cells indicate that the ratio of aldosterone to corticosterone production rates is about 1:19. However, based

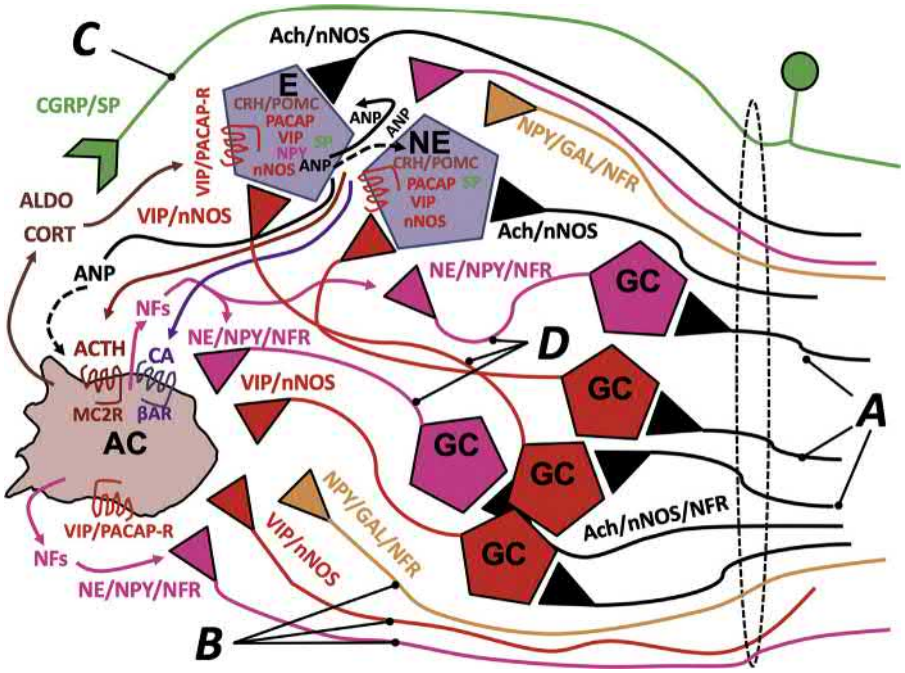

FIGURE 33.5 A proposed model for the intraadrenal neuroendocrine regulation based on comparative studies of reptiles, birds, and mammals. In birds, this model may operate with wide species differences. The neural regulation has both extrinsic and intrinsic components of the sympathetic nervous system. Its axonic terminals are represented by *black and colored triangles*. The extrinsic innervation is composed of (A), preganglionic sympathetic efferent axons containing acetylcholine (Ach) and neuronal nitric oxide synthase (nNOS) (*black*), (B), postganglionic sympathetic efferent axons containing vasoactive intestinal peptide (VIP) and nNOS (*red*), or neuropeptide tyrosine (NPY) and galanine (GAL) (*orange*), or NPY and norepinephrine (NE) (*pink*), and (C), sympathetic afferent (sensory) peripheral processes (dendrites) containing substance P (SP) and calcitonin gene-related peptide (CGRP) (*green*). *Dotted oval* represents the splanchnic nerve bundle which contains these extrinsic fibers. The intraadrenal innervation (D) is composed of the postganglionic sympathetic ganglion cells (GCs, *smaller colored pentagons*) of the cranial and caudal ganglia, embedded ganglia and the scattered GCs throughout the gland. A GC contains VIP and nNOS (*red*) or NPY and NE (*pink*). There is evidence that in some species, GCs also have phenylethanolamine N-methyltransferase for the synthesis of epinephrine (E), but it is not clear if this enzyme is active or if E is released from axonic terminals. Both preganglionic and postganglionic axons probably express neurotrophic factor receptors for axonal growth. Neurotrophic factors are probably elaborated by GCs, chromaffin cells, and adrenocortical cells and thereby in a feedback loop regulate the growth and function of presynaptic axons. For example, growth of NPY axons is stimulated by neurotrophic factors released by adrenocortical cells. Thus, many axonic terminals have cognate receptors for these neurotrophic factors (NFR). This neurotrophic loop probably remodels both the adrenocortical and chromaffin tissues during life-history cycle/stage transitions and periods of prolonged stress. The intrinsic endocrine component consists of the chromaffin cells (*larger purple pentagons*) and the adrenocortical cells (ACs). The chromaffin cells are also modifications of postganglionic sympathetic neurons and are of two functional types: E-secreting cells and NE-secreting cells. These cells also have the enzymatic machinery for an intrinsic corticotropin-releasing hormone (CRH)/adrenocorticotropin (ACTH) system in that they contain and process pro-opiomelanocortin. They also contain many neurotransmitters: pituitary adenylyl cyclase-activating peptide (PACAP), VIP, SP, and the nitric oxide-producing enzyme, nNOS. In addition, the E cells contain atrial natriuretic peptide (ANP). The intraadrenal ACTH interacts with melanocortin 2 (ACTH) receptors (MC2R) on ACs to stimulated corticosteroid [corticosterone (CORT) and aldosterone (ALDO)] synthesis and secretion (*brown arrows*). The intraadrenal CORT, in turn, stimulates E production. Whereas the intraadrenal ANP dampens corticosteroid production in ACs and inhibits NE cell function (*dotted black arrows*), it may stimulate the conversion of NE cells to E cells (*solid black curved arrow*). Both adrenocortical and chromaffin cells have VIP/PACAP receptors (VIP/PACAP-R). In general, activation of these receptors stimulates corticosteroid and catecholamine production. Furthermore, intraadrenal catecholamines interact with β-adrenergic receptors on ACs to augment corticosteroid production. SP from sensory endings stimulates ACs to produce corticosterone and aldosterone. In addition, it stimulates the release of catecholamines. CGRP and GAL also appear to be stimulatory for ACs. In this scheme, the parasympathetic components are omitted because of the absence of definitive work. See text for additional details. *Scheme drawn by R. V. Carsia.*

on studies in which both corticosteroids were measured, the average ratio of the baseline circulating concentrations of aldosterone to corticosterone is about 1:175 (Table 33.1). Younger birds tend to have higher circulating concentrations of each compared to those of adults.

The avian adrenal gland secretes additional steroids that presumably have important ontogenetic function and play a role in life-history-cycle transitions (Landys et al., 2006; Wada, 2008; Wingfield, 2013; Romero and Gormally, 2019). Cortisol is a significant secretory product during the embryonic and early posthatch period and then declines thereafter (Kalliecharan and Hall, 1974). Presumably, cortisol has a role in the development and maturation of several organ systems (see Carsia et al., 1987a). In some psittacine species, circulating cortisol is insensitive to exogenous ACTH (Lothrop et al., 1985; Walsh et al.,

TABLE 33.1 Baseline peripheral plasma concentrations of corticosterone and aldosterone in some galliform and anseriform birds in which both corticosteroids were measured in the same samples by radioimmunoassay (averages from 26 studies).

Bird order	Life-history cycle	Corticosterone (ng/mL)	Aldosterone (pg/mL)
Galliform birds[a]			
	Hatch	11	33
	Immature	11	46
	Adult	2	19
Anseriform birds[b]			
	Hatch	16	345
	Immature	8	308
	Adult	18	60

1985). Thus, the availability and action of cortisol may be less dependent on the hypothalamic-pituitary-adrenal (HPA) axis and more dependent on the regulation at the tissue level (e.g., in (Baker, 2010) the immune system; see Section 33.3.4). Furthermore, there are other factors that segregate the tissue actions of corticosterone and cortisol: isoforms of corticosteroid-binding globulin (CBG) that preferentially bind cortisol and thus influence its half-life for delivery to sensitive tissues (Schmidt et al., 2008, 2010), and isoforms of glucocorticoid receptors (GRs) in various target tissues that selectively bind cortisol (Schmidt et al., 2010). In addition, there is interplay between systemic delivery of corticosteroids to target tissues and the intrinsic local production within tissues (Schmidt and Soma, 2008; Schmidt et al., 2008). Corticosterone may be synthesized or regenerated in the brain (Newman et al., 2008) and locally may mediate the acute effect of stress on brain aromatase activity in a sex-dependent manner (Dickens et al., 2011a). The picture is further complicated by the local expression of 11β-hydroxysteroid dehydrogenases type 2 and 1 that can degrade and regenerate active glucocorticoids, respectively, within cells. Overall, despite its relatively low-circulating concentration relative to corticosterone, cortisol produced locally throughout the posthatch life of birds, e.g., within immune tissues and possibly the brain, suggests it has unique and important functions in both an organ-specific and age-specific manner.

In addition to cortisol, the adrenal gland is an important source of sex steroids, especially testosterone (Tanabe et al., 1986; Ottinger et al., 2001) during the embryonic and perinatal period that complements the gonads for establishing adequate levels of androgens and estradiol. This "adrenal-gonadal unit" establishes the dynamic balance between systemic delivery of sex steroids to the brain and their local production within the brain, a balance which is important for sexual differentiation of the hypothalamus and the establishment of important central nervous signals that support breeding, territorial, and courtship behaviors (Soma and Wingfield, 2001; Schmidt et al., 2008; Pintér et al., 2011).

33.2.2 Other secretory products

The chicken adrenocortical tissue is a major source of inhibin during embryonic development (Rombauts et al., 1994; Decuypere et al., 1997). Dexamethasone depresses inhibin release in ovo, whereas ACTH elicits a rise in inhibin release that parallels corticosterone release in primary cultures of embryonic chick adrenal cells. Furthermore, the adrenal gland continues to be a complementary extragonadal source of inhibin in the adult (see Vanmontfort et al., 1997 and Bruggeman et al., 2003) and activin as well (Chen and Johnson, 1996).

33.2.3 Synthesis of corticosteroids

Adrenal/interrenal steroidogenesis is carried out by microsomal and mitochondrial enzymes that bear active enzymatic sites which are highly conserved among vertebrates (e.g., Nomura et al., 1999; Freking et al., 2000; Kanda et al., 2000; Kamata et al., 2004; Baker et al., 2015). StAR is the hormone-sensitive, **st**eroidogenic **a**cute **r**egulatory protein that delivers free cholesterol from the outer mitochondrial membrane to the inner mitochondrial membrane where it can access the cholesterol side-chain cleavage

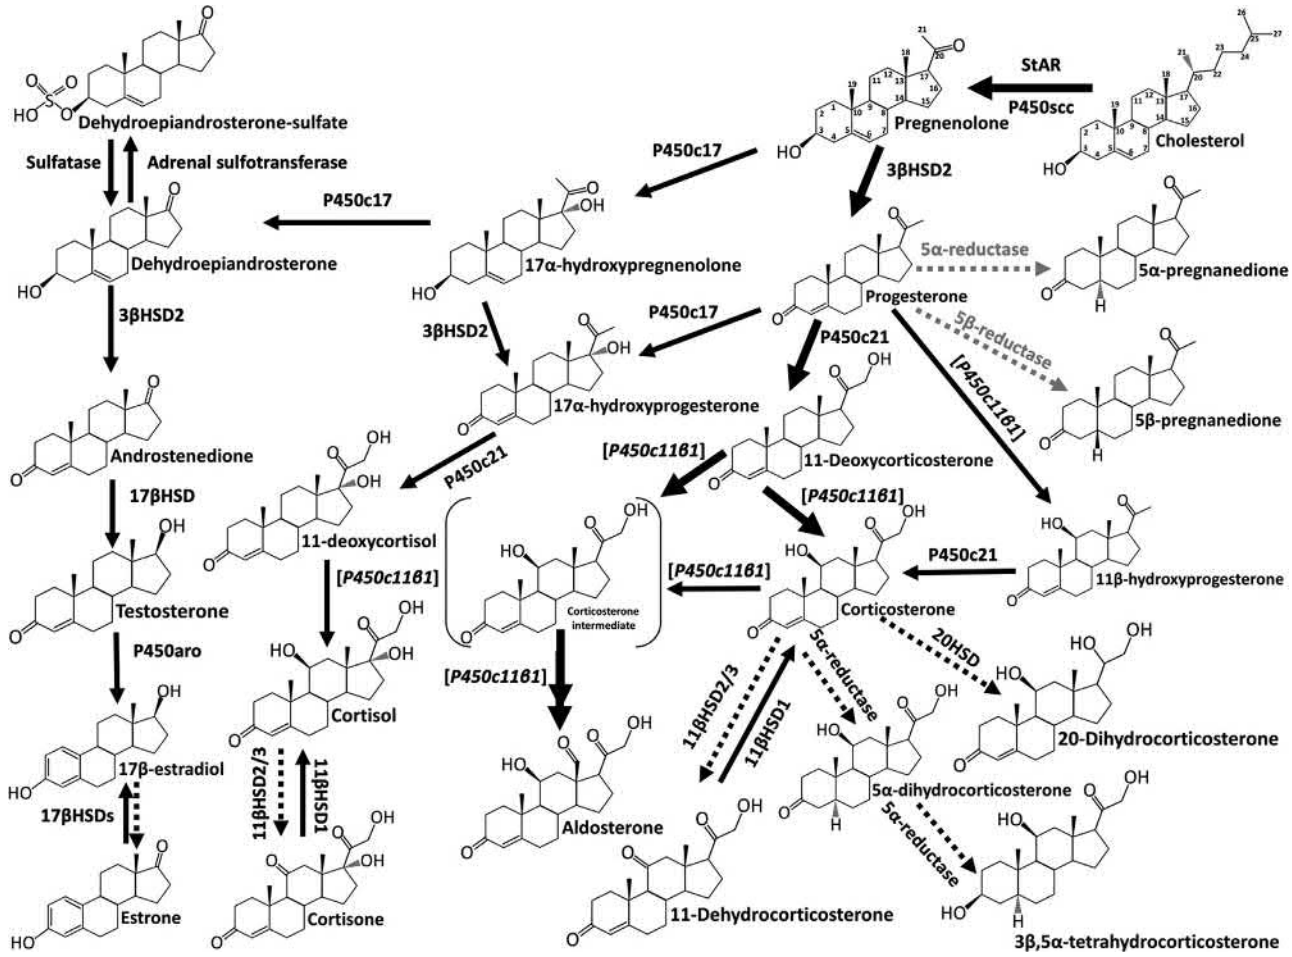

FIGURE 33.6 Steroidogenesis in the avian adrenal gland. *Thick arrows* indicate the predominant pathway of posthatch (postnatal) birds leading to corticosterone and aldosterone. *Thin arrows* indicate additional pathways that are more prominent in the embryonic and early posthatch (postnatal) periods, and during life-history-stage transitions; these are the pathways to cortisol and to the sex steroids. Also, the avian immune system may have a sufficient suite of enzymes to locally synthesize cortisol (Schmidt and Soma, 2008). *Dotted arrows* indicate steroid-inactivating or degrading pathways. Dotted *gray arrows* indicated degradative pathways of progesterone during the embryonic period. Solid *gray* and *black* bonds on steroids represent key alpha (down) and beta (up) positions, respectively, however, not all hydrogen bond positions are shown. StAR, steroidogenic acute regulatory protein; P450scc, mitochondrial cytochrome P450 cholesterol side-chain cleavage enzyme; 3βHSD2, microsomal/mitochondrial 3B-hydroxysteroid dehydrogenase/Δ5→Δ4 isomerase, type 2; P450c21, microsomal cytochrome P450 21-hydroxylase; P450c17, microsomal cytochrome P450 17α-hydroxylase/17,20-lyase; 17βHSD, microsomal 17-ketosteroid reductase; P450aro, microsomal cytochrome P450 aromatase; 17βHSDs, not fully characterized adrenal microsomal enzymes in birds; 11βHSD2/3, microsomal 11β-hydroxysteroid dehydrogenase, types 2 and 3; 11βHSD1, 11β-hydroxysteroid dehydrogenase type 1[Largely microsomal, although there is evidence for a significant cytosolic type-1 like enzyme.]; 20HSD, microsomal 20-hydroxysteroid dehydrogenase; and *P450C11β1*, mitochondrial cytochrome P450 11β-hydroxylase type 1.The last enzyme is italicized because is not clear if the avian adrenal gland expresses this or a similar enzyme. If there is just one enzyme, P450C11β1 or P450C11β1-like, it would catalyze the 11β-hydroxylation of 11-deoxycorticosterone to corticosterone and 11-deoxycortisol to cortisol. Also, under certain conditions, it would carry out (1) the 11β-hydroxylation of 11-deoxycorticosterone to a corticosterone intermediate, and then (2) an 18-hydroxylation step taking the corticosterone intermediate to 18-hydroxycorticosterone intermediate, and (3) an 18-methyl oxidase step (which is the key function of aldosterone synthase in some mammals) to aldosterone. *Double superimposed arrows* indicate steps 2 and 3. See text for additional details. *Pathway drawn by R. V. Carsia.*

enzyme, P450scc, to be converted to pregnenolone (Miller and Auchus, 2011). Not surprisingly, StAR is highly conserved in vertebrate steroidogenic tissues (Bauer et al., 2000). StAR-related-lipid-transfer-domain proteins are responsible for loading free cholesterol to the outer mitochondrial membrane to facilitate StAR activity.

The synthetic pathways of the major steroids secreted by the avian adrenal gland during the life cycle are shown in Figure 33.6. In this steroidogenic scheme, mitochondrial cytochrome P450SCC (or CYP11A1) (Nomura et al., 1997) mediates 20α-/22-hydroxylation and scission of the C20-22 carbon bond, producing pregnenolone and isocaproaldelhyde, a set of reactions traditionally called "20, 22-desmolase." Pregnenolone is converted to progesterone by 3βHSD2 (HSD3B2) (Nakabayashi et al., 1995), a non-P450 microsomal/mitochondrial dehydrogenase-isomerase

complex which mediates 3β-hydroxysteroid dehydrogenase and isomerase (Δ^5 double bond to Δ^4 double bond) activities. Microsomal P450c21 (CYP21A2) then mediates a 21-hydroxylation steps converting progesterone to 11-deoxycorticosterone. Corticosterone is the predominant corticosteroid product of the avian adrenal gland, albeit 11-deoxycorticosterone is also a significant secretory product. Corticosterone is formed from 11-deoxycorticosterone by an 11β-hydroxylation most probably via a mitochondrial enzyme.

Aldosterone is largely formed from 11-deoxycorticosterone and not from corticosterone because corticosterone is a poor substrate. Thus, 11-deoxycorticosterone undergoes an 11β-hydroxylation, converting it to enzyme-bound corticosterone which serves as an intermediate. This is followed by an 18-hydroxylation and lastly an 18-methyl oxidase step, producing the potent mineralocorticoid, aldosterone. As mentioned previously (Section 33.1.2.2), SCZ slices from the duck adrenal gland secrete predominantly aldosterone in response to ACTH and exclusively aldosterone in response to Ang II whereas the IZ tissue secretes predominantly corticosterone in response to ACTH and is refractory to Ang II (Klingbeil, 1985; Pierce et al., 1978; Holmes and Cronshaw, 1984, 1993). Dietary Na^+ restriction in the domestic turkey induces a subpopulation of adrenocortical cells that have a disproportionately enhanced aldosterone response to Ang II and K^+ (Kocsis et al., 1995a).

The current knowledge concerning the enzymes carrying out both glucocorticoid and mineralocorticoid synthesis in birds is controversial. A limited earlier analysis of avian genomes suggested that birds, just like some mammals, have just a single enzyme that carries out the steps to corticosterone and aldosterone (CYP11B1) (Baker et al., 2015). However, a more recent expanded analysis of eight diverse species from five orders indicates that except for the brown kiwi (*Apteryx australis*), which has a function CYP11B1, all others lack CYP11B1 (Nelson, 2018). The nature of an alternative enzyme(s) that carries out steps like CYP11B1 is unknown. Furthermore, how some vertebrate species with just a single enzyme, CYP11B1, selectively secrete aldosterone over corticosterone (or cortisol) from subpopulations of adrenocortical cells is an unresolved problem in steroid synthesis.

Other enzymatic activities are also apparent mainly during the embryonic and neonatal periods and at modest levels in the adult. Formation of cortisol is predominantly via 17α-hydroxylation of progesterone by a microsomal P450c17 (CYP17A1) (Ono et al., 1988) to form 17α-hydroxyprogesterone, then a 21-hydroxylation by microsomal P450c21 (CYP21A1) to form 11-deoxycortisol and finally an 11β-hydroxylation step by a mitochondrial P450c11β to form cortisol. A minor pathway is pregnenolone to 17α-hydroxypregnenolone via P450c17, and then to 17α-hydroxyprogesterone via 3βHSD2. There is some evidence that 11β-hydroxyprogesterone serves as a precursor for corticosterone (via a 21-hydroxylation step) and cortisol (via 17α- and 21-hydroxylation steps), albeit these pathways appear to be of little significance.

The main pathway for adrenal sex steroids uses a microsomal P450c17 (CYP17A1) (Ono et al., 1988) (has both 17α-hydroxylase and 17,20-lyase activities) that efficiently converts pregnenolone to 17α-hydroxypregnenolone and then to dehydroepiandrosterone (DHEA). The 3β-hydroxyl group of DHEA can be sulfated by an adrenal sulfotransferase. As mentioned previously, DHEA and DHEA-sulfate are in the avian circulation (Soma and Wingfield, 2001) and in the adrenal gland. Also, analysis of circulating steroids provides evidence for a "backdoor" pathway to androgen synthesis in birds using a group of aldo-keto reductase enzymes, but it is not clear if this pathway exists in avian adrenal/interrenal tissues (Prior et al., 2017).

Adrenal androstenedione can be converted to testosterone by a 17βHSD (Nomura et al., 1999), a microsomal, non-P450 enzyme. Indeed, androgens are detected in the avian adrenal gland (Ottinger et al., 2001; Soma and Wingfield, 2001). Furthermore, there is evidence that testosterone is aromatized to estradiol by a microsomal aromatase, P450aro (CYP19A1) (Shen et al., 1994) in that estradiol has been detected in the embryonic adrenal gland (Tanabe et al., 1979, 1986; Ottinger et al., 2001) and that it persists into the posthatch period (Ottinger et al., 2001). But this sex steroid pattern may not be uniform among the avian species in that in some species there may be an "adrenal-gonadal unit" in which the adrenals contribute precursors for gonadal steroidogenesis.

Degradation pathways exist in the avian adrenal gland during development, the posthatch period and in the adult. Metabolites of progesterone, corticosterone, cortisol, estradiol, and testosterone have been detected. It appears that the adrenal gland has the sets of enzymes to carry out both degradative and regenerative reactions. In the adult gland, a more prominent enzyme is 5α-reductase (Miller and Auchus, 2011; Langlois et al., 2010). This enzyme degrades corticosterone to 5α-dihydrocorticosterone (5α-pregnan-11β,21-diol-3,20-dione) and 5α-tetrahydrocorticosterone (5α-pregnan-3α,11β,21-triol-20-one). However, the importance of these enzyme activities in an organismal context is unclear.

33.2.4 Transport of corticosteroids

In birds, most circulating corticosterone and cortisol are transported bound in dynamic equilibrium to plasma proteins. More than 90% of circulating corticosteroids are bond to the α-2 globulin, CBG (that has a high affinity and low-binding capacity for corticosteroids). Minor amounts

are bound to low-affinity, high-capacity, nonspecific binding proteins (mostly albumin) (Wingfield et al., 1984). Complementing a previous study (Malisch and Breuner, 2009), a random survey containing more recent studies from different species suggests a fairly wide range of affinities (K_d), 1.2−8.3 nM, and capacities, 38−225 nM, for corticosterone. In chickens, corticosterone binds to CBG with an average K_d of about 2 nM and a capacity of about 50 nM (Fässler et al., 1986). In some species, cortisol binds to avian CBG with a similar affinity and capacity (Schmidt et al., 2010), however, in many species, it binds with affinities similar to the sex steroids (see Malisch and Breuner, 2009). CBG also binds progesterone with high affinity, testosterone, and dihydrotestosterone with a lower affinity but within the physiological range of these sex steroids. Binding of estrogen is negligible.

A number of factors affect the circulating concentration of CBG, and these responses vary with species and life-history stage (Malisch and Breuner, 2009) and over seasons (Romero and Gormally, 2019). Changes in CBG capacity in response to stress can be acute, occurring within 30 min (Breuner et al., 2006; Charlier et al., 2009; Malisch et al., 2010). It is also influenced by ontogenic processes, hormonal manipulations, and other physiological states (see Landys et al., 2006; Wingfield, 2013). Overall, the interaction between glucocorticoids, their cognate binding proteins, and their target tissues is complex and that the precise role played by CBGs in mediating the actions of glucocorticoids awaits further investigation.

33.2.5 Circulating concentrations of corticosterone and aldosterone

Investigations in which the circulating concentrations of corticosterone and aldosterone were measured in the same study are restricted to galliform (chicken, turkey, and Japanese quail) and anseriform (duck) species. The circulating concentration of corticosterone in unstressed birds is in the nonogram-per-milliliter range, whereas that for aldosterone is in the picogram-per-milliliter range (Table 33.1). There is a tendency for the circulating values to fall from hatch to maturity. Part of this is explained by the decrease in relative adrenal weight with age (Holmes and Phillips, 1976; Carsia and Weber, 1986). However, it also may be due to the decrease in adrenal sensitivity and maximal steroidogenic capacity with posthatch age (Carsia et al., 1985b, 1987a; Carsia and Weber, 1986).

33.2.6 Secretion, clearance, and metabolism of corticosterone and aldosterone

Not surprisingly, corticosteroid concentrations which are initially high in the adrenal gland and adrenal venous effluent (in micrograms per milliliter) and then are secreted at about a microgram per minute per kilogram (Assenmacher, 1973) are then rapidly diluted in the circulation and distributed to the extracellular fluid. Circulating concentrations of corticosteroids are maintained by the dynamic balance between metabolic clearance, adrenal secretion, and return to the general circulation by regeneration at the tissue level. Transmembrane passage of corticosteroids is rapid for all cells ($\sim 10^{-4}$ cm/s) (Giorgi and Stein, 1981) thus facilitating rapid clearance and metabolism in competent cells, particularly in the kidney and liver. Indeed, in a very limited number of studies, the average half-lives of corticosterone and aldosterone in the circulation are similar, about 8−15 min and 6−13 min, respectively, but there are differences among species, with physiological status, and after endocrine manipulations (Holmes et al., 1972, 1974; Holmes and Slikker, 1976).

The metabolic clearance rate for corticosterone is decreased with age (Holmes and Kelly, 1976) and by thyroidectomy (Kovács and Péczely, 1983). In addition, it appears to be influenced by nutritional status. In chickens subjected to dietary protein restriction, it is increased 85%, which translates to a fourfold increase in secretion rate from the adrenal gland (Carsia et al., 1988a).

Clearance from the circulation is facilitated by intracellular binding and sequestration and ultimately metabolism, primarily by the liver via hepatic 5α-reductase which converts corticosterone and aldosterone to inactive metabolites (Daniel and Assenmacher, 1971). The metabolites in urine exist as several polar and nonpolar forms including intact corticosteroids, some free and some conjugated to sulfate and glucuronide (Helton and Holmes, 1973; Holmes et al., 1974; Holmes and Slikker, 1976; Rettenbacher et al., 2004).

Glucocorticoids are the end-product signals of a system largely concerned with regulating energy flow—a system of which the HPA axis is a component. By contrast, mineralocorticoids are the end-product signals of a system largely concerned with maintaining salt and water balance—a system of which the renin-angiotensin-aldosterone system is a component. These steroid hormones work on specific effector tissues of each system. However, glucocorticoids are also essential to permit the full expression of almost all metabolic processes.

The effector molecules in the effector tissues are the GR and mineralocorticoid receptor (MR) which are ligand-inducible transcription factors. The MR binds corticosterone with an affinity that is more than 30 times that of the GR. Since the circulating concentration of corticosterone is about 20−300 times that of aldosterone, almost all of the MRs are fully occupied by corticosterone. Thus, in order for aldosterone to represent the system regulating salt and water balance, corticosterone (and cortisol) in the effector tissues needs to be either sequestered from the MR or rapidly degraded so that its intracellular concentrations exposed to the MR is extremely low.

FIGURE 33.7 Deduced amino acid sequences of adrenocorticotropin (ACTH) peptides [amino (N)-terminus to carboxyl (C)-terminus] from selected avian species based on their respective cDNAs. Green amino acids bind to the "docking" or "address" site on MC2R. In mammals, arginine $(R)^{15}$ is replaced by lysine (K); it is assumed that these amino acids are interchangeable, thus, $K^{15}/R^{15}K^{16}R^{17}R^{18}P^{19}$. Red amino acids $H^6F^7R^8W^9$ bind to the activation site of MC2R for functional binding and signal transduction (e.g., cyclic adenosine monophosphate production) and are uniformly conserved among vertebrates. Arginine $(R)^8$ is also essential for maintenance of the secondary structure of ACTH in the circulation (Ghaddhab et al., 2017). Purple amino acids are essential spacers and the proline $(P)^{12}$ (*underlined*) provides a kink inflection to properly position the activation and docking amino acids. Proline $(P)^{19}$ (*underlined*) presumably "kinks" the rest of the sequence (amino acids 20–39) out of the way for binding to the docking site. In this scenario (Liang et al., 2013), when the $R^{15}K^{16}R^{17}R^{18}P^{19}$ docking site is occupied, the $H^6F^7R^8W^9$ motif is now properly positioned for functional binding and activation of MC2R. Molecular studies have demonstrated that amino acids 20–39 are not necessary for binding and signal transduction but are important for stability in the circulation. Amino acid abbreviations: A, alanine; C, cysteine; D, aspartic acid; E, glutamic acid; F, phenylalanine; G, glycine; H, histidine; I, isoleucine; K, lysine; L, leucine; M, methionine; N, asparagine; P, proline; Q, glutamine; R, arginine; S, serine; T, threonine; V, valine; W, tryptophan; Y, tyrosine. Species names with GenBank accession numbers or reference are as follows: [a]*Struthio camelus* (Naudé et al., 2006); [b]*Anas platyrhynchos* (XM_013103743.2); [c]*Gallus gallus* (NM_001031098.1); [d]*Numida meleagris* (XM_021391833.1); [e]*Coturnix coturnix* (AB620013.1); [f]*Meleagris gallopavo* (Variants 1 and 2—XM_010708068.2 and XM_019613648.1); [g]*Columba livia* (XM_021298522.1); [h]*Opisthocomus hoazin* (XM_009942707.1); [i]*Pelecanus crispus* (XM_009480535.1); [j]*Aptenodytes forsteri* (XM_009283455.1); [k]*Haliaeetus leucocephalus* (XM_010583178.1); [l]*Corvus macrorhynchos* (AB555653.1); [m]*Taeniopygia guttata* (XM_002198019.3). *The compilation of sequences was provided by Colin G. Scanes, Ph.D., D.Sc. Color designation and description of amino-acids motifs by R. V. Carsia.*

The main enzymes that carry out the degradation of corticosterone and cortisol in target tissues are 11β-hydroxysteroid dehydrogenase 2 (11βHSD2) and 20-hydroxysteroid dehydrogenase (20HSD) (Vylitová et al., 1998; Baker, 2010; Ahmed et al., 2013) (Figure 33.6). 11βHSD2 catalyzes the oxidation of corticosterone and cortisol to the inactive metabolites, 11-dehydrocorticosterone and cortisone, respectively, and 20HSD converts corticosterone to 20-dihydrocorticosterone (see Figure 33.7). There also appears to be a second corticosterone (cortisol)-degrading enzyme, 11βHSD3, expressed in the chicken colon and to a greater extent in the kidney (Katz et al., 2008; Baker, 2010). These enzymes are obviously expressed in other avian groups. There is a robust expression of 11βHSD2 and 20HSD in the zebra finch brain and several peripheral tissues analyzed and to a lesser extent in the gonads, more so in the ovary than in the testis (Katz et al., 2010).

As mentioned previously, there are also enzymes that regenerate active glucocorticoids. In chickens is the enzyme catalyzing the reverse reactions (reductive), 11βHSD1, which regenerates corticosterone (and cortisol) (Katz et al., 2007; Baker, 2010). Thus, a balance in inactivation and reactivation of glucocorticoids provides a prereceptor modulation of corticosteroid signals in avian effector tissues (Kučka et al., 2006).

Corticosterone, along with sex steroids, does accumulate in the egg (Hahn et al., 2011) and in a species-specific manner (Quillfeldt et al., 2011). They may possibly serve as a signal from the mother to progeny concerning adverse environmental conditions (Okuliarová et al., 2010).

33.2.7 General regulation of adrenocortical function

33.2.7.1 Adrenocorticotropin

The most efficacious stimulator of avian corticosteroid secretion is corticotropin (adrenocorticotropic hormone; ACTH). ACTH is one of the several melanocortins derived from ther highly conserved protein, pro-opiomelanocortin (POMC) (Dores and Lecaude, 2005; Harris et al., 2014). The sequence of the first 19 amino acids is rigidly conserved for maintaining the functional secondary structure in the circulation (Ghaddhab et al., 2017) and most importantly, the conserved "docking" or "address" site and the binding/activation site (Liang et al., 2013; Yang and Harmon, 2020). The rest of the molecule is required for stability in circulation (see Figure 33.7 for details). Numerous studies in vivo and in vitro with isolated adrenocortical cells (Carsia, 1990) from several species demonstrate a dose-dependent and rapid (less than 5 min) corticosteroid response to ACTH. Not surprisingly, this

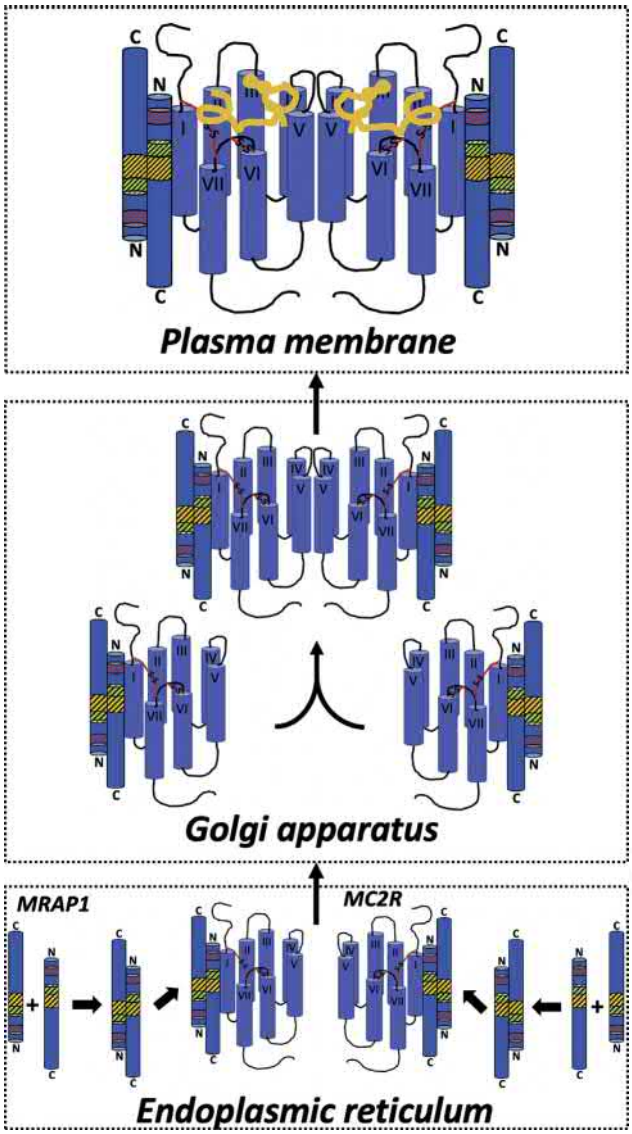

FIGURE 33.8 The functional MC2R is a heterohexameric complex formed from two MC2Rs and four MRAP1s. MRAP1 is a single-membrane spanning protein that forms an antiparallel homodimer for activity. The protomer with the extracellular amino terminus is the essential protein of the homodimeric complex (Malik et al., 2015). The blue region of MRAP1 is nonessential. The hatched orange region is the transmembrane domain. The hatched green region is essential for forming a stabile homodimer. In addition, the hatched orange and hatched green regions promote MC2R trafficking to the plasma membrane and transmembrane signaling after ACTH binding. The hatched red region is absolutely essential for functional ACTH binding to MC2R and signal transduction (i.e., G_s-protein activation and cAMP formation) (Rouault et al., 2017). In the endoplasmic reticulum, MRAP1 forms an antiparallel homodimer that couples with one MC2R. MC2R is a typical heptahelical GPCR. The MRAP1-MC2R heterotrimeric complex is transported to the Golgi apparatus where it couples with another MRAP1-MC2R heterotrimeric complex to form the functional, heterohexameric ACTH receptor complex (Fridmanis et al., 2017). It is postulated that a similar process can occur at the plasma membrane in which MRAP1 recruits and activates a pool of inactive MC2Rs (Clark and Chan, 2019). Two ACTH molecules (yellow) are bound by the functional, heterohexameric ACTH receptor complex. The ACTH molecules are depicted in their secondary structure. It is proposed that the amino-end helical region of ACTH orientates the binding amino acids to interact with transmembrane domains II, III, VI, and VII and the carboxyl-end loop of ACTH contains the "docking" amino acids that interact with transmembrane domains IV and V (Liang et al., 2013). The depicted protein interactions are purely schematic and are not to actual molecular scale nor do they reflect the actual interactions. *ACTH*, adrenocorticotropic hormone or corticotropin; *cAMP*, cyclic adenosine monophosphate; *GPCR*, G protein-coupled receptor; G_s, stimulatory G protein for cAMP formation; *MC2R*, melanocortin-2 receptor/ACTH receptor; *MRAP1*, melanocortin-2 receptor accessory protein 1. *Cartoon drawn by R.V. Carsia.*

rapid response needs to be considered when assessing corticosterone rhythms in birds (Breuner et al., 1999; de Jong et al., 2001; Romero and Reed, 2005; Romero and Gormally, 2019). In exotic avian species, ACTH stimulation test protocols result in a wide range of circulating corticosterone responses, from as little as 33−96% over baseline to as much as 2400% over baseline. This variation in maximal response is mostly due to the variation in the starting baseline level, i.e., the lower the baseline in the species, the greater the response (de Matos, 2008).

In birds, ACTH-induced corticosteroid production operates through a G-protein-coupled receptor, the melanocortin 2 receptor (MC2R) (Takeuchi et al., 1998; Boswell and Takeuchi, 2005), which is activated exclusively by ACTH (Veo et al., 2011). In addition, ACTH is a potent stimulator of the other four avian melanocortin receptors subtypes (Ling et al., 2004) and the presence of MC5R in chicken liver and adipose tissue raises intriguing questions about the possible role of ACTH in the direct regulation of avian metabolism (Thomas et al., 2018).

Comparative molecular studies (Veo et al., 2011) and numerous in-vitro studies with isolated adrenocortical cells from diverse avian species confirm that dissemination of the ACTH signal in avian adrenocortical cells is largely through the cyclic AMP (cAMP)-dependent pathway involving a stimulatory guanine nucleotide binding protein, adenylyl cyclase, cyclic adenosine monophosphate (cAMP), and cAMP-dependent protein kinase (see Carsia, 1990; McIlroy et al., 1999).

Cell-surface expression and function of the avian MC2R requires melanocortin-2 receptor accessory protein 1 (MRAP1) (Veo et al., 2011; Thomas et al., 2018). As expected, the important domains of MRAP1 are highly conserved in many vertebrates (Dores and Garcia, 2015). Chicken MRAP1 is small linear proteins of about 120 amino acids, having a single hydrophobic transmembrane domain (Barlock et al., 2014). Cytoplasmic MRAP1 forms an antiparallel homodimer that interacts with the MC2R to form a heterotrimeric complex (Rouault et al., 2017) (see Figure 33.8 for additional details). Formation of the heterotrimeric complex is essential for trafficking, eventually to the plasma membrane. The mature, functional ACTH

receptor is actually a dimer of the heterotrimeric complex, thus, a heterohexameric protein complex composed of four MRAP1s and two MC2Rs (Fridmanis et al., 2017). Stability and turnover differences between MRAP1 (shorter) and MC2R (longer) suggest that MRAP1 may recruit and activate a pool of inactive MC2Rs at the cell surface as well (Clark and Chan, 2019). This additional proposed model of recruitment of fully formed but inactive MC2Rs by MRAP1 at the plasma membrane may be advantageous in situations of significant stress.

33.2.7.2 Angiotensins

As in many vertebrates, angiotensins regulate avian adrenocortical function (reviewed in Holmes and Cronshaw, 1993). Indeed, in-vivo studies and in-vitro work with adrenal tissue and cells demonstrate that the effect is direct. This topic is discussed in detail under Section 33.2.8.

33.2.7.3 Other putative regulators

Studies indicate that avian adrenocortical function is modulated by secretory products of the immune system and other endocrine organs. Interpretations of results derived from these studies should be viewed with caution since they are restricted to anseriform and galliform species and in many instances are based on in-vitro systems that have not been substantiated in vivo. Nevertheless, these studies deserve attention. Such peripheral agents may directly stimulate or inhibit adrenocortical function or may act as positive or negative modulators of tropic-hormone-induced responses. However, a common theme with hormones not of pituitary origin that stimulate corticosteroid synthesis in vitro is the lack of organismal context, given the drastic effects of hypophysectomy on adrenocortical function.

33.2.7.3.1 Stimulators and positive modulators

33.2.7.3.1.1 Prolactin and growth hormone The pituitary secretory products, prolactin and growth hormone appear to have a positive influence on avian adrenocortical function (Figure 33.9). Both prolactin and growth hormone are increased with various stressors and growth hormone assists in the overall maintenance of the avian adrenal gland (Harvey et al., 1995; Angelier et al., 2013).

The importance of growth hormone in avian (*Gallus gallus*) adrenocortical maintenance is indicated by its restoration and augmentation of cellular steroidogenic capacity after hypophysectomy and in the absence of ACTH and other hormonal replacement (Carsia et al., 1985c). In addition, recombinant chicken growth hormone has been shown to raised circulating corticosterone (Cheung et al., 1988).

33.2.7.3.1.2 Calciotropic hormones In chicken adrenocortical cell preparations, extracts containing chicken parathyroid hormone (PTH) stimulate cAMP, corticosterone secretion and especially aldosterone secretion (Rosenberg et al., 1987, 1988a,b, 1989a). However, a more recent study with recombinant chicken PTH did not demonstrate a steroidogenic action (Lim et al., 1991). Nevertheless, avian forms of the PTH/parathyroid hormone-related peptide (PTHrP) receptor have been characterized (Pinheiro et al., 2012) and are expressed in many tissues. Furthermore, a PTH/PTHrP receptor in chicken adrenocortical cells, which is absent in chromaffin cells, has been demonstrated and PTHrP enhances ACTH-induced corticosterone production in vitro (Kawashima et al., 2005).

A similar potentiation of ACTH action is seen with chicken calcitonin, and here again, it appears to act through specific receptors on avian adrenocortical cells and not chromaffin cells (Nakagawa-Mizuyachi et al., 2009). Thus, calciotropic hormones appear to influence the action of ACTH on avian adrenocortical cells.

33.2.7.3.1.3 Humoral immune system ACTH is released from activated lymphocytes in response to CRH, and this release is inhibited by corticosterone (Hendricks et al., 1991, 1995a,b). However, it is not known whether sufficient numbers of lymphocytes populate the avian adrenal gland to influence corticosteroid secretion. In addition, the bursa of Fabricius may elaborate substances necessary for adequate corticosteroidogenic capacity during development and maturation (Pedernera et al., 1980) and for normal corticosterone response of adrenocortical cells to ACTH (El-Far et al., 1994).

33.2.7.3.2 Inhibitors and negative modulators

33.2.7.3.2.1 Thyroid hormones Evidence indicates that the thyroid hormone, 3,5,3′-triiodothyronine (T_3), is an important modulator of avian adrenocortical function (Figure 33.9). With some exceptions (Sharma and Chaturvedi, 2009), there is an inverse relationship between circulating T_3 concentrations and chicken adrenocortical function (i.e., after thyroidectomy with and without T_3 replacement) (Carsia et al., 1997). In hypophysectomized cockerels, T_3 replacement reduces corticosterone production by adrenocortical cells even more than that due to hypophysectomy, but it maintains normal cellular sensitivity to ACTH (Carsia et al., 1985c). There also may be influences at the pituitary level. In chickens, thyroid hormone status does not influence POMC mRNA levels (Sharma and Chaturvedi, 2009). However, in the rat (*Rattus norvegicus*) thyroid hormones negatively modulate POMC processing (i.e., prohormone convertase-1 expression) (Li et al., 2001). Since mRNA levels do not necessarily correlate with mature protein levels, the effect of thyroid hormones on avian POMC processing awaits investigation.

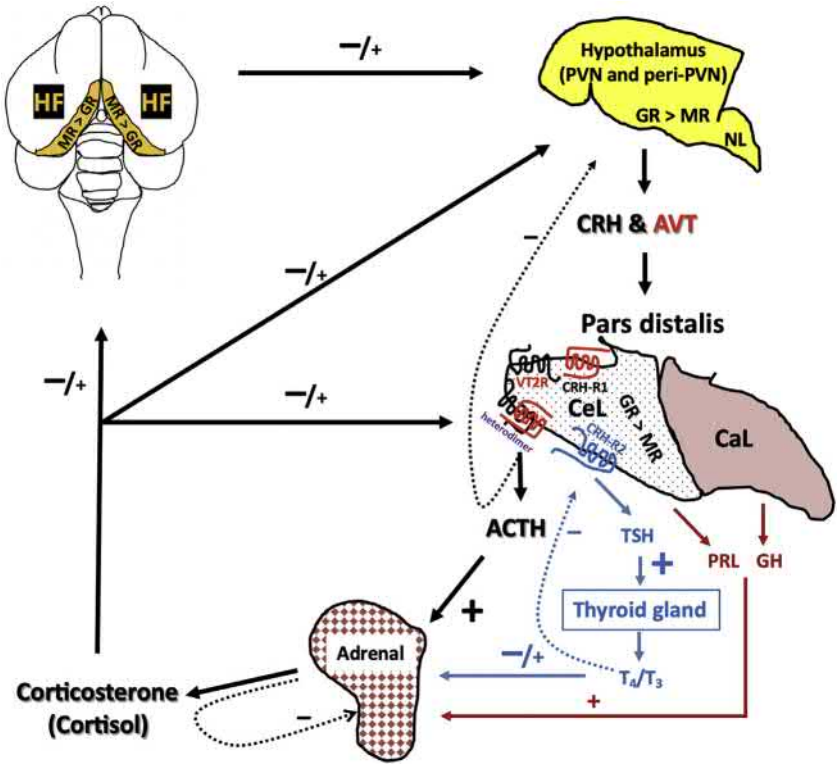

FIGURE 33.9 The hypothalamic-pituitary-adrenal (HPA) axis in birds. Negative (−) and positive characters (+) and their relative sizes when paired indicate the general consensus of the effect of a particular hormone. The hypothalamus is depicted in a sagittal view and with yellow fill. The neural lobe of the pituitary gland (NL), the paraventricular nucleus (PVN), and peri-paraventricular nuclear area (peri-PVN) are indicated. Top left is a dorsal view of the avian brain and the location of the hippocampal area (HF) is highlighted with orange fill. Relative influences or activities of the glucocorticoid receptor (GR) and mineralocorticoid receptor (MR) are indicated (GR > MR; MR > GR). The pars distalis of the pituitary gland is depicted in sagittal view with dot pattern indicating the cephalic lobe (CeL) and light brown fill indicating the caudal lobe (CaL). The adrenal gland is in brown pattern to depict the intermingling of chromaffin and adrenocortical tissues. Cartoons of structures are not drawn to actual relative size, with the pituitary disproportionately enlarged. Other abbreviations or acronyms are as follows: *ACTH*, adrenocorticotropic hormone (corticotropin); *AVT*, arginine vasotocin; *CRH*, corticotropin-releasing hormone; *CRH-R1*, type-1 corticotropin-releasing hormone receptor; *CRH-R2*, type-2 corticotropin-releasing hormone receptor; *GH*, growth hormone; *PRL*, prolactin; *VT2R*, type-2 vasotocin receptor; *T4/T3*, thyroid hormones 3,5,3′,5′-tetraiodothyronine, 3,5,3′-triiodothyronine; *TSH*, thyroid-stimulating hormone (thyrotropin). CRH and AVT (and sometimes mesotocin) interact with their respective receptors, CRH-R1 and VT2R, to stimulate the release of ACTH in a synergistic manner. Part of the synergism of CRH-R1 and VT2R is due to their separate signaling pathways, and it is also likely that part is due to their receptors undergoing heterodimerization. ACTH most likely exerts a negative short-loop feedback on CRH release. ACTH stimulates the secretion of glucocorticoids (mostly corticosterone) from adrenocortical cells of the adrenal gland. Its action is assisted by PRL, also released from the CeL, and GH, secreted from the CaL. Sufficient evidence indicates that in addition to ACTH, PRL and probably GH are released during stress. Glucocorticoids exert a negative long-loop feedback on both the pituitary gland and the hypothalamus to curtail ACTH release. However, some brain CRH neurons and pituitary VT2Rs are upregulated by glucocorticoids. Under most conditions, glucocorticoids exert a negative feedback on the HF which has indirect connections to the PVN and peri-PVN. However, under different conditions such as long-term stress, the negative feedback in the HF is reduced and stimulatory signals from the HF are relayed to the PVN for sustained CRH release and thus sustained activation of the HPA axis. Such a mechanism may explain continued glucocorticoid secretion during sustained stress and when circulating glucocorticoid levels are high. CRH also interacts with CRH-R2 to stimulate the release of TSH. TSH acts on the thyrocytes of the thyroid gland to release T4 and T3. Thyroid hormones appear to decrease VT2R expression and may also inhibit the expression of prohormone convertase-1, an enzyme that processes pro-opiomelanocortin to produce ACTH and other melanocortins. Overall, studies suggest that thyroid hormones have a negative impact on corticosteroid secretion. Finally, intraadrenal and circulating glucocorticoids exert a negative short-loop feedback on the adrenocortical cells to reduce the release glucocorticoids. See text for details of additional modulators of the HPA axis. *Cartoon drawn by R. V. Carsia.*

33.2.7.3.2.2 Androgens The effect of androgens on adrenocortical secretion appears to be variable depending on the species and type of endocrine manipulation. On the one hand, early work with orchiectomized chickens suggests that testosterone suppresses adrenocortical function (Nagra et al., 1965). More recent work with orchiectomized cockerels suggests that although androgen (testosterone and 5α-dihydrotestosterone) replacement suppresses adrenocortical cell response to ACTH, it maintains relative adrenal mass (Carsia et al., 1987b). On the other hand, exogenous testosterone in wild species seems to enhance circulating corticosterone, suggesting an increase in adrenocortical function (Ketterson et al., 1991; Schoech et al., 1999). Interestingly, orchiectomy is required to demonstrate the

effects of androgens on adrenocortical function in the domestic chicken (Nagra et al., 1965; Carsia et al., 1987b). Thus, it is quite possible that the testis elaborates both inhibitory and trophic substances that influence avian adrenocortical function.

In this connection, there are reported sex differences in adrenocortical activity and some of these are correlated to sexual maturity (see Madison et al., 2008). In addition, sex-dependent alterations in adrenocortical cellular sensitivity and maximal corticosterone response to ACTH have been reported (Carsia et al., 1987a, Carsia et al., 1988b; Kocsis and Carsia, 1989). Sex differences are also apparent at more proximal steps of the HPA axis, as for example, the axis response to CRH and arginine vasotocin (AVT) (Madison et al., 2008). However, the fact that these alterations at the cellular level are apparent during the embryonic and early posthatch period and prior to sexual maturity, (Carsia et al., 1987a; Kocsis and Carsia, 1989) argues that they may be, in part, sex-linked and separate from the greater levels of sex steroids in the circulation that accompany sexual maturity.

33.2.8 Regulation of aldosterone secretion

33.2.8.1 Role of angiotensin II

As in other vertebrates (Wilson, 1984; Holmes and Cronshaw, 1993; Kempf and Corvol, 2001; Nishimura, 2001), the avian kidney contains juxtaglomerular cells capable of producing renin. Renin cleaves fowl angiotensinogen ([Asp^1, Val^5, Ser^9]tetradecapeptide renin substrate) to form the decapeptide, angiotensin I ([Asp^1, Val^5, Ser^9]Ang I). The Ang II octapeptide produced from this decapeptide ([Val^5]Ang II; $M_r = 1031.19$) is that of most vertebrates including ovine and bovine species (thus, H-Asp^1-Arg^2-Val^3-Tyr^4-Val^5-His^6-Pro^7-Phe^8-OH), whereas other mammalian species produce [Ile^5]Ang II. In several species studied thus far (Japanese quail, duck and turkey), plasma Ang II concentrations range from 30 to 70 pg/mL (2.9×10^{-11}–6.8×10^{-11} M) but can increase to 100–400 pg/mL (9.7×10^{-11}–3.9×10^{-10} M) with perturbations to electrolyte and hemodynamic balance and with adaptation to saltwater (see Kocsis et al., 1995a).

Earlier in vivo studies demonstrated a direct regulation of aldosterone production by Ang II. Infusions of Ang II into ducks (Gray et al., 1989) showed a dose-dependent aldosterone response exclusive of alterations in circulating corticosterone increases circulating aldosterone. In addition, an exclusive, dose-dependent aldosterone response to Ang II has been demonstrated with duck adrenal tissue, specifically from the subcapsular region (Klingbeil, 1985; Holmes and Cronshaw, 1993). However, the distinction of functional zones exhibited by the duck adrenal gland may be less apparent or absent in other species. It may be that in other avian species, perturbations in electrolyte and hemodynamic homeostasis or other stressors are required to induce zona glomerulosa-like function in a subpopulation of adrenal steroidogenic cells (Kocsis et al., 1995a). Ang II does not stimulate cholesterol side-chain cleavage in turkey adrenocortical cells (Kocsis et al., 1995a). Presumably, the prevailing basal level of precursors within the cells is sufficient to support aldosterone synthesis. Thus, in vitro, a background influence of ACTH greatly enhances the efficacy of Ang II. Other evidence suggest that Ang II plays a role in remodeling of adrenocortical tissue during prolonged stress, as for example, dietary protein restriction (Carsia and Weber, 2000).

Finally, although it is fairly clear what the releasing factors for aldosterone are in birds with decreased plasma Na^+ and no cephalic (salt) glands, it is not clear what the aldosterone-releasing factors are in birds with cephalic glands and excessive Na^+ intake or when birds with cephalic glands undergo dehydration. It does not appear to be Ang II or changes in plasma K^+. Furthermore, the interaction of hormones regulating aldosterone secretion in birds that live exclusively in marine and desert environments has received much less attention (see Hughes, 2003).

33.2.8.2 Mechanism of Ang II action in avian adrenocortical cells

Studies with duck adrenal membrane preparations (Gray et al., 1989) and isolated turkey (Kocsis et al., 1994a,b, 1995a,b,c; Carsia and McIlroy, 1998) and chicken (Holmes and Cronshaw, 1993) adrenocortical cells indicate that the avian adrenal gland possesses high affinity Ang II receptors, having a K_d of 0.9–2 nM and concentration of 30,000–150,000 sites/cell. It should be pointed out that chickens are odd in that mature birds exhibit an absence of an aldosterone response to Ang II both in vivo and in vitro even though their adrenocortical cells express high affinity Ang II receptors (Holmes and Cronshaw, 1993).

Turkey (Murphy et al., 1993) and chicken (Kempf and Corvol, 2001) Ang II receptors have also been cloned. They are both 359-amino acid proteins (sharing 99.7% identity) and exhibit a 75% sequence identity with the mammalian type 1 receptor, albeit there are frank differences in pharmacological and physicochemical properties between mammalian and avian forms. Both avian forms have been shown to couple to the phosphoinositide/lipid-protein kinase C pathway (Murphy et al., 1993; Kempf and Corvol, 2001). Studies with isolated adrenocortical cells suggests that optimal signal transduction also requires calmodulin (Kocsis et al., 1995b). However, differences in tissue expression exist between turkeys and chickens. For example, the cloned turkey receptor is exclusively expressed in the adrenal gland (Carsia et al., 1993), whereas

the chicken receptor has a broader tissue expression (Kempf and Corvol, 2001). But thus far, the story is incomplete regarding the function of avian Ang II receptors at the cellular and molecular levels (Kocsis et al., 1995b; Kempf and Corvol, 2001; Nishimura, 2001).

33.2.8.3 Action of adrenocorticotropin on aldosterone secretion

Whereas an ample number of studies demonstrate the selective action of Ang II on avian aldosterone secretion, the action of ACTH is less specific, stimulating both aldosterone and corticosterone secretion. Although less potent, ACTH is 2−10-fold more efficacious than Ang II in stimulating aldosterone secretion in studies with avian adrenal tissue and avian adrenocortical cell preparations. However, the specificity and importance of Ang II reside not in its ability to greatly stimulate aldosterone secretion, but in its ability to link perturbations in electrolyte and hemodynamic balance to aldosterone secretion—a role not readily fulfilled by ACTH. As an example, stress raises both plasma corticosterone and aldosterone (Rosenberg and Hurwitz, 1987), but in response to dietary Na^+ changes, plasma aldosterone is greatly affected whereas plasma corticosterone is unaffected or modestly affected (Rosenberg and Hurwitz, 1987; Kocsis et al., 1995a). Furthermore, in vitro studies indicate that Ang II becomes equally efficacious to ACTH when some ACTH is included (Kocsis et al., 1994a).

33.2.8.4 Action of atrial natriuretic peptide on aldosterone secretion

Avian ANP was originally demonstrated as a diuretic agent in extracts from chicken hearts (Gregg and Wideman, 1986). It is a 29-amino acid peptide ($M_r = 3158.45$) that has significant structural homology to mammalian ANPs (Miyata et al., 1988). Avian ANP is stored and released from both atrial and ventricular cardiocytes (Toshimori et al., 1990), but is also produced by adrenal chromaffin cells (Wolfensberger et al., 1995). In ducks and chickens, the plasma concentration of ANP is about 70−80 pg/mL ($\sim 2.5 \times 10^{-11}$ M) and is inversely related to changes in blood volume in response to hemodynamic and electrolyte perturbations (Gray et al., 1991a; Gray, 1993). ANP receptors are found in both renal and adrenal tissue of the duck (Gray et al., 1991b). In adrenocortical cells, it is present at a concentration of ∼90,000 sites/cell (Kocsis et al., 1995c). The receptors have an apparent K_d of 1−3 nM (Gray et al., 1991b; Kocsis et al., 1995c). In the duck, infusions of avian ANP inhibit plasma aldosterone responses to Ang II without affecting circulating corticosterone (Gray et al., 1991b). In addition, in chicken adrenocortical cells, ANP is a potent (EC_{50} ∼1 nM) and efficacious inhibitor (>90%) of maximal ACTH and PTH-induced aldosterone secretion without affecting corticosterone secretion (Rosenberg et al., 1988b, 1989b). ANP appears to act at several intracellular loci (Rosenberg et al., 1989b), and cyclic GMP appears to be its second messenger (Rosenberg et al., 1988b, 1989b). Interestingly, in turkey adrenocortical cells, ANPs are as efficacious as Ang II in stimulating aldosterone production and actually augments maximal aldosterone production induced by Ang II, K^+, and ACTH (Kocsis et al., 1995c). Thus, more broadly, the actions of ANPs on adrenocortical function may be species-specific.

33.2.9 Overview of the hypothalamic-pituitary-adrenal axis

The HPA (Figure 33.9) axis is composed of (1) hypothalamic neurons in the paraventricular nucleus (PVN) which contain the releasing hormones, CRH, AVT [and sometimes mesotocin (MT)], (2) the corticotropes of the cephalic lobe of the par distalis which contain enzymes that synthesize and process (prohormone convertases) POMC to produce adrenocorticotropic hormone (corticotropin) (ACTH), and (3) the steroid-secreting cells of the adrenal gland which express the melanocortin-2 receptor (MC2R) that exclusively binds ACTH. The resultant end-product glucocorticoids facilitate the mobilization and partitioning of energy stores to meet general physiological demands, physiological adjustments during a stress response, and to assist in the recovery from periods of stress (MacDougall-Shackleton et al., 2019). Thus, the HPA axis operates within a larger regulatory system for energy flow and partitioning, especially for the central nervous system. However, the different components of the axis can have a level of independent and complex regulation: a regulation (a) suited for a life-history stage (Lattin et al., 2012a), or (b) for confronting a changing and unpredictable environment accompanying season (Dickens et al., 2011b; de Bruijn and Romero, 2018; Romero and Gormally 2019), or (c) that is altered -by genetic selection (Carsia and Weber 1986; Carsia et al., 1988b; Hazard et al., 2007).

CRH and AVT are the main stimulators of ACTH secretion from corticotropes, the ACTH-secreting cells of the cephalic lobe (Berghman et al., 1998). CRH is a 41 amino acid peptide that binds to the type 1 CRH receptor (CRH-R1) on corticotropes and activates adenylyl cyclase to elevate intracellular cAMP, resulting in the release of ACTH (Carsia et al., 1986; Kuenzel et al., 2013).

AVT is a nonapeptide that binds to the type 2 VT receptor (VT2R) (and the type 4 VT receptor) on corticotropes. VTRs activate phospholipase C, leading to the generation of inositol-1,4,5-triphosphate and diacylglycerol

for the mobilization of intracellular Ca^{2+} (see Kuenzel et al., 2013). Interestingly, AVT has role in water balance in that it recruits the HPA axis in response to osmotic stress (Sharma et al., 2009b).

Because CRH and AVT operate through different signal transduction cascades, their combined action leads to synergistic release of ACTH (Mikhailova et al., 2007). In addition, there is evidence that this synergistic effect is also due to heterodimerization of the CRH-R1 and VT2R (Mikhailova et al., 2007; Cornett et al., 2013).

It is well established that glucocorticoids exert a negative feedback on both the hypothalamus and pituitary gland to decrease CRH, and POMC in a classical negative feedback (Denver, 2009). However, this negative feedback is finely modulated by changes in the pituitary VT2R. High circulating concentrations of corticosterone increase VT2R expression and chemical adrenalectomy decreases it (Sharma et al., 2009a). Thus, the modulating effect of glucocorticoids on VT2R expression may explain the observed glucocorticoid programming of the HPA axis for enhanced stress response in zebra finches (Spencer et al., 2009).

In addition, there are two short-loop negative feedbacks operating in the HPA axis. ACTH itself appears to exert a short-loop negative feedback on the hypothalamic CRH neurons (Janowski et al., 2009), and glucocorticoids induced a short-loop negative feedback on the adrenocortical cell, probably by reducing MC2R expression and signal transduction (McIlroy et al., 1999).

Another highly important brain region in this scheme is the hippocampal (HP) formation which is highly homologous to the mammalian HP (see Smulders, 2017). Although the HP formation has indirect connections to the hypothalamus [more specifically, the PVN and periparaventricular nuclear area (peri-PVN)], it is important for glucocorticoid circadian rhythms and modulation of the HPA axis during the stress response. Under most conditions, glucocorticoids exert a negative feedback on the HF which synergizes with the negative feedback to the PVN and peri-PVN to reduced HPA activity. However, under different conditions such as long-term stress, the negative feedback in the HF is reduced and stimulatory signals from the HF are relayed to the PVN for sustained CRH release and thus sustained activation of the HPA axis (Zhu et al., 2014). This may be another mechanism that may explain continued glucocorticoid secretion during sustained stress and when circulating glucocorticoid levels are high (Romero and Gormally, 2019).

There is also considerable cross-talk between the HPA axis and other endocrine axes such as the hypothalamic-pituitary-thyroid (HPT) axis and hypothalamic-pituitary-gonadal (HPG) axis. For example, CRH also binds to the type 2 CRH receptor (CRH-R2) on thyrotropes and stimulates the secretion of thyroid-stimulating hormone (thyrotropin) (TSH) (De Groef et al., 2005, 2006). This is not surprising since thyroid hormones regulate intermediary metabolism and the HPA and HPT axes interact tightly to regulate certain developmental processes and hatching in birds. TSH acts on the thyrocytes of the thyroid gland to release T4 and T3. As mentioned previously (Section 33.2.7.3.2.1), thyroid hormones appear to decrease VT2R expression, inhibit the expression of prohormone convertase-1, an enzyme that processes POMC to produce ACTH and other melanocortins, and largely have a negative impact on corticosteroid secretion at the adrenal level. The opposite occurs with low-thyroid hormone status (Carsia et al., 1997; Sharma and Chaturvedi, 2009). Likewise, the HPG axis may interact with the HPA axis since there are sex differences in the plasma corticosterone response to CRH an AVT (Madison et al., 2008) and in AVT release and hypothalamic AVT receptor expression in response to osmotic stress (Chaturvedi et al., 2000).

Taken collectively, studies indicate that there are multiple pathways to elicit ACTH release from the cephalic lobe for optimal rhythms of corticosteroid secretion and for greater corticosteroid responses to address a variety of environmental and homeostatic stressors. The adrenal gland in turn has intrinsic mechanisms to permit the episodic release of corticosteroids of varying magnitude in responses to varying ACTH levels. This involves not only the rapid transcriptional regulation of such important proteins, MC2R, MRAP, StAR, and CYP11A but also the rapid induction of inactivation pathways (Liu et al., 2013). Finally, the resultant circadian and ultradian rhythms of free glucocorticoids are highly synchronized between the circulation, the subcutaneous tissue, and the brain (Qian et al., 2012). This underscores the precision of how glucocorticoids are distributed to different compartments for target-tissue specific functions.

33.2.10 Adrenocortical function in development, maturation, and senescence

The chicken (*Gallus gallus*) is the most studied model to describe the development of the avian adrenal gland. Thus, the pattern of development of this precocial species described herewith may be somewhat different from that of semiprecocial, semialtricial, and altricial species.

The chick adrenal begins as an adrenogenital primordium that is apparent at about 3 days of development. Development of steroidogenic cells requires the nuclear receptor, steroidogenic factor-1 (SF-1/NR5A1), which is expressed in the adrenogenital primordium (Smith et al., 1999). SF-1 promotes cell growth, limits cell death (apoptosis), and regulates the expression of genes involved in steroidogenesis, the MC2R, and StAR. In the laboratory mouse (*Mus musculus*), the MC2R is required for postnatal adrenal development and adrenal steroidogenesis (Chida

et al., 2007), and this is most likely true for avian species. Additional transcription factors are necessary for adrenocortical cell differentiation (Pihlajoki et al., 2013). At this time, the expression of key steroidogenic enzymes is detected in the chick embryo (Nomura et al., 1999) and in the developing zebra finch adrenal gland (Freking et al., 2000). However, in-situ hybridization detects these key enzymes at about five days of development (Kanda et al., 2000) and this is in agreement with a more recent gene-expression study (Kamata et al., 2004). Also, at about 5 days of development, the segregation of the adrenogenital primordium into the adrenal gland and the gonad is apparent (Smith et al., 1999) as well as the histological identification of steroid-secreting cells arranged in cords (Chimenti and Accordi, 2008). From days 7−15 of development, chromaffin cells penetrate gland and complete morphogenesis of the adrenal gland is complete by day 15.

It is thought that the adrenal gland is capable of steroidogenic function as early as day five of development, well before morphogenesis is complete. Embryonic circulating corticosterone levels slowly rise to day 15, but are independent of pituitary ACTH, even though immunoreactive ACTH is present in corticotropes at day 7 and embryonic adrenocortical cells can respond to ACTH. However, negative feedback is probably established by day 11. After day 15 to hatch, the gland is under ACTH control and CRH neurons become detectable in the hypothalamus a day earlier (see Jenkins and Porter, 2004; De Groef et al., 2008; Ellestad et al., 2011). So, there is general agreement that the adrenal gland of this precocial species is under the control of pituitary ACTH at day 15 of development. From that day to hatch, circulating corticosteroids reach their peak. This rise is matched by an abrupt increase in maximal cellular corticosteroid response and maximal cellular sensitivity to ACTH (Carsia et al., 1987a). However, 1−2 days posthatch, chicks have a stress hyporesponsive period (see Wada, 2008). This is due to a proximal HPA axial block since adrenocortical cells are fully responsive to ACTH (Carsia et al., 1987a). Interestingly, there is evidence for an age-dependent window for "imprinting" the avian adrenal gland for a long-term, enhanced setpoint of response to ACTH (Avrutina et al., 1985). In chickens, this appears to be about 2−4 weeks posthatch. For example, subjecting cockerels to transient protein restriction over this period induces long-term potentiation of adrenocortical cell function (Weber et al., 1990).

In altricial birds, the time-frame for HPA axis development is shifted later in the posthatch period. It is hypothesized that the peak corticosteroid response to a fully developed axis occurs at fledging (Wada, 2008). Here again, birds of an earlier age can respond to an ACTH challenge indicating that the reduced corticosteroid response prior to fledging is proximal to the adrenal gland. It is thought that in altricial species, this uncoupling of the hypothalamic-pituitary unit from the adrenal prevents increases in circulating corticosteroids in response to stress which could have an adverse effect on growth and immune function. In addition, body condition of nestlings, such as fat stores, impact on the HPA axis response to stress and on circulating CBG which modulates the target-tissue effects of the prevailing circulating levels of corticosterone (Müller et al., 2010).

Overall, a limited number of studies indicate a gradual decline in adrenocortical function with age (Schmeling and Nockels, 1978; Avrutina et al., 1985; Davis and Siopes, 1987) and during senescence. In chickens, this decline, in part, may be due to a decrease in adrenocortical cell sensitivity and response to ACTH (Carsia et al., 1985b, 1987a).

33.3 Physiology of adrenocortical hormones

The action of corticosteroids in birds is highly complex, sometimes quixotic and paradoxical, depending on species, gender, life-history stage, habitat, and a changing environment within a particular habitat (Romero and Gormally, 2019). This corticosteroid hormonal pleiotropy is largely due to the expression and interaction of their cognate receptors and the intracellular coactivators and transcription factors. The MR, GR, and membrane glucocorticoid receptor (mGR) have decreasing affinities to glucocorticoids [∼0.2 nM (∼69 pg/mL), ∼6 nM (∼2 ng/mL) and ∼20 nM (∼6.9 ng/mL), respectively]. Other studies use available mammalian receptor antagonists to dissect the function of these receptors, however, complete antagonists are lacking. Finally, little is known about the repertoire of intracellular coactivators and other transcription factors that mediate the activated forms of the corticosteroid receptors. Some of the factors contributing to the quixotic pleiotropic actions of corticosteroids are described in Table 33.2. Despite the complexity of corticosteroids actions, an overview of the corticosteroid receptors and the complex functions that they are thought to regulate are discussed in subsequent sections below.

33.3.1 Corticosteroid receptors and their action in target cells

The structure of avian forms of the GR (Kwok et al., 2007) and MR (Proszkowiec-Weglarz and Porter, 2010) has been determined. It is believed that there is one form of the GR (Kwok et al., 2007), albeit, it is likely that there are transcriptional isoforms and post-translational isomorphs (Table 33.2). In traditional ligand-binding and competitive-binding studies, these manifest as the low-affinity site and

TABLE 33.2 Some factors contributing to the pleiotropic effects of the glucocorticoids via the glucocorticoid receptor.

1. GR isoforms and post-translationally modified glucocorticoid receptors (GRs) (isomorphs)	a. Isoforms: alternative translation initiation sites producing GRs of different sizes b. Isomorphs: post-translational modifications (phosphorylation, acetylation, ubiquitination, SUMOylation (small ubiquitin-like modifiers)
2. Non-nuclear genomic GRs	a. GRs associated with the plasma membrane b. GRs retained within the cytoplasm c. GRs associated with mitochondrial genome (liganded are transactivators; unliganded are transrepressors)
3. Nuclear genomic GRs	a. Liganded monomers b. Unliganded monomers c. Typical liganded homodimers d. Liganded and unliganded heterodimers with other nuclear receptors or transcription factors e. Indirect interactions to DNA via tethering to transcription factors (transactivators or transrepressors)
4. Steroid receptor coactivation/corepression	GRs can interact with nuclear coactivators and corepressors, especially in the brain
5. Epigenetic mechanisms	a. GRs can recruit histone-modifying enzymes that can alter future responses to glucocorticoids by functioning as a "switch" for glucocorticoid enhancement or repression of target genes. This may be the basis for transgenerational effects of stress and glucocorticoid action. b. More broadly, other nuclear receptor response elements (e.g., androgen receptor) overlap with glucocorticoid response elements. Thus, active GRs may modify reciprocal response elements. This has clear implications for the role of GRs in modulating the transcriptional landscape of other steroid hormones. c. Some noncoding RNAs contain pseudo-glucocorticoid response elements. Thus, competent GRs are sequestered from target gene promoters.

All of these factors may have superimposed, tissue-specific characteristics. These factors may explain the lack of consistent correlation between tissue concentrations of glucocorticoid receptors and the "expected" tissue response to glucocorticoids. Note: the first category can distribute into the other categories.

high-affinity site for corticosterone binding. Both share high homology with mammalian corticosteroid receptors, and for the most part, function as homodimers after corticosteroid binding.

Localization of the unstimulated GR and MR is mainly to the cytoplasm, and there is active translocation to the nucleus with corticosteroid treatment (Proszkowiec-Weglarz and Porter, 2010). Transfection of receptors shows that aldosterone is two–three times more effective than corticosterone for receptor activation. Interestingly, like aldosterone, the glucocorticoid corticosterone is 10 times more effective in activating the MR than the GR (Proszkowiec-Weglarz and Porter, 2010). However, the mammalian GR antagonist, onapristone, only partially blocked the corticosterone-activated chicken GR, and the mammalian MR antagonist, spironolactone, was a very weak antagonist of the activated chicken MR and actually had agonistic activity. Thus, the mammalian corticosteroid receptor antagonists (Figure 33.10) do not always work with the same fidelity in avian studies.

Roughly 5–10% of classical corticosteroid receptors are associated with the plasma membrane, and there are receptors that operate within the cytoplasm as well. It is not clear whether homodimerization is a requirement but mGR do associate with other membrane proteins for signal transduction (Vernocchi et al., 2013). In general, membrane and cytoplasmic localization most often leads to pathways using extracellular signal-regulated kinases or mitogen-activated protein kinase for relatively rapid cellular responses (within seconds to a few minutes). Thus, GRs in these compartments, the plasma membrane, the cytosol and the nucleus, and also the mitochondrial compartment, contribute to the extraordinarily wide range of glucocorticoid actions (Table 33.2) (Scheschowitsch et al., 2017).

Corticosteroid nuclear signaling is also highly complex and is more than the well-characterized interaction of a homodimerized GR with glucocorticoid-response elements on DNA (e.g., Adams et al., 2003) (Table 33.2). Liganded monomers can bind and transactivate half-site regions of DNA, and unliganded monomers may repress transactivation. Liganded monomers can heterodimerize with MR monomers or monomers of other nuclear receptors, or other transcription factors and act as either transactivators or transrepressors. The picture is complicated further with

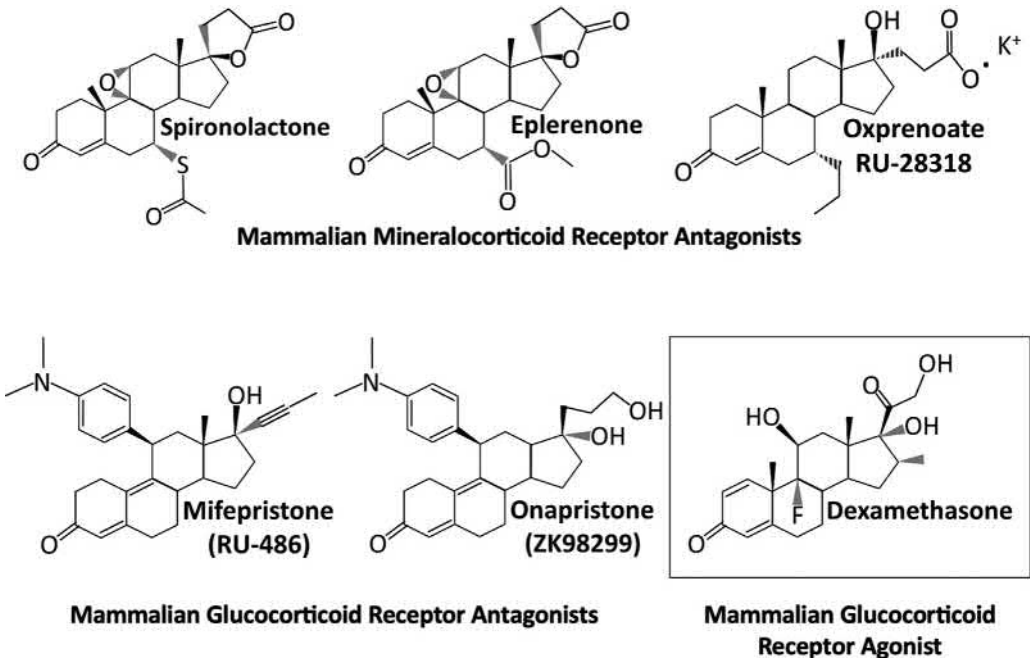

FIGURE 33.10 Chemical structure of mammalian mineralocorticoid and glucocorticoid receptor antagonists, and the potent glucocorticoid receptor agonist, dexamethasone. The use of these compounds in avian corticosteroid receptor studies has yielded mixed results, since they sometimes are only partially active or have agonist/antagonist activity opposite their usually complete action in mammalian receptor studies. *Molecules drawn by R. V. Carsia.*

competing GR isoforms (i.e., receptors of different sizes by alternative translation initiation) or post-translationally modified GRs (isomorphs) (i.e., phosphorylation, acetylation, etc.) that can compete with the function of full-sized monomers (Kadmiel and Cidlowski, 2013). For example, cytosolic and membrane-associated corticosteroid receptors differentially bind corticosterone and cortisol in a tissue-specific manner which is thought to be due to post-translational modifications (Schmidt et al., 2010). In addition, specific tissues may modulate co-activators, co-repressors, or other steroid receptor coactivators, especially the nervous system (Sun and Xu, 2020). Lastly, specific tissues may have epigenetic mechanisms (post-translational modifications of histone-modifying enzymes; noncoding RNAs) that further modify the action of GRs (Bartlett et al., 2019).

Corticosteroid receptors have been described through standard ligand- and competitive-binding studies on cytosolic and nuclear preparations of many tissues from diverse species (Breuner and Orchinik, 2001, 2009; Schmidt et al., 2010; Lattin et al., 2012b). The binding sites are sufficiently different from mammalian types in that known mammalian MR antagonists fail to displace corticosterone from the high-affinity site (MR) and similarly, the mammalian GR antagonist, mifepristone (RU-486; mifepristone) is a variable and often weak antagonist of the low-affinity site (GR). The affinities of these MRs and GRs for corticosterone are fairly consistent: K_ds of about 0.2 and 6 nM, respectively, with a membrane-binding site of about 14−30 nM. Since the affinity of avian CBG is about 2 nM, the high-affinity site (MR) can easily draw corticosterone from CBG compared to the low-affinity site (GR). Thus, corticosterone most likely activates the avian MR and only in certain tissues with high 11βHSD2 and 20HSD activity is aldosterone selectively more active. One caveat is that at the tissue level, receptor concentration may not necessarily correlate with physiological response to corticosteroids (Lattin et al., 2015).

The cloned avian GR and MR also serve as molecular tools to assess receptor expression in the avian brain (e.g., Dickens et al., 2011b). However, studies of corticosteroid receptor expression based on messenger RNA should be viewed with caution because of poor correlation with actual acceptor protein (i.e., corticosteroid receptor) levels in neuronal tissue as determined by ligand binding (Medina et al., 2013).

33.3.2 Corticosteroids and intermediary metabolism

Studies in birds indicate that glucocorticoids exert profound effects on protein, carbohydrate, and lipid metabolism (see Landys et al., 2006; Scanes, 2009). Glucocorticoids increase plasma glucose levels primarily by stimulating proteins that shuttle glucose transporters from cell membranes to the intracellular compartment (Horner et al., 1987). They also metabolize proteins when other available energy stores are inadequate. As a result, there is a tendency for prolonged elevated glucocorticoid levels to decrease body mass.

Baseline glucocorticoids are permissive for processes that maintain adequate food intake and optimal body mass, and food choice is influenced by glucocorticoids operating through an interaction between the MR and GR. Glucocorticoids also appear to work on the alimentary system by increasing transit time and the uptake of glucose, calcium, and phosphate.

Further complicating the picture is that high glucocorticoids may differentially increase oxidative stress. This appears to result in shortened telomere length and other DNA damage in tissues (Flint et al., 2007; Costantini et al., 2008; Romero and Gormally, 2019). Also, the general oxidative stress impacts on the interpretations of changes in key metabolic indicators.

Since most studies use some form of glucocorticoid depot or glucocorticoid feeding regimen, the normal rhythms of glucocorticoids and, in turn, the complementary rhythms of delivery to target tissues, and the normal responses of interacting endocrines to those rhythms are largely disrupted. Thus, it is not clear whether the responses in birds to exogenous glucocorticoids are physiological or pharmacological. Nevertheless, some conclusions as to their action can be drawn from the large number of studies conducted in diverse avian species.

33.3.2.1 Protein metabolism

The action of glucocorticoids largely results in protein catabolism (see Landys et al., 2006; Scanes, 2009). The amino acids enter the citric acid cycle as an energy source and also shunt to hepatic, renal, and possibly intestinal sites (Watford, 2005) for gluconeogenesis to maintain adequate glucose levels. Both the reduction of glucose transporters from cells and the shunting of amino acids for gluconeogenesis contribute to either raising or maintaining glucose levels. In domestic fowl, the important enzyme for gluconeogenesis is cytosolic phosphoenolpyruvate carboxykinase. In young chickens, the activity of this enzyme is localized in both the kidney and liver, whereas in the adult, it is predominantly in the kidney.

Frank changes in circulating glucose are not always apparent because of facilitated entry into cells through the action of insulin. In domestic fowl, corticosterone induces hyperinsulinemia. However, a number of molecular markers also indicate insulin resistance in the liver and muscle and an increase in muscle glycogen (Lin et al., 2007). This paradox may be due to species, dose of exogenous glucocorticoid, route of delivery, and duration of treatment.

Since one of the largest sources of protein is muscle, it is not surprising that there is muscle breakdown. Strong indicators of generalized protein catabolism and more specific muscle protein breakdown are increases in circulating uric acid and the concentration of 3-methyhistidine in muscle, respectively. In domestic fowl, both sarcoplasmic and myofibrillar protein breakdown is apparent and protein synthesis is depressed (Dong et al., 2007). However, in wild species, there is evidence for a differential effect in which sarcoplasmic reticular proteins are preferentially degraded whereas myofibrillar proteins are initially spared, presumably to preserve flight muscle. The effect of glucocorticoids on protein metabolism is clearly concentration-dependent, suggesting that these steroid hormones finely modulate protein metabolism.

33.3.2.2 Lipid metabolism

Exogenous glucocorticoids, at concentrations reflecting ranges just exceeding circulating baseline levels and probably into stress levels, do have an impact on lipid metabolism (see Landys et al., 2006; Scanes, 2009). Again, as with protein catabolism, lipid stores are accessed to preserve circulating glucose and to provide an alternate energy source. Corticosteroids play a significant role during periods of prolonged food deprivation to maintain metabolic processes and the required energy partitioning by operating in three phases: phase I, glucose metabolism; phase II, fatty acid metabolism after glucose stores are exhausted; and phase III, protein catabolism, once fatty acid stores are depleted (see de Buijn and Romero, 2018). Evidence suggests that the action of glucocorticoids on lipid metabolism is mediated through the low-affinity GR in that some actions are blocked by RU-486 (mifepristone). Thus far, only the low-affinity, GR-type receptor is detected in avian adipose tissue (Lattin, et al., 2012b).

In birds with positive energy balance, glucocorticoids also stimulate lipogenesis and fat deposition in the liver and increase abdominal fat pad size. This lipogenic effect may be driven largely by insulin. In adequately fed, growing poultry, all glucocorticoid-driven effects on lipid metabolism are seen: an increase in adiposity and hepatic lipogenesis, an increase in circulating free fatty acids, and a decrease in glucose utilization (Scanes, 2009).

33.3.3 Corticosteroids and electrolyte balance

Birds regulated both plasma electrolytes and plasma volume within fairly narrow limits. Corticosteroids are critical for maintaining electrolyte and water balance. Most of the action of corticosteroids is mediated by the high-affinity MR. Thus, prevailing glucocorticoids are sufficient to maintain this balance. However, specific detection systems of perturbations in this balance activate the MRs in the main target tissues, the kidney, intestine, and hindgut, by deploying the potent mineralocorticoid, aldosterone. Since some extreme perturbations also call in the HPA axis, it is

especially important that glucocorticoid-inactivating enzymes (11βHSD2, 20HSD) are upregulated and/or activated in these target tissues to permit aldosterone action (see Hughes, 2003; Landys et al., 2006; Laverty et al., 2006). This is especially important in birds with life-history stages between freshwater and marine habitats, or between water-replete environments and arid environments.

Interestingly, the mechanism of aldosterone action on these target tissues is similar between birds without and with cephalic (salt) glands. Birds without salt glands cannot tolerate high Na^+ intake, but they do respond to low Na^+ intake. In this situation, there is the expected increase in circulating aldosterone in order to maintain adequate plasma Na^+ concentrations. Aldosterone acts on the kidney to reabsorb Na^+ from the glomerular filtrate. In addition, it increases the Na^+ channels and their activity in the colon and coprodeum to reabsorb lost Na^+ from the ureteral fluid. Furthermore, it induces ureteral fluid reflux from the coprodeum to more orad (proximal) segments for additional cycles of Na^+ reabsorption.

In estuarian and marine birds with salt glands, aldosterone levels are maintained and elevated with high Na^+ intake through an unknown mechanism. The actions of aldosterone are for the most part the same as in birds without salt glands. Birds with salt glands tend to have larger kidneys and greater rates of glomerular filtration compared to birds without salt glands. Thus, there is an increase in Na^+ and water reabsorption at the kidney and hindgut with refluxing to augment reabsorption. However, in birds with salt glands, the resultant excess circulating Na^+ is secreted from the salt glands, which are stimulated by high-plasma osmolality and high-extracellular fluid volume but are not under the control of aldosterone. In this way, water is added to the extracellular fluid without the high concentrations of Na^+, thereby maintaining a plasma volume and osmolality compatible with life.

33.3.4 Corticosteroids and immune function

The obvious importance of corticosteroids in immune regulation is evinced by a growing body of literature indicating that the immune tissues of birds have an intrinsic system for either the local production of corticosteroids (Lechner et al., 2001) and/or the enzymes capable of reactivating circulating corticosteroid metabolites (Schmidt et al., 2008). Furthermore, it appears that avian immune tissues possess both MRs and GRs, with the suggestion that the MRs are activated preferentially by corticosterone (and aldosterone?) and the GRs by cortisol (Schmidt et al., 2010; Lattin et al., 2012b). Interestingly, the developing avian immune system appears to contain the steroidogenic enzymes necessary to locally synthesize cortisol de novo from cholesterol (Schmidt and Soma, 2008).

In general, birds have a different repertoire of immune organs, immune cells, and elaborated signaling molecules and immune-regulating genes compared to those of mammals. For example, birds lack lymph nodes for antigen presentation and rely predominantly on tissue dendritic cells. Nevertheless, the observed effects of glucocorticoids on the avian immune system appear consistent with that seen in mammalian immune system, that is, the effects are largely immunosuppressive through their cross-talk with several immune signaling pathways (see Odihambo Mumma et al., 2006; Kaiser et al., 2009; Shini et al., 2010; Petta et al., 2016). Exogenous corticosterone reduces the relative weight of the spleen and the bursa of Fabricius and stimulates heterophils and reduces leukocytes thereby increasing the heterophil/leukocyte ratio. Other research on this topic are beyond the scope of this chapter, but the overall consensus is that glucocorticoids may finely modulate immune response, and its group of cognate receptors may serve as an important avian immune rheostat to ensure optimal immune response in birds.

33.3.5 Corticosteroids and behavior

Behavior strategies used by birds, especially breeding behavior, are energy-costly. Glucocorticoids and other hormones function to partition energy flow in order to balance breeding-related activity and self-maintenance and survival-oriented activities (Landys et al., 2006; Cornelius et al., 2013a,b; Wingfield, 2013). This balance is strongly influenced by the investment in breeding for the perpetuation of the species (Cornelius et al., 2013b). Those species with a high investment in a breeding cycle because of limited opportunities for breeding or because of short life spans, employ mechanisms to dampen the HPA axis, allowing for just basic maintenance levels of corticosterone for permissive functions that support other hormones involved in energy partitioning. For those species with greater life spans that permit numerous opportunities for breeding, greater emphasis is on maintaining an active HPA axis in order to exploit those opportunities. Since many activities are associated with preparation for breeding, migration, territorial behavior, nest building, etc., it is not surprising that glucocorticoids regulate these activities.

In general, glucocorticoids affect activity patterns, cognitive and learning processes, reproductive parameters such as courtship, copulation, and parental behavior such as interaction with offspring and procurement of food for offspring (Möstl and Palme, 2002; Rubolini et al., 2005). Since glucocorticoids regulate a number of locomotory patterns of birds, it is not surprising that locomotory activity and circulating glucocorticoid levels are tightly linked (Landys et al., 2006). The effect of glucocorticoids is rapid, concentration-dependent, and is not blocked by the GR antagonist RU-486 (mifepristone). This suggests that the receptor mode employed to regulate locomotory activity is nongenomic.

Glucocorticoids are essential for processes related to migration. They regulate the replenishment of energy stores

at stopover points and at final breeding grounds by increasing brain neurotransmitters controlling the increase in food intake, by decreasing thermogenesis and by promoting fat deposition (Cornelius et al., 2013a). They also regulate the transition from migration to breeding in that high-circulating levels inhibit the progression into breeding if environmental conditions are not conducive for nesting.

Of recent interest and of great importance is the role of glucocorticoids in the behavioral responses of birds to anthropogenic stressors and the world-wide encroachment of urbanization (Bonier, 2012; Wingfield, 2013). Evidence indicates that these persistent abiotic stressors can shape endocrine traits including glucocorticoid responses. As mentioned previously, glucocorticoids can be deleterious to survival or to species propagation by disrupting breeding. The emerging picture is that due to the variations in the HPA axis plasticity among avian species, urban stressors may differentiate species into urban avoiders, urban adaptors. and urban exploiters (Bonier, 2012).

33.4 Adrenal chromaffin tissue hormones

33.4.1 Catecholamine synthesis and secretion

Catecholamines are widely synthesized throughout the postganglionic sympathetic nervous system which includes the adrenal chromaffin tissue. They are also synthesized in some tissues as, for example, the brain (Yamsaki et al., 2003), but these sites are not thought to contribute substantially to the pool in circulation.

The biosynthetic pathway for the adrenal catecholamines (Ghosh et al., 2001; Mahata et al., 2002; Trifaró, 2002) is outline in Figure 33.11. The rate limiting step in

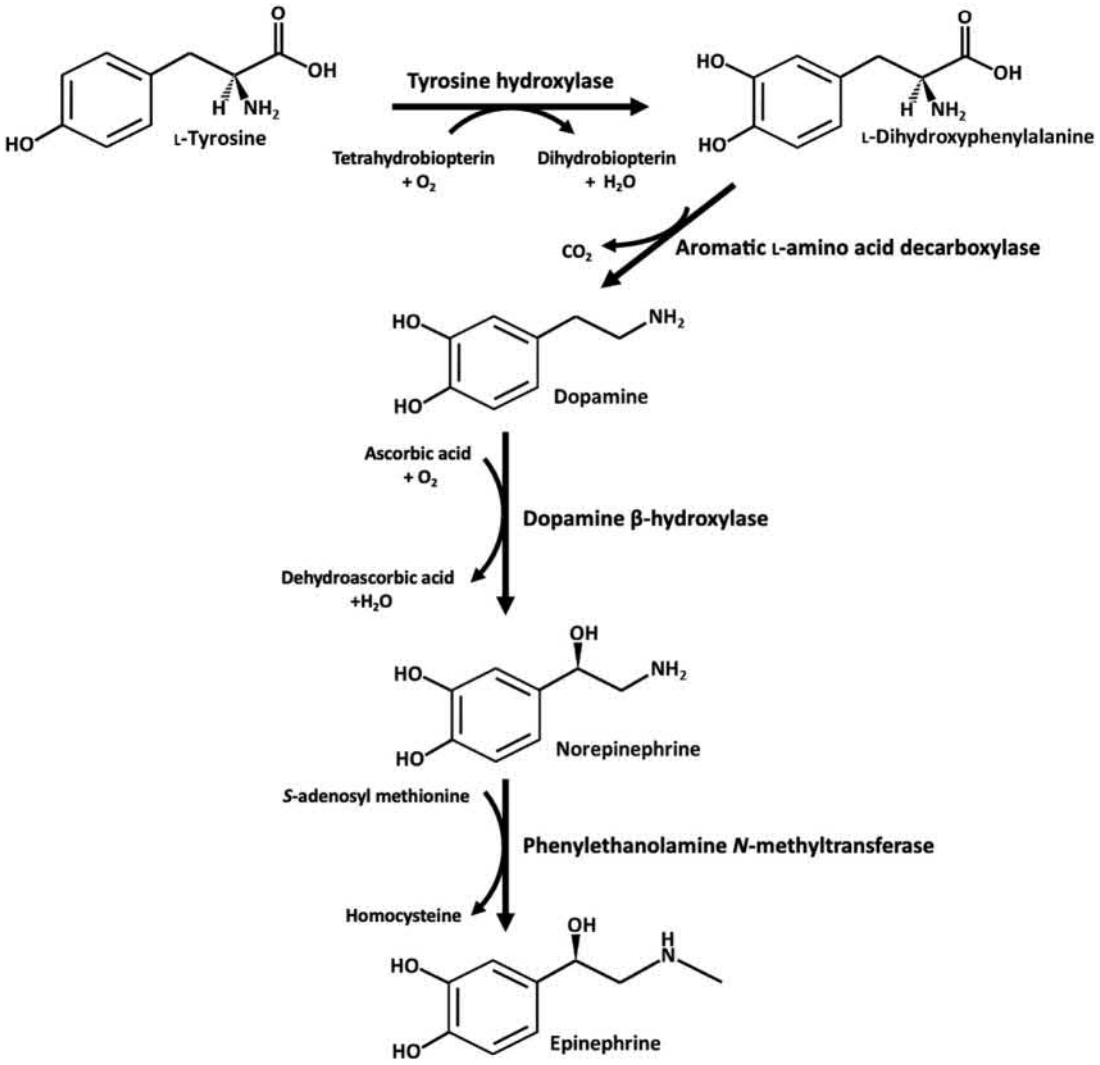

FIGURE 33.11 Biosynthesis of norepinephrine and epinephrine. Solid *black* and *hatched* bonds on molecules represent key beta (up) and alpha (down) positions, respectively, however, not all hydrogen bond positions are shown. See text for additional details. *Pathway drawn by R. V. Carsia.*

catecholamine biosynthesis is tyrosine hydroxylase. Catecholamines exert a negative feedback on tyrosine hydroxylase. Concerning the description of catecholamine release from the adrenal gland, it is best to use the framework of the catecholamine pathway in the "fight or flight" response to a particular stressor.

The perception of a stressor by the bird impacts on the proximal sympathetic nervous system that is relayed to preganglionic neurons of the spinal cord. The axons of these neurons comprise splanchnic nerves destined for the chromaffin tissue of the adrenal gland. Acetylcholine released from preganglionic sympathetic (splanchnic) nerve terminals interacts with both nicotinic and muscarinic receptors to stimulate phosphorylation of tyrosine hydroxylase, for rapid catecholamine synthesis and release, and upregulates tyrosine hydroxylase synthesis for more long-term stimulation. Phosphorylation lowers the K_m of tyrosine hydroxylase for tetrahydrobiopterin, a cofactor necessary for tyrosine hydroxylase activity. VIP and PACAP also stimulate the phosphorylation of tyrosine hydroxylase.

Tyrosine hydroxylase catalyzes the conversion of tyrosine to L-dihydrophenylalanine (L-DOPA). L-DOPA is converted to dopamine by aromatic L-amino acid decarboxylase (L-DOPA decarboxylase). Dopamine is either secreted or undergoes further conversion to NE by dopamine β-hydroxylase with ascorbic acid as a cofactor.

The final step to E is carried out by phenylethanolamine *N*-methyltransferase (PNMT) in which the *S*-methyl group of *S*-adenosyl methionine is transferred to the primary nitrogen group of NE. All of these enzymes have some requirement for innervation and are affected by numerous intra-adrenal peptides. However, PNMT is strictly GR-dependent.

The release of catecholamines into the circulation occurs by the well-studied, stimulus-secretion coupling mechanism. In addition to catecholamines, there are a number of neuropeptides that are co-released (see Section 33.1.2.3). Furthermore, chromogranins and secretogranins are also released. Chromogranins are necessary for sequestration of synthesized catecholamines in secretory granules. The peptides derived from chromogranins have autocrine and paracrine effects on catecholamine release (Trifaró, 2002; Mahata et al., 2010; Tota et al., 2012).

There is no preferential release of E or NE from isolated chicken chromaffin cells in response to acetylcholine analogs (Knight and Baker, 1986). In vivo, however, the secretion of E and NE from the avian adrenal gland is thought to be finely regulated by a number of neural-derived and blood-borne factors and hormones resulting in the differential release of catecholamines (Ghosh et al., 2001). Yet, it is not known precisely how the differential adrenal secretion of E and NE occurs in response to disparate physiological conditions and stressors. Since the preganglionic fibers of splanchnic nerves originate in the spinal cord and since chromaffin cells exert an influence on the presynaptic endings, it may be that preganglionic neurons are connected to either NE- or E-secreting chromaffin cells. What is fairly clear is that the adrenal gland is nearly the sole contributor to circulating E and most of the NE in response to acute stressors (Butler and Wilson, 1985; Lacombe and Jones, 1990).

33.4.2 Circulating catecholamines and stress response

The most recent and consistent values of circulating catecholamines in birds are obtained from studies with the domestic chicken (*Gallus gallus*) and duck (*Cairina moschata*) in which catecholamines were measured using high-pressure liquid chromatography with electrochemical detection. The plasma concentrations of NE and E in growing and mature chickens average 0.52 and 0.96 ng/mL, respectively, whereas those of the duck average 0.45 and 2.10 ng/mL, respectively. Dopamine also exists at variable but comparable concentrations (Butler and Wilson, 1985; Cheng et al., 2001; Pohle and Cheng, 2009). In the chicken, NE, but not E, shows a diurnal rhythm (de Jong et al., 2001).

Catecholamines are degraded mainly in the liver by catecholamine-O-methyltransferase and monoamine oxidase and the inactive products are removed by the kidney. Monoamine oxidases are also present in the adrenal gland and thus can modulate intra-adrenal levels of catecholamines (Ghosh et al., 2001).

Adrenal catecholamines are part of the first wave of acute stress response, i.e., the "fight-or-flight response." The E response to stress stimulates immediate hepatic glycogenolysis to provide glucose for critical tissues. In addition, catecholamines appear to interact with glucagon to regulate thermogenesis in cold stress (Abdelmelek et al., 2001; Filali-Zegzouti et al., 2005). Furthermore, catecholamines enhance the activity of the HPA axis at all levels ultimately driving more glucocorticoid release. In turn, the action of catecholamines is dependent on glucocorticoids (Sapolsky et al., 2000; Cyr et al., 2009).

Glucocorticoids enhance cardiovascular sensitivity to catecholamines. The effect of glucocorticoids occurs at multiple levels of catecholamine action. They inhibit reuptake of catecholamines by sympathetic terminals, reduce the catecholamine-degrading enzymes, catechol-O-methyltransferase and monoamine oxidase, and increase the binding parameters and transmembranous signaling of β-adrenergic receptors. Indeed, a large part of the modulation of catecholamine action occurs through the regulation of adrenergic receptor function.

In wild avian species, the adrenal catecholamine response to stress is complex (see Romero and Gormally, 2019). The highly conserved "fight or flight" response of

the catecholamine pathway is more nuanced as might be expected with the myriad life-history-cycle and life-history-stage transitions of wild birds. Within a species, aspects of the pathway and the responses of target tissues are affected by season.

33.4.3 Some physiological actions of norepinephrine and epinephrine

Catecholamines have diverse effects on immune cells. For example, continuous infusion of physiological concentrations of NE and E enhance chicken leukocyte migration and differentially affect the phytohemagglutinin wattle response (McCorkle and Taylor, 1993). In addition, NE and E, in vivo and in vitro, have contrasting effects on immunoglobulin plaque-forming cells from splenic lymphocytes, and these contrasting effects are probably mediated by α- and β-adrenergic receptors (Denno et al., 1994). Catecholamines also differentially affect macrophage effector functions, in vitro (Ali et al., 1994).

The metabolic effects of catecholamines are widespread in that they interact with other regulating hormones such as insulin, prolactin, thyroid hormones, growth hormone, and glucagon. Catecholamines influence carbohydrate and lipid metabolism. E stimulates glycogenolysis in chicken hepatocytes via β-adrenergic receptor activation and cAMP production, which, in turn, activates glycogen phosphorylase. Thus, the effect of catecholamines leads to a rapid increase in blood glucose levels (Thurston et al., 1993). Catecholamines (NE and presumably E) also stimulate gluconeogenesis via α-adrenergic receptor activation of intracellular calcium mobilization (Cramb et al., 1982). It is probable that the effects of E on glycogenolysis, gluconeogenesis, and also lipogenesis (see below) are physiological roles for adrenal E, as these metabolic parameters are influenced by concentrations of E that are found in the circulation of a stressed bird.

In chickens, during periods of behavioral inactivity, there is a positive relationship between circulating catecholamines and free fatty acids. Thus, catecholamines, at least in the liver, may be physiological regulators of lipid metabolism. The synthesis of fatty acid (lipogenesis) by liver tissue and cells is inhibited by E and to a lesser extent by NE. This effect is mediated via both α- and β-adrenergic receptors, and at least partially, by - cAMP acting as the intracellular messenger (Campbell and Scanes, 1985). Lipolysis in fat cells is stimulated by E in several species of birds and appears to be mediated via β-adrenergic receptors and - cAMP (Campbell and Scanes, 1985).

33.4.4 Changes in development, maturation, and senescence

Experiments with precocial species (again, mainly *Gallus gallus*) indicate that the adrenal chromaffin cells are derived from caudal thoracic (region of somites 18−24) populations of neural crest cells (sympathoadrenal progenitor cells) (see Shtukmaster et al., 2013; Unsicker et al., 2013). Recent evidence indicates that the adrenal chromaffin cells and postganglionic sympathetic neurons are derived from a common precursor cell population. In the chick embryo at about day two, this population delaminates from the neural tube and migrates ventrally to the area of the dorsal aorta. Under the induction of bone morphogenic proteins elaborated from the aorta, the cells acquire catecholaminergic features, as for example, the expression of tyrosine hydroxylase. Cells that reach the region of the adrenal gland at around embryonic day six gradually lose neuronal features such as the expression of neurofilament proteins and gain chromaffin cell features. This transformation from neuronal type to chromaffin type does not require the GR or even adrenocortical tissue (Gut et al., 2005; Huber, 2006). However, the differentiation to E cells and the expression of PNMT is absolutely GR dependent and is apparent in chromaffin cells at day five, albeit E cell differentiation does not require penetration into the developing adrenocortical tissue (Chimenti and Accordi, 2008). Indeed, chromaffin cell migration and penetration into the developing adrenocortical tissue does not occur until around day eight or nine and is not complete until day 15. In the chick, in addition to catecholamines, a variety of peptides are elaborated by the adrenal chromaffin cells postnatally. Some of these peptides have been described previously (see Section 33.1.2.3).

E is detected in the chick embryonic circulation somewhere between embryonic days 10−13 (see von Blumröder and Tönhardt, 2002). The importance of the adrenal gland in providing catecholamines for embryonic homeostasis is unclear since catecholamines can come from both adrenal and neuronal sources. However, a consistent observation is that circulating levels of NE predominate over those of dopamine and E. In the chick embryo, plasma catecholamines increase approaching hatch (von Blumröder and Tönhardt, 2002). NE appears to be an important catecholamine that supports the embryo for pipping and hatching, and the metabolic changes associate with the perihatch transition.

There appears to be an extreme range of variation in the adrenal NE and E content of birds of different phylogenetic groups (see Ghosh et al., 2001). Although there has been recent interest in birds as comparative models to study the mechanisms of aging (Holmes et al., 2001; Holmes and Ottinger, 2005; Ricklefs, 2010), there is little information concerning the endocrine changes associated with aging. The chromaffin catecholamine content and content response to endocrine alterations appear to vary among different species with age. However, a consistent emerging picture that is shared with the limited number of vertebrate species studied thus far is that chromaffin activity increases with age in disparate avian species (Ghosh et al., 2001).

Since there is a suggestion that glucocorticoids increase with age-related failure in adaptation to environmental and seasonal stressors (Koren et al., 2012), presumably similar changes occur with adrenal catecholamines. Clearly, more definitive studies are needed to understand the specific age-related changes in adrenocortical and adrenal chromaffin function in birds.

Acknowledgments

The author thanks Robert M. Dores, PhD, for helpful discussions on avian MC2R and MRAP1. The author is especially indebted to Colin G. Scanes, PhD, ScD, for his invitation to write and update this chapter and for his invaluable guidance throughout its revision.

VLDL Very-low-density lipoprotein

34.1 Introduction

The endocrine pancreas of the chicken (and of birds in general) displays several peculiarities (Hazelwood, 2000; Simon, 1989). Before discussing the current knowledge, we will recall the basics from these previous reviews. Most of these are certainly connected and interacting.

1-Birds have high-plasma uric acid and glucose levels despite normal plasma insulin levels [(Simon et al., 2011), for chicken]. Such high-plasma glucose levels (2−2.15 g/L in the fasting state) would be harmful for humans.

2-In chickens and ducks, high doses of exogenous insulin are required to induce hypoglycemia and huge doses are not lethal. The chicken features high-blood glucose,

Sturkie's Avian Physiology. https://doi.org/10.1016/B978-0-12-819770-7.00048-7

low-insulin sensitivity and as will become apparent in this chapter, the weak insulin release elicited by glucose in isolated chicken pancreas is characteristic of type 2 diabetes in human.

3-Experimental diabetes models are not available for chickens. Pancreatectomies are rarely complete; plasma glucose regulation is however impaired during refeeding. Diabetogenic drugs [alloxan or streptozotocin (STZ)] are inefficient, even when glycemia is decreased before STZ injection. Some isolated cases of diabetes have been described in pet birds, although not cited here.

4-Glucagon exerts a potent hyperglycemic effect; it is the lipolytic hormone in birds. The glucagon-induced cAMP increase is comparatively small but long-lived; the feedback decrease of cAMP by fatty acids appears inefficient in chicken adipocytes. Insulin lacks an antilipolytic effect in chicken adipocytes. Several peptides have been shown to have an antilipolytic effect in vitro: avian pancreatic polypeptide (APP), somatostatin, gastrin, and gut glucagon-like immunoactivity; however their function in chicken physiology has not been fully quantified in vivo.

5-Chicken insulin is "hyperactive" whereas duck insulin is "hypoactive." Chicken insulin has accordingly been suggested as more potent at inducing hypoglycemia in chicken than sheep or bovine insulin (in (Hazelwood, 2000)). The extent of the difference may have been overestimated: at high concentrations, similar nadir (maximal hypoglycemic effect) should be achieved irrespective of insulin type. [This is the case for insulin binding and phosphorylation of artificial substrate in solubilized chicken liver or brain insulin receptors (IRs)].

6-The importance of the insulin/glucagon ratio in the control of metabolism has been demonstrated in chickens and ducks. In vivo, this ratio is governed by opposite insulin-glucagon variations in response to nutritional status (fed vs. fasting). Glucagon-insulin interactions are however more complex. Insulin immuno-neutralization in fed chickens (i.e., a nutritional status for high-insulin demand, a protocol previously developed in ducks, [Mirsky et al., 1964, in (Dupont et al., 2008)] evokes a rapid (less than 30 min) and large rise in plasma glucose levels. Surprisingly, injection of a glucagon antagonist [des-His^1 (Glu^9) glucagon] has no effect on plasma glucose level in fed chickens in (Dupont et al., 2008); a hypoglycemic effect might be expected. This strongly suggests that in normally fed chickens, the control of plasma glucose level relies more on insulin than on glucagon in (Dupont et al., 2008, 2012). The presence of glucagon is however essential: in the pathological model of "hypoglycemia-spiking mortality syndrome" where pancreatic glucagon content is extensively depleted following a virus infection, chickens do not eat and ultimately die from starvation in a profound hypoglycemic status (Davis and Vasilatos-Younken, 1995). To inhibit pancreatic glucagon release, glucose requires the presence of insulin (Dupont et al., 2008), which confirms previous results obtained in ducks and later on in mammals [see Miahle's group references in (Simon, 1989)].

7-Chicken (and bird) metabolism is also peculiar in several ways (see other chapters in this book). In short, gluconeogenesis is active in liver and kidneys but appears able to be regulated only in kidneys. Liver is the organ for de-novo lipogenesis.

8-Insulin exerts pleiotropic effects in chickens during embryonic and posthatch development. The major typical effects on carbohydrate, lipid, and protein metabolism have been demonstrated. Insulin stimulates glucose and amino acid transport in various cells. The insulin effect on glucose transport is however limited in muscle and still doubtful in chicken adipocytes. Insulin stimulation of amino acid transport requires protein synthesis. Insulin greatly stimulates liver lipogenesis and expression of lipogenic enzymes. In contrast, insulin stimulation of lipogenesis remains marginal, if any, in chicken adipocytes. (Lipogenesis is also intrinsically low in human adipocytes). Glucagon counteracts insulin stimulation of lipogenesis in chicken liver.

9-Finally, birds have a high-body temperature (about 42°C in chickens) and a high-metabolic rate and anabolism. They are able to adapt to long catabolic states and to survive long periods without food.

This chapter offers a synthetic view of current knowledge, focusing on major aspects of glucagon and insulin control for the sake of brevity. References have been kept as few as possible; early major original contributions for chickens and birds are acknowledged and listed only by first author's name and date but not referenced, including ours, when quoted in recent publications. For evident reasons, knowledge of the role of the endocrine pancreas is far more advanced in mammals; on several occasions, it was necessary to refer to it. Again, to save space, these data are listed in the text by first author's name and date. Readers will need to connect to Pubmed to have access to full references.

34.2 Pancreas embryogenesis and development

34.2.1 Morphology of avian pancreas (Fig. 34.1)

In most birds, the pancreas is situated in the duodenal loop and consists of three lobes: the dorsal, ventral, and splenic lobes: the splenic lobe is contiguous with the rest of the pancreas, but in some birds, it can be completely separated. A fourth lobe, sometimes confusingly called the "third lobe," is a part of the ventral lobe and is distinguishable in galliform birds (which include chickens and quail).

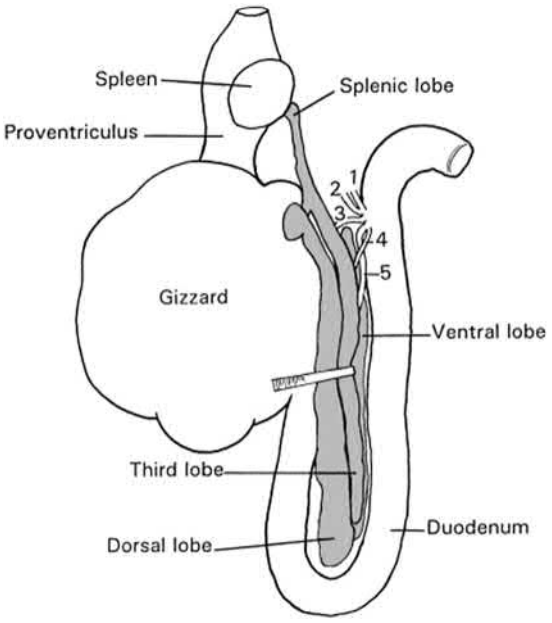

FIGURE 34.1 The anatomical relationship in the chicken of the four lobes of the pancreas (shaded) and neighboring organs (blood supply and liver not shown) viewed from the dorsal aspect. 1. cystic duct; 2. hepatic duct; 3. dorsal pancreatic duct; 4. duct of the third lobe; 5. ventral pancreatic duct. *After Mikami, S.I., Ono, K., 1962. Glucagon deficiency induced by extirpation of alpha islets of the fowl pancreas. Endocrinology 71, 464–473, The Endocrine Society.*

34.2.2 Distribution of avian pancreatic endocrine cells between the different pancreatic lobes

The endocrine pancreas contains clusters of cells called the islets of Langerhans, which are distributed throughout the exocrine parenchyma. These represent only 1%–2% of the whole gland. In contrast to mammals in which only one type of islets occurs, three types of islets are found in birds: the light, the dark, and the mixed islets. They differ in shape, size, and staining characteristics. The light islets (or B-islets) remain clear after classical staining procedures (Heidenhain's iron haematoxylin) and are essentially composed of β–and δ-cells secreting insulin and somatostatin, respectively, and occasionally very few α-cells secreting glucagon. The dark islets (or A-islets) are composed essentially of α– and δ-cells secreting glucagon and somatostatin, respectively. They are larger in size than the B-islets. The mixed islets are composed of numerous β-cells and a few α- and δ-cells. Some wild bird species have mixed islets (randomly distributed) rather than light and dark islets (Steiner et al., 2010). A fourth type of endocrine cell is found in the pancreas: the F cells. These cells synthesize and release APP; they occur as single cells or in groups disseminated in the exocrine parenchyma mainly in the dorsal and ventral lobes. Some F-cells can be found within the islets. Isolated δ-cells (as numerous as F-cells) are also found as dispersed extrainsular endocrine elements. The splenic lobe and to a lesser extent the third lobe (when present) notably contain more islet tissue per unit volume than do the dorsal and ventral lobes (Rideau, 1988).

The feature unique to the avian pancreas is the predominance of the glucagon-producing over the insulin-producing cells in the ratio of approximately 2:1 (Andrew et al., 1984 in (Manakova and Titlbach, 2007)). In addition, somatostatin-producing δ-cells are also more numerous in the avian pancreas than in that of mammals (Rideau, 1988). The existence, distribution, and relative frequency of various (neuro-)endocrine cells (biotin, serotonin, NPY, and chromogranin) have been demonstrated in the pancreas of avian species (Ku et al., 2000; Lucini et al., 2000).

The islet tissue is richly vascularized, irrigated by the pancreaticoduodenal artery and drained by the pancreaticoduodenal vein. Innervation of the pancreatic islets of birds is not as apparent as it is in mammals. Electron microscopic studies have clearly shown that the main endocrine cellular types of the pancreas of the domestic fowl are associated with nerve terminals. The nerve supply to the islets is however less abundant than that to the acinar cells; it is also less marked to the A-islets than to the B-islets. In contrast, δ cells are richly and directly innervated in chickens (Rideau, 1988).

34.2.3 Development of avian pancreas

The pancreas is of endodermal origin; it is formed from the embryonic foregut. In birds, it arises from three buds, a dorsal bud and right and left ventro-lateral buds (Rawdon, 1998) that appear at the stage of 22–31 somites (56–67 h) and begin to fuse at day seven of embryonic development (Hamburger and Hamilton stage 30, HH 30) (Matsuura et al., 2009).

The determination of endoderm to form dorsal and ventral bud derivatives occurs before formation of the buds. In mammals, the signaling pathways underlying the pancreatic development process include the Hedgehog system, the homeobox gene Pdx1, and Notch signaling. The vast majority of neurogenin-3 (ngn3)-expressing cells are committed to the endocrine lineage (Rosenberg et al., 2010). Two transcription factors, Pax4 and Arx, have competing roles in the commitment of the first of ngn3-positive cells to generate either the α/PP-cell lineage or the β/δ-cell lineage. Subsequently, within cells that are committed to the β/δ-cell lineage, persistence of pax4 expression seems to select for the β-cell lineage, whereas suppression of pax4 expression selects for the δ-cell lineage (Gittes, 2009).

Early in vitro studies by Rawdon using the dorsal pancreatic bud of five-day chick embryo established that pancreatic mesenchyme may play an instructive role with respect to the early development of the chick pancreas.

Results also suggested that the notochord plays an early role in induction of the pancreas although experimental evidence were lacking (Rawdon, 1998). Past decade studies confirmed and extended Rawdon's observations (Rawdon, 1998). Prepancreatic endoderm first receives pancreas-inducing signals from the underlying somatic mesoderm, inducing Pdx1 expression as early as 4 ss (1.5-day-old embryos) (Katsumoto et al., 2009). The regulation of pancreatic endocrine development by Notch is also found in chicken; inhibition of Notch signaling results in increased endocrine differentiation, whereas activation of the Notch1 receptor blocks endocrine development and maintains the proliferation of pancreatic progenitor cells in the embryonic chicken pancreas (Ahnfelt-Ronne et al., 2007). Neurogenin 3, which is transiently expressed in pancreatic endocrine progenitors, is responsible for the activation of a transcription factor cascade which ultimately leads to the maturation of endocrine cells in chicken endoderm (Rosenberg et al., 2010). The origin of the ventral pancreatic precursor cells has been studied less extensively; they are located at sites in which Pdx1 expression is detected by in situ hybridization (Matsuura et al., 2009).

Organization, volume, and ratio among the different endocrine cell types vary throughout embryonic development and postnatal life. The dorsal bud is the major source of insulin, glucagon, and somatostatin cells, whereas the ventral buds generate PP cells (Rawdon, 1998). In the dorsal bud, glucagon immunoreactive cells appear first at 2.25−2.5 days of incubation; then insulin cells at 3−5 days and somatostatin cells at 3.25 days (Manakova and Titlbach, 2007). Pancreatic polypeptide cells appear only later, at 7 days in the splenic lobe (Cowap, 1985). In contrast to the dorsal bud, insulin cells have not been identified in prospective ventral bud derivatives until 13 days of incubation (Manakova and Titlbach, 2007). Development of exocrine tissue is delayed in comparison to that of endocrine tissue (Manakova and Titlbach, 2007).

34.2.4 Pancreatic hormone levels during development and after hatching

Circulating concentrations of insulin and glucagon rise during development of the chicken embryo. In Cobb 500 chick embryos and hatched chicks, plasma insulin increased from 10 days of embryonic life (E) (30 pg/mL) reaching 1000 pg/mL at 17 days after hatching (Lu et al., 2007). Plasma insulin concentrations, at 3−4 ng/mL in fed growing ducks and chickens, are similar to those of mammals (Simon et al., 2011). They are low at 1 day posthatch and increase with age up to 28 d, with higher insulin sensitivity in 1-day-old chicks than in 21-day-old broiler chickens, as observed in the latest strain of broiler chickens (Shiraishi et al., 2011b) and in previous reports on egg-laying or meat-type chickens. Plasma insulin concentration decreased by 45%−50% after 6 h of fasting in 19 to 47-day-old in male and female modern meat-type chickens (Christensen et al., 2013). A low-plasma glucagon concentration (59 pg/mL) was found in embryos at 10 d of incubation, remaining low until 17 d E and then increasing approximately threefold by the time of hatching (Lu et al., 2007). Values between 152 and 450 pg/mL were measured in fed and 6h fasted modern meat-type chickens, respectively (Christensen et al., 2013). It should be noted that in some of these experiments, the feeding pattern of chickens was not always synchronized with light-dark cycles.

34.3 Factors controlling pancreatic insulin and glucagon release in birds

34.3.1 Insulin

Whereas in mammals, glucose is the primary physiological regulator of insulin secretion, the insulinotropic effect of glucose is less obvious in birds in vivo and in vitro. In vivo raising blood glucose levels in ducks and chicken only transiently increases insulin levels (Rideau, 1988). The high-basal plasma glucose concentrations found in chickens may itself contribute to the relative insensitivity of the chicken β-cell to glucose: impairment of glucose-induced insulin release has been reported in hyperglycaemic mammalian models. The mechanisms are however presently unknown in chickens. Somatostatin which is present at high concentration in the chicken pancreas (Weir et al., 1976 in (Rideau, 1988)) may also exert inhibitory paracrine effects on the β-cell and partly explain the insensitivity of the β-cell to fuel nutrients. However somatostatin immunoneutralization in isolated-perfused chicken pancreas has only transitory effects on insulin release at high-glucose concentration (42 mM) and no effect at low levels (14 mM) (Honey et al., 1981 in (Rideau, 1988)). In vitro studies provided further insight into the mechanisms responsible for the relative glucose insensitivity of chicken β−cell. Using isolated and perfused duodenum-pancreas from adult hens in (Rideau, 1988, 1998) first showed that the pancreatic β-cell is relatively insensitive to glucose as very high and nonphysiological glucose concentrations (30 to 40 mM) are required to induce a modest insulin release. This insensitivity was confirmed and extended to other fuel nutrients, which are potent insulinotropic agents in mammals, using isolated duodenum-pancreas from young chickens. D-glucose and D-Glyceraldehyde require high concentrations to evoke either very weak or delayed insulin release; leucine and its ketoacid (α-KIC) are even totally ineffective. The chicken β-cell remains however sensitive to depolarizing agents (K^+), tolbutamide (which closes K^+ATP-dependent channels), and potentiators of insulin secretion (acetylcholine or cAMP) (Rideau, 1988). Therefore, initiation of insulin

secretion by fuel nutrients, the critical and specific step of the β-cell, appears different in chickens and mammals, whereas potentiating mechanisms (arginine, acetylcholine, and cAMP in the presence of low glucose concentration) and membrane depolarization events (K^+ and arginine) are present in chickens as in mammals.

The key role of glucokinase (GK) in the regulation of insulin release and hepatic glucose utilization has been well described in mammals. Though the GK gene is not referenced in the chicken genome at Ensembl, we isolated a chicken GK cDNA and showed that GK messenger is expressed in chicken liver and pancreas (Berradi et al., 2005 in (Rideau et al., 2010) for review Panserat et al., 2014). A human GK antibody identified a GK protein in chicken liver, the amount and activity of which was insulin-dependent (Dupont et al., 2008). Furthermore, RO0281675 (a specific GK activator in mammals) caused severe hypoglycaemia in chickens but surprisingly without significantly increasing insulin levels, contrary to results obtained in mammals (Rideau et al., 2010). Thus, liver glucose utilization is substantially enhanced following liver GK activation. Though GK is present in the chicken pancreas, pancreatic GK activation may not be sufficient to cause insulin secretion, which confirms in vitro studies reported above and supports the conclusion that the coupling between intra-B-islet metabolism and insulin release is different in chicken B-islets. The lack of insulinotropic effect of leucine or α-KIC (metabolized in the mitochondria) suggests that the inefficiency is located beyond the pyruvate step in the chicken β-cell.

Isolated chicken B-islets are necessary to further understand the insensitivity of the chicken β-cell to "insulinotropic" fuel nutrients. Although functional islets were isolated in various mammalian species more than 40 years ago, isolation of avian islets of Langerhans has proven to be especially difficult due to the fact that the morphology of the isolated A- and B-islets had not been characterized. Ruffier et al. described isolation of functional A- (glucagon) chicken islets (Ruffier et al., 1998). Glucose-stimulated insulin release from B-islets isolated from the dorsal lobe of chick pancreas has been reported (Datar et al., 2006). In our opinion, however, the specificity of these preparations remains to be established as dithiocarbazone staining method stains both B- and A-islets in chickens (Ruffier et al., 1998).

Resistance to diabetogenic drugs. The extreme resistance of birds to the diabetogenic drugs alloxan and STZ was described very early. In mammals, the β-cell specificity of these drugs is mainly due to the fact that they are selectively transported by the β-cell glucose transporter, GLUT2 (Lenzen, 2008). GLUT2 expression was reported in the liver and kidney in chickens (Kono et al., 2005) but also in chick islets (Modak et al., 2007). Within the mammalian β-cell, alloxan selectively inhibits glucose-induced insulin secretion through specific inhibition of GK; in addition, it induces ROS formation, resulting in the selective necrosis of β-cells. STZ's effects are attributed to its specific alkylating potency, which modifies biological macromolecules and DNA fragments and ultimately destroys the β-cells (Lenzen, 2008). Compared with mouse islets, chicken islets generate smaller amounts of ROS under STZ. Consequently less damage to proteins, lipids and DNA can be expected in chicken than in mouse islets. These results may partly explain why STZ does not induce diabetes in chicken, even at high doses (Modak et al., 2007).

Despite the peculiarities present in chickens in the coupling between metabolism and insulin release, insulin release is under the control of multiple components in vivo and in vitro. Though glucose or a mixture of amino acids separately increases plasma insulin to a small extent, they act synergistically when combined in vivo. Refeeding with gradually increasing amounts of food results in gradual rises in plasma insulin levels, adjusting glucose to a similar level. Changes in glucose-insulin balance are observed in several experimental conditions or models, including genetically fat and lean lines of chickens, dwarf chickens (*dw/dw*), hypothyroidism, corticosterone treatment, and chronic exposure to high temperature (Rideau, 1997) (Table 34.1). The incretin effect is not documented in chickens, but a variety of other stimuli including nutrients (glucose, arginine), hormones (cholecystokinin, glucagon, corticosterone, GH) (Rideau, 1988), and neuronal stimuli (Karmann et al., 1992) increase plasma insulin levels. The effects of Ghrelin/obestatin and GLP-2 on insulin release are not known in birds. Conversely, insulin secretion is inhibited by epinephrine and somatostatin (Rideau, 1988). Though the existence of leptin in the chicken is still debated, a recombinant "chicken" leptin (or leptin analog) potently inhibits insulin secretion from the perfused chicken pancreas (Benomar et al., 2003).

34.3.2 Glucagon

Fasting markedly increases circulating concentrations of glucagon in chickens (Edwards in (Scanes, 2009). In modern meat-type chickens, plasma glucagon levels increased 3.5−3.7 fold after 6 h of fasting while plasma glucose was depressed by 11% (Christensen et al., 2013). Glucagon secretion is inhibited by glucose in vivo in domestic birds (Honey et al., 1980 in (Rideau, 1988)) and in wild species in (Scanes and Braun, 2012). Exogenous glucose (42 mM) inhibited glucagon release by 27% from isolated A-islets of Langerhans (Ruffier et al., 1998). Conversely, glucagon release is stimulated by amino acids, free fatty acids, cholecystokinin, somatostatin, and insulin in vivo (Scanes and Braun, 2012). A tonic suppression effect on glucagon by insulin is suggested in a model of insulin immune-neutralization in chickens (Dupont et al., 2008). As for

TABLE 34.1 Experimental or genetical models exhibiting changes in the plasma glucose-insulin relationship in chickens.[a]

[a]ND, *not determined. Refeeding experiments have been performed following a fast in several of these models. Results, not summarized in the table, can be found in Simon (1988) and in Simon et al., 2000 (LGl-HGl). Corticosterone was injected 5–6 mg doses/kg. Insulin sensitivity was evaluated through the hypoglycemic effect of exogenous insulin. Results of glucose tolerance in HG-LG chickens are unpublished data (Simon et al.).*

insulin, the effect of gastrointestinal peptides and adipose tissue hormones on glucagon secretion is unknown in birds.

The mechanisms underlying the secretion of glucagon from α-cells are largely unknown in chickens. In mammals, α-cells contain a comparable secretory "machinery" as in β-cells: a glucose transporter (in this case the ubiquitous GLUT-1), GK, K^+ATP channels, L-type voltage-gated calcium channels, and secretory granules (Le Marchand and Piston, 2010). However, α-cell secretory activity is quite different from that of β-cells. The mechanisms underlying the glucose inhibition of α-cell secretory activity are poorly understood. Two nonexclusive models have been proposed: a direct inhibition by glucose and an intraislet paracrine inhibition arising from non-α-cells. The paracrine control might involve somatostatin released from δ-cells and insulin, zinc or GABA released from β-cells. Recently Le Marchand and Piston suggested that in the absence of cell–cell contacts, isolated α-cells function similarly to β-cells, i.e., glucagon secretion increases as a function of glucose concentration. However in the islet, glucose inhibits glucagon release downstream the calcium step, presumably at the level of vesicle trafficking or exocytotic machinery (Le Marchand and Piston, 2010).

34.3.3 Somatostatin

Somatostatin (also known as growth hormone-inhibiting hormone or somatotropin release-inhibiting factor) is a 14-amino acid peptide that regulates the endocrine system. The interaction of somatostatin with thyrotropin releasing hormone signifies the physiological role of somatostatin in control of digestion, growth, and reproduction in the chicken. Chicken somatostatin is present in two forms: somatostatin-14 (SST-14) and somatostatin-28 (SST-28), which are encoded by the same gene (PSS1) as in mammals. Ontogenic expression profile of chicken SSTs is time and tissue specific (Malik et al., 2013). Chicken pancreatic A-, B-islets, and D-cells contain only SST-14 peptide form (Takayanagi et al., 1996 in (Trabucchi et al., 2003)). Another somatostatin gene variant (PSS2) exists in many species, including chickens. PSS2 messenger is expressed in chicken pancreatic islets or pancreas, and in a few specific brain structures, less numerous than structures expressing PSS1 messenger (Trabucchi et al., 2003).

34.3.4 Avian pancreatic polypeptide

APP was first isolated and characterized from chicken pancreas (Kimmel et al., 1968); it is a member of the neuropeptide Y family [PP, peptide YY (PYY) and neuropeptide Y (NPY)]. PYY and PP are gut endocrine peptides almost exclusively expressed in the digestive system, whereas NPY is expressed in the central and peripheral nervous systems at all levels of the gut–brain axis. All three peptides are 36 amino acids long and act on G-protein-coupled receptors; five receptor subtypes have been described. In mammals, PP is released from the endocrine pancreas following a meal and acts preferentially via Y4 receptors. It inhibits gastric emptying, intestinal electrolyte, water secretion intestinal motor activity, and peristalsis. PP also reduces appetite (Holzer et al., 2012). In chickens, APP is released in response to gut peptides and amino acids (Colca and Hazelwood, 1982 in (Rideau, 1988)).

Y4 receptors are expressed in a large number of peripheral tissues and in the brain (Lundell et al., 2002). APP primarily acts by inhibiting gastrointestinal tract motility and gall bladder and exocrine pancreas secretion in chickens (Hazelwood, 1993 in (Hazelwood, 2000)). It also exerts metabolic effects: liver glycogenolysis, hypoglycerolemia, lowering of plasma free fatty acids level. One study though suggests that APP increases food intake in White Leghorn chickens (Denbow et al., 1988).

34.4 Insulin and glucagon peptides

34.4.1 Insulin/preproinsulin, proinsulin, and C-peptides

The chicken insulin gene was cloned and sequenced as early as 1980 (Perler et al., in (Simon et al., 2004)); it is localized on GGA5 and exhibits the "ancestral" structure containing two introns: intron-1 interrupts the 5′ un-translated region and intron-2 [about 3.5 kb, vs. 141−786 bp in other animal species, Steiner et al., 1985, in (Simon et al., 2004)] interrupts the coding sequence. It encodes a preprohormone, i.e., preproinsulin, which contains the signal peptide (rich in hydrophobic residues), the insulin B-chain, the connecting peptide (C-peptide), and the insulin A-chain. Until now there is no evidence for the existence of a second insulin gene in birds in (Simon et al., 2004).

Insulin has been purified and sequenced in chickens, turkeys, ostriches, geese, and Pekin and Muscovy ducks in (Chevalier et al., 1996). The insulin gene has been cloned and sequenced in other bird species including humming bird and 28 other species [Fan et al., 1993, in (Simon et al., 2004)]. From deduced amino acid sequences, bird insulins appear highly conserved. As compared to human insulin, minor neutral changes on the B-chain concern few residues at both ends: B1, B2, B3, B20, B27, or B30 (out of 30 positions). On the A-chain, changes concern positions A8-10 (out of 21 positions). In our study (Simon et al., 2004), some uncertainty remains for the last six amino acids of the A-chain because the reverse primer was targeting the corresponding codons and the stop codon. Changes on the A-chain (at A8-10 positions) between bird and human insulins are not neutral. This region is the most variable and considered as the most immunogenic part. Accordingly, most antibodies prepared against mammalian insulins do not cross-react with chicken or duck insulin.

At the A8 position a histidine residue is found in most bird species, as opposed to a glutamic acid residue in six species of the Anseriform order and a threonine in human insulin. The A8 position is now thought to be involved in the insulin binding site to the IR (site 1, Sajid et al., 2009); the synthesis of human insulin analogs wearing different residues at the A8 position confirmed an early hypothesis, namely, the presence of histidine at A8 confers the properties of chicken insulin to such analogs [high-binding affinity and low-dissociation rate, Weiss et al., 2001, 2002; Wan et al., 2004 and references quoted in (Chevalier et al., 1996)]. Chicken insulin is the only natural super analog thus far described (at least twice as potent as human or pig insulins in bioassays or binding assays in many species, Kemmler et al., 1978, Schauder and Buck, 1969, Simon et al., 1974, 1977, in (Chevalier et al., 1996)).

A8 glutamic acid, as found in the Anseriform order, increases the thermodynamic stability of the molecule, which should make "duck-type" insulins even more potent than "chicken-type" insulins (Weiss et al., 2001). In fact the presence of negatively charged residues such as glutamic or aspartic acid at this position decreases the affinity of analogs for the receptor (Weiss et al., 2001). Duck insulin accordingly exhibits low affinity in rat liver membranes (Chevalier et al., 1996) and low bioactivity in rat fat cells (Moody AJ, personal communication). The fact that chicken or Pekin and Muscovy ducks IRs (IRs) do not discriminate so extensively, accordingly to potencies observed with rat IR, may be specific to bird IRs (see IR section). So, thus far, only two types of insulin have been found in 30 bird species: the hyperactive "chicken-type" insulin and the hypoactive "duck-type" insulin. From alignments of nonmammalian insulins [see references in (Simon et al., 2004)], A8 histidine was present early in the ancestor insulin molecule and disappeared in mammals (which possibly decreases the risk of hypoglycemic events and tumorigenicity). The appearance of A8 glutamic acid in anseriform birds and some snakes may have occurred independently in these species.

As in other species, bird C-peptides have been much less conserved; 14 changes out of 28 amino acid residues are found in 29 bird species (Simon et al., 2004). In other animal species, C-peptides are longer [31−38 amino acids, Gross et al., 1989 and Wahren et al., 2000, in (Simon et al., 2004)]. Whether the shortness of bird C-peptide modifies the rate and yield of insulin synthesis is unknown. C-peptide is linked to B- and A-insulin chains through two dibasic residues at both ends (RR or KR, as in other species). In mammals, proteolytic cleavage and removal of these two pairs is performed by specific endopeptidases: PC3/PC1 and PC2 prohormone convertases and carboxypeptidase E. Such endoproteases have been detected in chicken embryos using heterologous antibodies [Hernandez-Sanchez et al., 2002; Teshigawara et al., 2001, in (Simon et al., 2004)]. Though predicted to be 28 residues long in all bird species, purified duck (*Anas platyrhynchos*) C-peptide is only 26 amino acids long in (Simon et al., 2004). Such extensive cleavages are also suggested in all the birds studied (with a possible exception in *Passer*, in Simon et al., 2004). In mammalian species, at least two acidic amino acids surrounding a hydrophobic residue are present at the NH2-terminal end of C-peptide

(e.g., EAED, EVE, and EAE); such a structure has been found to be critical for a normal rate of conversion of proinsulin to insulin. A very similar structure is observed in bird species studied (DVE, DIE, or DAE, Simon et al., 2004). C-peptide has long been considered as devoid of physiological functions on its own (other than structuring the precursor during insulin biosynthesis). C-peptide is now considered to control e-NOS, Na^+, K^+-ATPase, alpha−enolase, and several transcription factors (Wahren et al., 2012; Ishii et al., 2012). The central segment (ELGGGP-GAG) or the COOH-terminal pentapeptide fragment (EGSLQ) of human C-peptide mimics the action of the entire peptide in several assays. The central part is very different in bird species and C-terminal fragments are acidic (QEEYE, HEEYQ, QEEFE, or PEEYE). The C-peptide may therefore have acquired specific biological functions only in mammals, unless the still putative receptor co-evolved in bird species.

The length of available preproinsulin gene reading frames is similar in all bird species [187 nucleotides at the 5′-end and 134 nucleotides at the 3′-end (Simon et al., 2004)]. In contrast, the size of the PCR products varies greatly [from 2.7 kb in Passeriformes (*Passer*, *Turdus* and *Pica*) to about 4.5 kb in Palaeognathae species (*Struthio*, *Rea* and *Dromiceius*)]. Phyllogenetic analyses supported the monophyletic origin of birds and identified the Palaeognathae group as an isolated group at 100%, strongly suggesting this group is basal. After the branching of Palaeognathae, a galloanserae was identified (at 63%) whereas all other Neognathae clustered at 99%. If we accept Palaeognathae, rather than Passeriformes are basal to Neornithes, intron-2 must have evolved from a very long ancient form (likely close to that found in present day Palaeognathae species) toward the shorter form found in Passeriformes.

In humans, some insulin gene polymorphisms are associated with diabetes. Some polymorphisms have been described in chicken (Bennett et al., 2006; Qiu et al., 2006) and in duck (one paper in Chinese, Kong et al., 2008) insulin genes. In the chicken, polymorphisms (mostly SNPs), thus far identified, are located in 5′-and 3′-UTR or intron. In these pioneer studies significant associations were found for body weight at hatching, 28 d or 55 w and small intestine length but not with abdominal fat weight at 13 w of age. Further studies conducted at other ages and involving other physiological parameters may reveal other associations.

34.4.2 Glucagon and glucagon-like peptides

34.4.2.1 Glucagon structure and physiological effects

Glucagon (a member of the VIP-secretin family of peptide hormones) is a 29-amino acid peptide, very similar across species. In mammals, glucagon is encoded by a single proglucagon gene, and there is a single mRNA which generates a single protein precursor that contains glucagon and two structurally related peptides at its carboxyl terminus: glucagon-like peptide 1 (GLP-1) and glucagon-like peptide 2 (GLP-2). The post-translational proteolytic processing of this unique precursor is tissue-specific. In the pancreas, glucagon is one of the major peptides released by the α cells of A-islets in response to low glucose levels, whereas GLP-1 and GLP-2, but not glucagon, are produced in intestinal L cells and central nervous system.

Chicken glucagon is also a 29-amino acids-long peptide that is derived from a single proglucagon gene, which expresses multiple mRNA transcripts with different coding potentials (Richards and McMurtry, 2008). In the case of the domestic fowl, the preproglucagon precursor is 151 amino residues long. Chicken glucagon differs from rat and human glucagon by only one amino acid (ser vs. asn at position 28) and from duck glucagon by two amino acids (ser vs. asn at position 28 and thr vs. ser at position 16). In contrast to mammals, the chicken proglucagon gene expresses two classes of proglucagon mRNA transcripts (PGA and PGB): class A mRNA (PGA) codes for glucagon and GLP-1 and resembles lower vertebrate transcripts such as those found in fish, while class B mRNA (PGB) codes for glucagon, GLP-1, and GLP-2 and is more like mammalian transcripts. Pancreas and proventriculus displayed the highest expression levels of class A and class B mRNA. Two prohormone convertases (PC) (PC2 and PC1/3) cleave the precursor into active peptides: PC2 mRNA is predominantly expressed in the pancreas and proventriculus, whereas PC1/3 mRNA is more highly expressed in the duodenum and brain. Fasting and refeeding have no effects on proglucagon mRNA expression in various chicken tissues: pancreas, proventriculus, duodenum, or whole brain. This indicates that transcriptional regulation does not account for acute changes in plasma glucagon resulting from short-term changes in energy status in birds (Richards and McMurtry, 2008, 2009). The proglucagon gene is also expressed in various neurons of the avian retina (Fischer et al., 2006) and in chicken adipose tissue (Cogburn, personal communication), where in contrast to other tissues, PGB mRNA levels appear insulin-dependent (Ji et al., 2012).

In birds, glucagon has several physiological roles and peculiarities that have been already described in Hazelwood, fifth Edition. Plasma glucagon levels are much higher in birds than in mammals. Chicken, ostrich, and pigeon glucagons were initially found to be less potent than mammalian glucagon, but this was not confirmed in a subsequent study (McCumbee and Hazelwood, 1978; Ferreira et al., 1991; Tung et al., 1977; Huang et al., 1987 in Simon, 1995). In turkeys, pig, or chicken, glucagon were found to be equally effective in promoting hyperglycemia, increase in plasma nonesterified free fatty acid levels, and a decline in

circulating levels of T_3 and T_4 (McMurtry et al., 1996). Long-term injection of glucagon has been shown to induce uncoupling protein expression in skeletal muscle of ducks consistent with the thermogenic action of this hormone in birds (Raimbault et al., 2001). Glucagon is also important in the chicken eye for regulating ocular growth (Vessey et al., 2005). Honda et al. found that central, but not peripheral, administration of glucagon suppressed food intake and induced hyperglycemia in chickens and that these effects were mediated by the downstream actions of corticotrophin-releasing factor [Honda et al. (2007) in (Honda et al., 2012)]. Thus, glucagon may serve as a neurotransmitter in the avian central nervous system as has been suggested for mammals (Mayo et al., 2003).

34.4.2.2 GLP-1

Chicken GLP-1R is expressed in pancreatic D cells that secrete somatostatin (Watanabe et al., 2014; Hiramatsu, 2020; Kolodziejski et al., 2018). Similar localization of chicken GLP-1R has been observed in the pancreatic islets of other avian species, northern bobwhites, and common ostriches (Watanabe et al., 2018). Restricted feeding increases the frequency of occurrence of GLP-1-immunoreactive cells in the chicken small intestine (Monir et al., 2014a), thereby indicating that L cells secrete GLP-1 in response to food ingestion in the chicken small intestine. Proteins and amino acids, such as lysine and methionine, are the triggers that induce GLP-1 secretion from chicken ileal L cells (Monir et al., 2014b; Nishimura et al., 2015). Significant correlation has been observed between dietary protein ingestion and frequency of occurrence of GLP-1-immunoreactive cells in the chicken ileum (Monir et al., 2014c). In addition, GLP-1 blood concentration and GLP-1 mRNA in the duodenum and GLP1-R in the pancreas are decreased in response to in ovo injection of synbiotics (Kolodziejski et al., 2018). GLP-1 slows down nutrient assimilation by inhibiting gastric emptying and acid secretion. Central but not peripheral administration of GLP-1 inhibits food intake and crop emptying in chickens and shifts fuel utilization from carbohydrates to lipids without affecting overall energy expenditure (Tachibana et al., 2007). The hypothalamus is involved in the anorexic effect of GLP-1 in chicks (Tachibana et al., 2004 in (Tachibana et al., 2007)). Moreover, the anorexigenic effect of central GLP-1 administration is mediated by the GLP-1 receptor because co-administration of a specific GLP-1 receptor antagonist (exendin 5−39) or N-terminal fragments attenuates the anorexia, while injection of the antagonist alone increases food intake in layer-type but not broiler chicks (Furuse et al., 1998). These results indicate the potential for variable responses in food intake to endogenous GLP-1 among different strains of poultry. Expression of the GLP-1 receptor mRNA in chicken pancreas is consistent with a possible incretin role for GLP-1 in birds (though not yet demonstrated in chicken, see earlier).

34.4.2.3 GLP-2

In mammals, GLP-2 plays a role in intestinal growth and nutrient absorption by maintaining the integrity of mucosal epithelial cells. Secreted by enteroendocrine L-cells in response to the presence of nutrients, GLP-2 promotes crypt cell proliferation and suppresses apoptosis in mucosal epithelial cells. Elevated expression of GLP-2 receptor mRNA in chicken duodenum is consistent with the proposed role for GLP-2 in intestinal growth and function. GLP-2 is co-stored with GLP-1 within the same secretory granule of L cells in the chicken ileum (Nishimura et al., 2013). Nevertheless, the distribution and frequency of occurrence of GLP-2-immunoreactive cells differs from those of GLP-1-immunoreactive cells in the chicken small intestine. GLP-2 immunoreactive cells are mainly located in crypts, and their frequency of occurrence is lower than that of GLP-1-immuno-reactive cells (Monir et al., 2014c). Chicken GLP-2R mRNA is widely expressed in adult chicken tissues, including pancreas and various parts of the gastrointestinal tract where it could play a role in embryonic intestine development (Mo et al., 2014). Shousha et al. reported no effect of ICV or intraperitoneal administration of GLP-2 on food intake, body temperature, or locomotor activity in Japanese quail (Shousha et al., 2007). However, these studies involved the use of rat GLP-2, which shares only 52% amino acid identity with chicken GLP-2 and may lack activity in avian species. In both broiler and layer chicks, GLP-2 functions as a potent anorexigenic peptide in the brain, as well as GLP-1 (Honda et al., 2015).

34.5 Glucagon and insulin receptors

34.5.1 Glucagon receptors

In mammals, the biological actions of glucagon are mediated by a specific glucagon receptor (GCGR; Authier and Desbuquois, 2008), a receptor belonging to G protein-coupled receptor subfamily B, which also includes the receptors for GLP-1, GLP-2, vasoactive intestinal polypeptide, growth hormone-releasing hormone, and growth hormone-releasing hormone-like peptide. Stimulation of the glucagon receptor modulates adenylate cyclase, initiates the production of cAMP, and thereby activates extracellular signal-regulated protein kinase 1/2 via cAMP-dependent protein kinase A (cAMP-PKA, Fig. 34.2). In addition, it also activates signaling pathways via cAMP-independent interactions leading to stimulation of phospholipase C and release of Ca^{2+} from IP_3-sensitive intracellular Ca^{2+} stores.

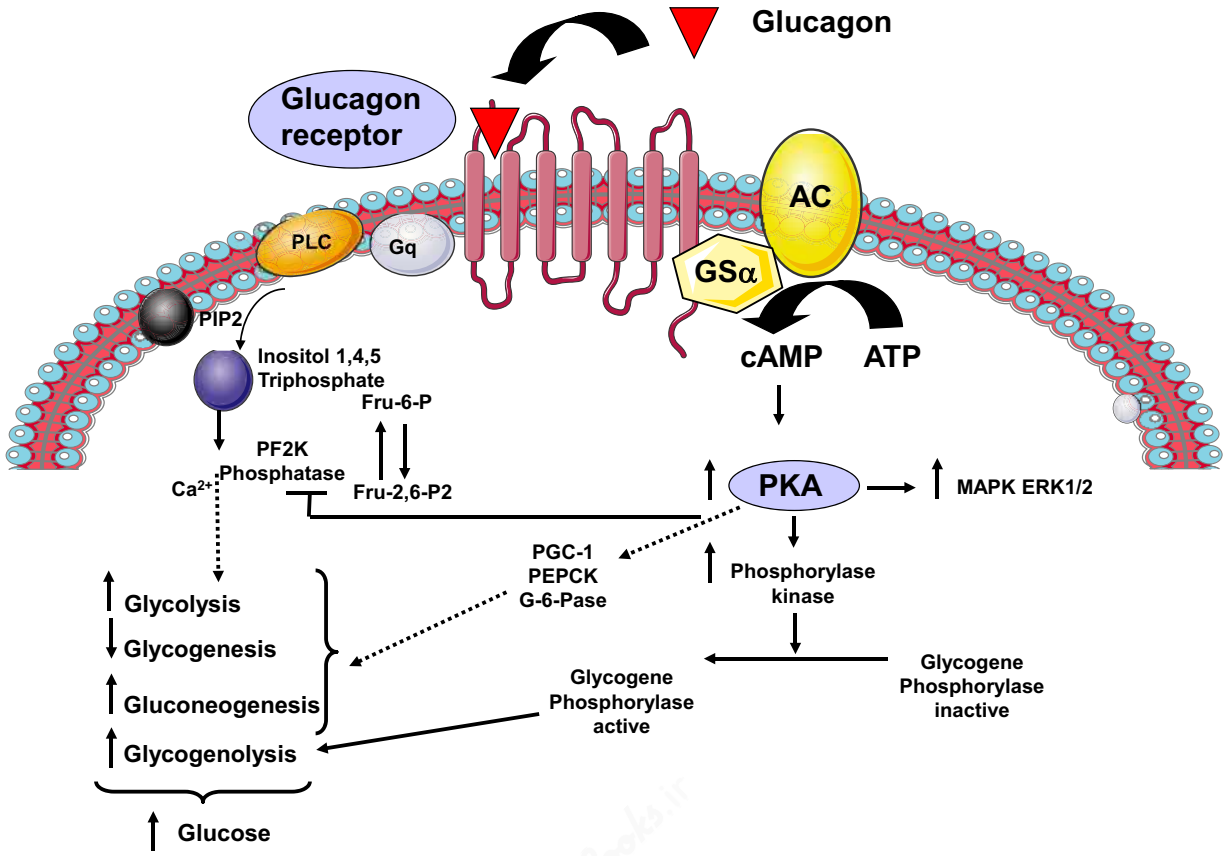

FIGURE 34.2 Glucagon receptor signaling.

The chicken glucagon receptor gene was cloned from adult brain tissue (Wang et al., 2008a, 2008b); it encodes for a short glucagon receptor of 496 AA (GCGR-s) or a long receptor variant of 554 AA, designated glucagon receptor variant 1 (GCGR-v1). The chicken GCGR-s shares high AA sequence identity with that of man (70%), rat (69%), mouse (69%), and Xenopus (64%). Functional analysis confirmed that both GCGR-s and GCGR-v1 can be activated by glucagon and are functionally coupled to the cAMP-PKA signaling pathway. The glucagon receptor is widely expressed in all tissues including the hypothalamus, with the greatest expression found in the liver, suggesting that glucagon plays a wide range of roles in both hepatic and nonhepatic chicken tissues through the two receptors, GCGR-s and GCGR-v1 (Richards and McMurtry, 2008). Recently, Wang et al. identified a novel ligand-receptor pair, named GCGL and GCGL receptor (GCGLR) from chicken brain (Wang et al., 2012) GCGL is a novel GCG-like peptide of 29 amino acids that shares high-amino acid sequence similarity with mammalian and chicken GCG (62−66%). GCGLR is a GCGL-specific receptor, which shares relatively high-amino acid sequence identity with chicken GCGR and structurally related receptors (GLP1R, GIPR, and GLP2R). GCGL mRNA expression is mainly detected in the CNS, spinal cord, and testis, whereas GCGLR is more widely expressed in chicken tissues (Wang et al., 2012).

34.5.2 Insulin receptor

Early studies on ontogeny, structure, binding affinity, binding characteristics, number, internalization, up- and down-regulation of IRs in chicken or turkey tissues have already been reviewed (Simon, 1989). Since then, changes in IR number have been described in the hypothalamus, at least at the level of IR messenger, in layer and broiler-type chicks under ad libitum conditions (Shiraishi et al., 2011a); changes in hypothalamic IR mRNA in response to photoperiodism are dependent upon gonad hormones (Anraku et al., 2007). In chicken liver plasma membranes, hepatocytes and thymocytes, insulin binding capacity (IR number) is lower than in rat or veal in (Simon, 1989), which may contribute to the low-insulin sensitivity of chickens. However, in crude liver membranes (i.e., plasma and intracellular organite membranes), the IR number is about the same in chickens and rats (Dupont et al., 2004). A high proportion of IR may therefore be internalized in chicken liver (Krup and Lane, 1981, 1982 in (Simon, 1989)).

Chicken IR shows a heterotetrameric structure (two α and two β subunits linked by disulphide bonds as described in mammals and other species [reviewed in (Simon, 1989)]. The α subunit (about 135 kDa) is entirely within the extracellular compartment and binds insulin; the β subunit (about 95 kDa) contains a large hydrophobic fragment (inserted into the membrane), crosses the cell membrane and extends into the intracellular compartment. In chickens, as in other species, the α subunit of brain or muscle receptors is smaller than that of liver receptor α subunit, in part as a result of differences in glycosylation (reviewed in Simon, 1989).

In mammals, both IR α and β chains are synthesized from a single mRNA, which is encoded by 22 exons. In mammals, exon 11 is alternatively spliced, which results in two IR isoforms (IR-A and IR-B) that differ by the absence or presence of 12 amino acids at the C-terminus of the α subunit, respectively. IR-A and IR-B isoforms display differences in ligand affinity binding, kinase activity, receptor internalization, and recycling as well as intracellular signaling capacity and tissue distribution (De Meyts, 2012). According to Hernández-Sánchez et al., the region corresponding to exon-11 is missing in chicken IR; chicken tissues would only express the "IR-A" type, i.e., the IR type showing the highest insulin affinity (Hernández-Sánchez et al., 2008). This may account for the fact that chicken IRs exhibit much higher affinity for IGFs than mammalian IR. It may also explain why chicken or duck IR do not discriminate chicken, pork, and duck insulins very well (Chevalier et al., 1996).

In its intracellular part, the IR β subunit is a tyrosine kinase activated by autophosphorylation following insulin binding to the α subunit. The chicken IR tyrosine kinase activity shows the same features as those from other species [reviewed in (Kato et al., 2000; Simon, 1989)]. Chicken liver or kidney IR tyrosine kinase activities (basal and maximal activities) are regulated, for instance, by nutritional conditions (such as fasting or refeeding), as in mammals. In contrast, muscle and adipose tissue IR kinase activity, as well as β subunit tyrosine phosphorylation, do not decrease in the fasting state or increase in refed animals, despite alterations in plasma insulin (Adamo et al., 1987; Dupont et al., 2008, 2012). Thus, for still unknown reasons, the regulation of the tyrosine phosphorylation of IR β subunit and kinase activity differs between species and tissues. As depicted in Fig. 34.3 (for chicken tissues), once

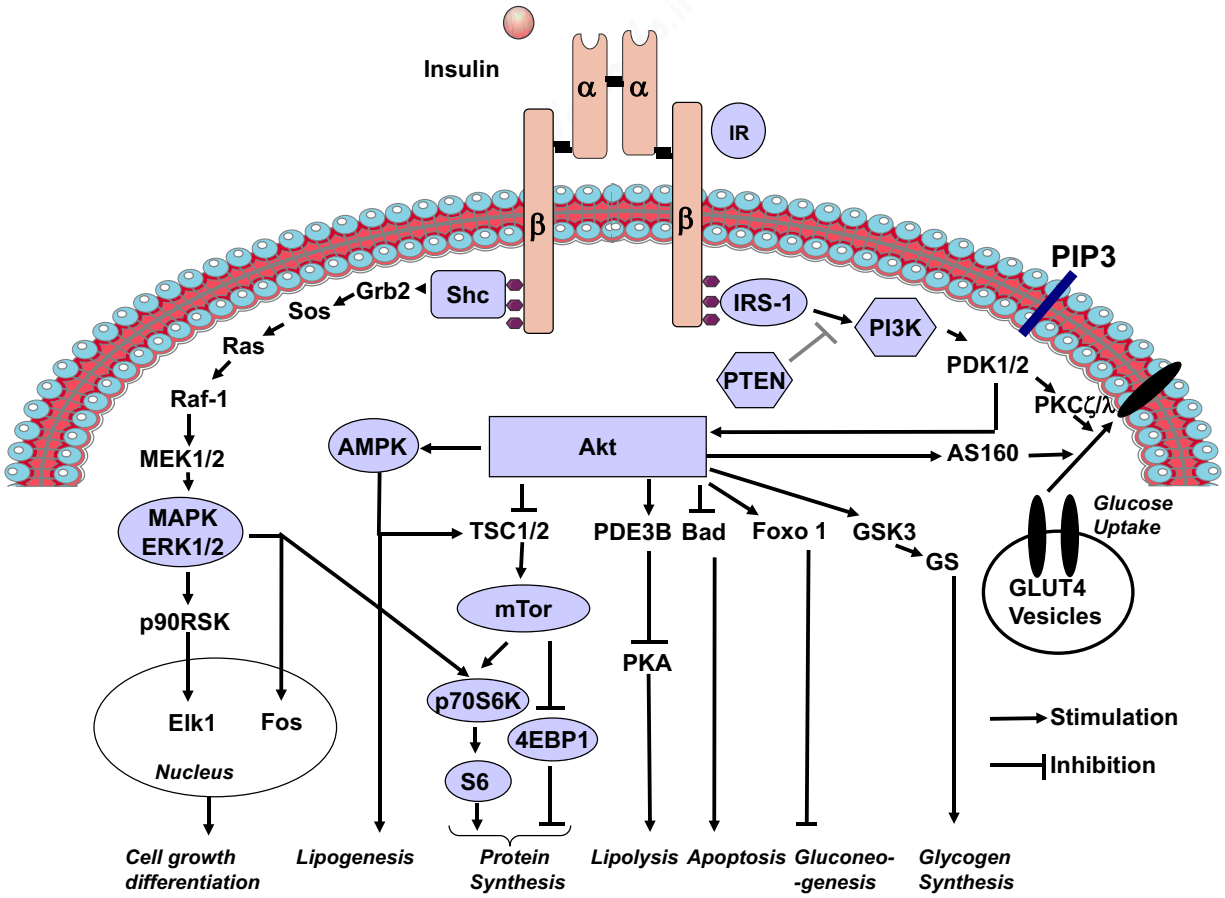

FIGURE 34.3 Insulin receptor signaling. *Adapted from mammals; only steps highlighted in blue have been characterized in chicken tissues.*

activated, the IR tyrosine kinase phosphorylates several intracellular substrates on specific tyrosine residues, which represents the proximal and early events initiating and propagating the insulin signal through a cascade of reactions leading to the multiple actions of insulin. Phosphorylated IR substrates activate directly or indirectly various protein (serine-threonine) or lipid kinases including PI3K, Akt, P70S6K, and MAPK ERK1/2. Several of these postreceptor steps also regulate insulin cell sensitivity, enabling alterations of insulin sensitivity without changes in IR number or kinase activity.

34.5.2.1 Proximal insulin receptor substrates

In mammals, at least 11 intracellular IR substrates have been identified (reviewed in Taniguchi et al., 2006; Siddle, 2012; Machado-Neto et al., 2018). These include the family of insulin receptor substrate (IRS) proteins (IRS-1−6) and Src homology collagen protein (Shc). Four different IRS proteins (IRS-1-4) have been reported in various mammals, and two additional IRS proteins have been detected in man (IRS5/DOK4 and IRS6/DOK5). These last two additional IRS proteins are involved in insulin signaling but are not involved in phosphatidylinositol 3′-kinase (PI3K) activation (the major insulin signaling step). Other IR substrates such as Gab1, Dok, APS, SH2B, Cbl, and Crk have been also described in mammalian tissues or cells (cited by Siddle, 2012).

The coding region of chicken IRS-1 gene has been cloned and sequenced (Taouis et al., 1996). The deduced chicken IRS-1 protein (cIRS-1) presents high sequence identity with its human, rat, and mouse homologs. Chicken IRS-1 is at least present in the liver, muscle, and adipose tissue and interacts with the IR [Dupont et al., 1998 in (Dupont et al., 2009, 2012), (Dupont et al., 2012)]. Interestingly or surprisingly enough, the tyrosine phosphorylation of cIRS-1 and PI3K activity (see later) is accordingly insulin-dependent upon nutritional conditions or insulin status in the liver but not in muscle or adipose tissue [Dupont et al., 1998 in (Dupont et al., 2008, 2009, 2012)], suggesting a tissue-specific regulation and a relative insulin refractoriness in chicken muscle and adipose tissue. Coding sequences have recently been described for IRS-2, IRS-4, Crk, Cbl, and APS chicken homologs (Ensemble release 71, April 2013 at http://www.ensembl.org/Gallus_gallus/index.html); they are respectively located on chromosome 1, 4, 19, 1, and 19, respectively. However, the presence of these substrates as proteins and their insulin sensitivity remains to be established in chicken tissues. Cbl and Crk, which in mammals mediate insulin signals and are associated with lipid rafts, are upregulated, at the messenger level, in chicken adipose tissue by fasting (Ji et al., 2012). In mammals, this pathway stimulates glucose uptake, in addition to and independently of PI3K activation. Whether these potential substrates contribute to the apparent refractoriness of PI3K activity to insulin that is observed in chicken skeletal muscle and adipose tissue remain unknown. It should be noticed however that insulin stimulation of glucose transport in chicken adipose tissue, if any, is very poor (see later).

In a chicken hepatoma cell line (LMH cells), cIRS-1 repression substantially increases Shc expression (Taouis et al., 1998). Shc is phosphorylated on tyrosine residues in response to insulin and therefore serves as an additional IR substrate in the absence of IRS-1. Chicken liver, muscle, and adipose tissue express homologs of the three mammalian Shc isoforms (Dupont et al., 2008, 2012). Interestingly, tyrosine phosphorylation of Shc (52 kDa) is dependent on insulin status; it increases after refeeding or insulin injection and is inhibited after insulin immunoneutralization in chicken liver but also, surprisingly, in leg muscles, in contrast to IRS-1. Also surprisingly, neither insulin privation nor fasting alter Shc tyrosine phosphorylation in adipose tissue (Dupont et al., 2009, 2012). In chicken liver, Shc, mainly the 52 kDa isoform, interacts with IR whereas the 46 kDa isoform associates with IRS-1 (Dupont et al., 1998 in (Dupont et al., 2009)). The 52 kDa Shc isoform also interacts with the p85 regulatory subunit of phosphatidylinositol 3-kinase (PI3K). Shc (52 kDa) is thus a key substrate for the IR in the chicken because, first, it is able to associate with PI3K, and second, in contrast to IRS-1, the extent of its tyrosine phosphorylation is dependent on insulin levels. Furthermore, in liver, Shc (52 kDa) phosphorylation is inhibited after insulin immuno-neutralization (Dupont et al., 2008). The possible existence of different subtypes of IR complexes signaling through IRS-1 or Shc has been investigated in the liver. The presence of a large complex involving IR, IRS-1, Shc (mainly the 52 kDa isoform), and the regulatory subunits of PI3K has been demonstrated; a third complex including IRS-1 and the 46 kDa Shc isoform is also present in chicken liver (Dupont et al., 1998 in (Dupont et al., 2009)). No such interactions have been described in mammalian tissues, and the functions of these complexes in chicken liver and their presence in other chicken tissues remain to be established.

34.5.2.2 PI3K/Akt

PI3K has been characterized in chicken liver, leg muscle, and adipose tissue [Dupont et al., 1998 in (Dupont et al., 2009, 2012)] and in LMH cells (Taouis et al., 1998 in (Dupont et al., 2009)). Liver PI3K activity depends upon the nutritional state (prolonged fasting vs. refeeding) in several experimental models (Dupont et al., 1998, 1999 in (Dupont et al., 2009)). Furthermore, PI3K activity

increases in response to insulin injection and is inhibited following insulin immunoneutralization (Dupont et al., 1998 in (Dupont et al., 2008, 2009)). This is in agreement with the changes observed for early steps of the insulin signaling cascade (tyrosine phosphorylation of IR β subunit, IRS-1, and Shc). Conversely, in muscle, the PI3K activity and, as previously mentioned, tyrosine phosphorylation of IR and IRS-1, are totally unresponsive to insulin levels in experimental models that alter insulin sensitivity, such as long-term corticosterone treatment and genetically selected fat and lean lines of chickens [Dupont et al., 1999 in (Dupont et al., 2009)]. As mentioned earlier, only the phosphorylation of the 52 kDa Shc isoform is reduced in muscle by fasting and increased by refeeding. Comparison of the responses to exogenous insulin in chickens and rats suggests that this phenomenon is specific to chicken. Furthermore, PI3K activity in leg muscle is about 30 times greater in the chicken than in the rat (Dupont et al., 2004). This "constitutive" hyperactivity of PI3K in chicken muscle may overstimulate the feedback inhibitory pathway described in mammals (see earlier), thereby desensitizing chicken muscle to insulin. The p85 regulatory subunit of PI3K itself exerts strong inhibitory control of IRS signaling in mammals (Taniguchi et al., 2006). However, lipid phosphatases such as phosphatase and TENsin homolog deleted on chromosome 10 (PTEN) may also contribute to this relative insulin insensitivity of the early steps of insulin signaling in chicken muscle. We have detected PTEN in chicken tissues, including muscle (Vaudin et al., 2006); however, the role of PTEN in the control of insulin signaling in chicken tissues remains to be determined. In adipose tissue, insulin signaling is even more peculiar; insulin privation did not alter early steps and PI3K activity, but also other downstream elements such Akt [see next paragraph (Dupont et al., 2012)].

Akt has been detected in several chicken tissues including liver, muscle (Bigot et al., 2003; Dupont et al., 2008), adipose tissue, and granulosa cells (Dupont et al., 2012; Tosca et al., 2006). The phosphorylation of Akt on Ser 473 is increased following feeding of posthatched chicks (Bigot et al., 2003); this is prevented when feeding is delayed (48 h) then rapidly restored following food intake. In fed chickens, insulin immuno-neutralization significantly decreases Akt phosphorylation in both liver and muscle, but not in adipose tissue (Dupont et al., 2008, 2012). Thus, insulin is presumably involved in Akt activation in chicken muscle, despite the fact that chickens exhibit particular features in the early steps of the insulin signaling cascade (IR, IRS-1, and PI3K). This issue remains unresolved. Potential mechanisms involved in the atypical feature found for insulin signaling in chicken muscle and adipose tissue have been discussed in (Dupont et al., 2008, 2012).

34.5.2.3 P70S6K

p70S6 kinase, a further downstream step, has been characterized in a quail muscle (QM7) cell line and in chicken skeletal muscle (Tesseraud et al., 2003, and Duchêne et al., 2008 in (Dupont et al., 2009)). p70S6K activity increases significantly in both pectoralis and gastrocnemius muscles after refeeding for 30 min following 16 h starvation, and also in fasting chickens after a single insulin injection (Bigot et al., 2003). Similarly, p70S6K activity in the muscle of neonatal chicks is correlated with the plasma insulin concentration, strongly suggesting an insulin-dependent p70S6K activation (Bigot et al., 2003). In the liver, stimulation of phosphorylation of P70S6K1 and activation of S6K (using specific artificial substrate) was not detectable (Dupont et al., 2008), though insulin stimulation of phosphorylation of S6 ribosomal protein was observed in the same conditions (Duchene et al., 2008b). Furthermore, p70S6K phosphorylation decreases in leg muscles but not in adipose tissue in response to insulin immuno-neutralization (Dupont et al., 2008, 2012). These findings and those for Akt are again surprising in view of the relative insulin refractoriness of chicken muscle to exogenous insulin (Dupont et al., 2004). However, p70S6K has been found to be involved in another feedback loop, which attenuates the ability of insulin to activate PI3K. Indeed, there is evidence in mammals that p70S6K inhibits insulin signaling by increasing the serine/threonine phosphorylation of IRS-1. In chicken muscle, refeeding and insulin injection increases the phosphorylation of both p70S6K on key residues (T389, T229, and T421/S424) and its downstream target, the ribosomal protein S6 (downstream insulin signaling steps). However, in these conditions, the phosphorylation of IRS1 on Serine 632 and Serine 635 residues is also induced (Duchene et al., 2008b). In mammals, the phosphorylation of these sites inhibits the insulin signal. Thus, the AKT/p70S6K may inhibit IRS1 tyrosine phosphorylation in chicken muscle.

34.5.2.4 mTor

The mammalian target of rapamycin (**mTor**) is an evolutionarily conservative Ser/Thr protein kinase that can perceive signals such as nutritional status, and growth factors to regulate cell growth, proliferation, apoptosis, and other physiological processes (Avruch et al., 2006). It is rapamycin-sensitive, stimulated by insulin, growth factors, energy signals, and amino acids. In mammals, amino acids, especially branched-chain amino acids (including leucine, isoleucine, and valine) or leucine alone, were reported to be important regulators of body protein turnover and translation initiation. Leucine alone can stimulate protein synthesis to the same extent as a complete amino acid

mixture by activating factors of mRNA translation initiation, primarily through mTor signaling pathway, including ribosomal protein S6 kinase (**S6K1**) and eukaryotic initiation factor 4E binding protein 1 (**4E-BP1**) in a dose-dependent fashion. In avian species, mTor signaling pathways have been described in chicks (Wang et al., 2012). In neonatal chicks, high-dietary leucine activates target of rapamycin signaling pathways in skeletal muscle, and this pathway is attenuated with aging (Deng et al., 2014). In broilers, the mTor pathway is involved in retarding muscle development and protein synthesis by glucocorticoids (Wang et al., 2015). In chicken adipocyte, mTor is also involved in the negative effect of adiponectin on the lipids deposition (Jun et al., 2014) suggesting that this pathway is an important energy sensor in avian species as in mammals.

34.5.2.5 MAPK ERK1/2 pathway

MAPK ERK has been identified in various chicken tissues (Duchene et al., 2008a). In contrast to mammals, ERK1 is not present in bird tissues; ERK2 is the only phosphorylated isoform detected (Duchene et al., 2008a). It is activated in chicken myoblasts and LMH cells in vitro by insulin (Duchene et al., 2008a). U0126, an inhibitor of the MAPK ERK pathway, completely abolishes insulin-induced S6K1 phosphorylation and activity in chicken myoblasts in vitro, implicating MAPK ERK2 in the control of S6K1 by insulin in avian cells (Duchene et al., 2008a). MAPK ERK2 phosphorylation in chicken liver muscle and adipose tissue in vivo is strongly reduced by insulin immuno-neutralization (Dupont et al., 2008, 2012). However, the role of MAPK ERK2 in insulin action in vivo in chicken has not been investigated. This signaling could be crucial to chicken growth, and this pathway may participate in the insulin-dependent regulation of p70S6K, because Shc, which is upstream, seems to be a key IR substrate in chicken muscle.

From the elements of insulin signaling thus far studied in chickens, insulin signaling appears to work in chicken liver as expected from the knowledge gained from mammals. In contrast, in muscle and adipose tissue, insulin cascade appears refractory, suggesting the presence of inhibitory counter-regulatory mechanisms in these tissues.

34.6 General effects of glucagon and insulin

34.6.1 Insulin and embryonic or posthatch development

The insulin gene is expressed early during embryonic development in extra-pancreatic tissues prior to development of the pancreas, showing specific regulations in (de la Rosa and de Pablo, 2011). Insulin accelerates growth of embryos explanted at Hamburger Hamilton stage 4, without increasing mitoses; some specific developmental genes are upregulated (Patwardhan et al., 2004). A fine tuning of insulin gene expression is required to sustain adequate morphogenesis. In chicken neurulating embryos and chicken embryo retina, proinsulin is expressed but not cleaved to insulin. Whereas this precursor is considered to exert marginal biological activity in peripheral tissues, if any, it exerts antiapoptotic effects in those tissues at this developmental stage, probably through a hybrid insulin-IGF receptor in (de la Rosa and de Pablo, 2011). Furthermore two transcription-induced chimerisms have been identified with the adjacent tyrosine hydroxylase gene [*TH*-insulin (de la Rosa and de Pablo, 2011)]. (In man, a similar mechanism has been described between the insulin gene and *IGF2*, the adjacent gene). The insulin gene is also expressed in the neural tube and somites of chicken embryos. Addition of insulin (or IGFs) to other specific factors in the incubation medium cocktail stimulates somite cell proliferation and myogenesis (Pirskanen et al., 2000). This effect is blocked by an insulin antibody and IR antibody, showing that insulin acts as a myogenic signal early in embryogenesis. Insulin also supports in vitro multiplication of one-day-old broiler muscle satellite cells and delays their differentiation (Sato et al., 2012). Surprisingly, an opposite effect is observed between insulin and IGF1 for MyoD and myogenin messengers. Insulin or tolbutamide administration to day-old broiler chicken increases Pax7 messenger (a striated cell marker) in breast muscle at 3 days of age and their body weight at 50 days, without changing their body composition (Sato et al., 2012). These interesting effects deserve further characterization. In satellite cell-derived myotubes, insulin, (at high doses though, compared with IGF1) stimulates glucose (see earlier) and amino acid transport and protein synthesis and inhibits proteolysis (Duclos et al., 1993a, 1993b).

34.6.2 Insulin-glucagon and food intake

Pioneer studies suggested that insulin contributes to the regulation of food intake [through inhibitory or stimulatory mechanisms in (Simon, 1989)]. Intracerebroventricular injection of insulin (through the melanocortin system) or glucagon inhibits food intake in young Leghorn chickens [(Honda et al., 2007; Shiraishi et al., 2011b) and quoted references]. Surprisingly insulin is inefficient in young broiler chickens in fasted or fed conditions [(Shiraishi et al., 2011b) and quoted references], suggesting a difference in their set-point or sensitivity; in broiler chickens, plasma insulin levels are higher, which appear to decrease hypothalamic IR mRNA expression (Shiraishi et al., 2011b). Insulin immuno-neutralization in fed growing chickens decreased food intake, most likely by inducing very high-plasma glucose levels (Dupont et al., 2008).

34.6.3 Insulin and the endocrine system

Insulin interacts with glucagon (see introduction) and with other endocrine systems. As early as 1hr after insulin immuno-neutralization (Dupont et al., 2008), plasma T_3 levels decreased. (No reliable measurements were obtained for T_4). After 5 h of insulin deprivation, liver D2-and D3-deiodinase messengers decreased or increased, respectively. Thus, insulin is another partner involved in bird liver T_4 metabolism [Darras et al., 2006, in (Dupont et al., 2008)]. The IGF system also appears partly insulin-dependent. Liver *IGFBP-1* messenger (microarray and qRTPCR measurements) and plasma IGFBP-1 protein levels increased after insulin immuno-neutralization. (Plasma IGF-1 was not measured). Microarrays also revealed that liver *IGFBP-2* and muscle *IGF1R* messengers increased or decreased, respectively. [Similar impairments are found in diabetic patients, Palsgaard et al., 2009, in (Simon et al., 2012)]. In another study (Nagao et al., 2001), 2d fasting decreased plasma IGF1 and increased *IGFBP-2* messenger in liver and gizzard of WL chickens (but not in brain or kidney); exogenous insulin further decreased plasma IGF1 levels and largely inhibited liver and gizzard *IGFBP-2* messenger (6h refeeding also inhibited liver and gizzard *IGFBP-2* messenger but accordingly increased plasma IGF1 levels).

34.6.4 Insulin and glucose metabolism

The severe and rapid hyperglycemia induced by insulin deprivation in fed chickens certainly depends upon multiple changes in glucose metabolism in several tissues. In liver, where glucose transport is not insulin-dependent, glucose utilization was probably greatly depressed as suggested by the drop in liver GK messenger and protein contents (see earlier discussion about the existence and the regulation of liver GK activity). In mammals, other insulin-dependent mechanisms are inhibition of liver gluconeogenesis and glucose production. Gluconeogenesis is considered to escape insulin control in chicken liver (introduction). In our transcriptome study, 27 messengers from the glycolysis/gluconeogenesis or pyruvate metabolism pathways were differentially expressed in liver following insulin deprivation, including *G6PC2* (glucose-6-phosphatase catalytic,2 messenger which increased), suggesting that liver glucose production may also be insulin-inhibitable in chicken liver. Unfortunately this was not assessed in euglycemic-hyperinsulinemic clamp experiments performed on chickens (Chou and Scanes, 1988; Hamano, 2006). Indirect evidence (prolonged fasting and corticosterone experiments) suggests that insulin also inhibits kidney gluconeogenesis by inhibiting cytosolic phosphoenolpyruvate carboxykinase activity (Bisbis et al., 1994a, 1994b and quoted references).

Insulin greatly stimulates glucose uptake in muscles and adipose tissues of mammals by recruiting insulin-sensitive Glut-4 transporters at the cell surface from an intracellular pool (Fig. 34.3). So far, no Glut-4 glucose transporter has been identified in chickens or house sparrows (*Passer domesticus*) as protein or messenger. This may be the consequence of the lack of cross-reactivity of antibodies or the absence of Glut4 in chicken or birds since no Glut-4 homolog sequence is found in the chicken Ensembl database; [an ortholog gene to human Glut-4 (*SLC2A4*) gene is however described in the Anole lizard and several fish species]. Functional and immunoreactive-Glut4 transporters have been observed in duck leg muscle [Thomas-Delloye et al., 1999, in (Dupont et al., 2009)]. Only chicken Glut-1, -2, -3, -8 have been characterized as messengers and/or proteins (Carver et al., 2001; Seki et al., 2003; Kono et al., 2005; Sweazea and Braun, 2006 in Zhao et al., 2012; Humphrey et al., 2004). It has been hypothesized that Glut-8 (encoded by *SLC2A8* gene) may act in chickens as Glut-4 does in mammals (Kono et al., 2005 in Zhao et al., 2012). In vivo, exogenous insulin increases glucose uptake moderately in some muscles but not in adipose tissue (Tokushima et al., 2005). (Surprisingly, insulin stimulated or inhibited ^{3}H-2DG uptake in liver and brain, respectively). Thus, an insulin-sensitive glucose transport is present in chicken; it however requires extensive characterization.

Currently, an increasing number of studies report QTLs as controlling growth and/or body composition and some physiological parameters in various avian species. In several cases, these QTL regions harbor glucose- and/or insulin-dependent genes. This aspect cannot be reviewed here; some references can be found in (Nadaf et al., 2009).

34.6.5 Insulin-glucagon and lipid metabolism

Several transcription factors controlling mRNA expression of lipogenic enzymes also appear insulin-sensitive in chicken liver in vivo [SREBP1, PPAR-gamma, and THRSP alpha (spot-14) and FASN messengers (Dupont et al., 2008)]. Carbohydrate-responsive element-binding protein (ChREBP, encoded by the *MLXIPL* gene) is another transcriptional factor involved in glucose metabolism, glucotoxicity and/or lipogenesis in liver, adipose tissue, and pancreas in mammals (Leclerc et al., 2012). ChREBP is also activated in parallel with lipogenesis in chicken liver (Proszkowiec-Weglarz et al., 2009). In our insulin neutralization experiment, several other enzyme messengers involved in lipogenesis or fatty acid oxidation decreased or increased, respectively, following insulin deprivation (Simon et al., 2012), extending the role of insulin in chicken liver lipid metabolism. In abdominal fat tissue, 5 h of fasting altered the level of 2016 messengers. Plasma glucagon increase certainly accounts for a major part of these changes (Ji et al., 2012). Insulin neutralization in fed chickens altered the expression of only 92 genes, 72

of which were also differentially expressed by 5 h of fasting. All genes that were affected by both treatments changed in the same direction (up- or downregulated in both groups). Most messengers that were specifically altered by insulin-neutralization (but not by fasting) were either poorly or not described; however, glucagon precursor (class B-preproglucagon) and glucagon receptor precursor were in this category and were up- and downregulated, respectively. A local insulin-dependent paracrine glucagon regulation, which needs full characterization, is suggested in chicken adipose tissue. In general, a contribution of insulin to adipose tissue development and metabolism (in addition to its control of liver lipogenesis) can be expected, despite the very atypical feature exhibited by chicken adipocytes.

Differentiation of chicken adipocyte precursors (obtained from the stromal vascular fraction of fat tissue) or trans-differentiation of fibroblasts, epithelial oviduct or primordial germ cells into adipocytes have been successfully performed using media rather similar to those used for mammalian adipocyte differentiation (Khuong and Jeong, 2011; Li et al., 2010; Liu et al., 2010; Ramsay and Rosebrough, 2003). Insulin is required but unable to support differentiation alone; IGF-1 or T3 are unable to replace insulin (Ramsay and Rosebrough, 2003). Chicken serum and dexamethasone can be deleted, provided oleic acid is introduced into the differentiation medium. Unless oleic acid exerts a specific effect, this supports the conclusion that to overcome their intrinsically low-lipogenic activity and achieve a full adipocyte phenotype, chicken adipocyte precursors need exogenous fatty acids (Liu et al., 2009; Matsubara et al., 2005, 2008). Several transcription factors are involved in adipogenesis: C/EBPalpha, PPARgamma, and SREBP1 in chicken (Liu et al., 2009, 2010; Sato et al., 2009; Wang et al., 2008a, 2008b) and duck (Xiong et al., 2010).

In adipocytes of mammals, lipolysis is under the control of several lipases, including the adipose triglyceride lipase, encoded by the *PNPLA2* gene and the hormone-sensitive lipase (HSL), encoded by the *LIPE* gene (Zechner et al., 2009). HSL (*LIPE*) disruption in normal or *ob/ob* mice leads to several changes in the endocrine pancreas and adipocytes which resemble the chicken feature (Osuga et al., 2000; Wang et al., 2001; Haemmerle et al., 2002, quoted in Zechner et al., 2009; Mulder et al., 2003; Harada et al., 2003). Though not identified in chicken, the *LIPE* gene is present in the Anole lizard and several fish. If the *LIPE* gene is really missing in chicken, some of the chicken physiological peculiarities may be due to this.

34.6.6 Insulin and protein metabolism

In addition to its general effects on protein metabolism (introduction and Tesseraud et al., 2007a), insulin acts in the ubiquitin-proteasome proteolytic pathway. It inhibits the expression of atrogin-1 messenger in quail muscle (QT6) fibroblasts (Tesseraud et al., 2007b) and in vivo in chicken muscle (Dupont et al., 2008). Following insulin immuno-neutralization, several messengers coding for enzymes of the oxidative pathway decreased. This pathway is also altered in muscle of human diabetics in (Simon et al., 2012).

34.6.7 Insulin and gene expression

In mammals, insulin stimulates the translation of pre-existing mRNA and coordinates (stimulates or inhibits) the expression of multiple genes in various tissues. Multiple insulin responsive elements (IREs) have been identified on target genes (other IREs are likely to be identified, Mounier and Posner, 2006). To our knowledge, the characterization and the functionality of IREs, as such, are still missing in chickens. The fact that several transcription factors or enzymes involved in lipid metabolism are also insulin sensitive in chickens (see earlier) suggests that major IREs have been conserved or have co-evolved in chickens. A total of 1573 and 1225 signals were altered by insulin deprivation in liver and muscle, respectively, including several transcription factors. Several messengers have been associated with energy expenditure, insulin resistance, metabolism sensing, obesity, and/or diabetes in mammals (Simon et al., 2012). The chicken elongation factor-2 (EF-2) gene, a major factor in protein synthesis in mammals, is also under the control of insulin and 8-bromo-cAMP or phorbol ester (Lim and Kim, 2007). Insulin deprivation in fed chickens (but not fasting) decreased *EGR1* (early growth response 1) messenger in liver and muscle but not in adipose tissue. However *TOE1* (target of egr 1, member 1) was also specifically decreased by insulin deprivation and not by fasting in adipose tissue (Ji et al., 2012). *EGR1* target genes are largely unknown, particularly in the field of metabolism.

Finally, microRNAs (miRs) represent another mechanism in the regulation of gene translation. At least miR-196 and −200b showed significant and opposite changes in response to insulin-neutralization (an increase in liver vs. a decrease in muscle, Bouhallier, Rouault and Simon, unpublished data). Gene targets of miR-196 and −200b need to be identified; so far miR-196 has been involved in chicken embryo development (McGlinn et al., 2009) and miR−200b in chicken liver lipid metabolism (Hu et al., 2012).

34.7 Experimental or genetical models

Table 34.1 summarizes results about fasting plasma glucose-insulin relationships, glucose tolerance, insulin sensitivity, and fattening in various experimental or genetical chicken models. Most of these results have been discussed in previous publications. (The effect of prolonged fasting has also been investigated, see above). The table is shown to support some general considerations. It should be

noted that in all these experiments, the feeding pattern of chickens has been consistently synchronized with light-dark cycles. In these conditions, as in mammals, fasting plasma glucose level appears as an indicator or a central node, which reflects or integrates general metabolism. Though the primary mechanism is unknown, changes in glucose-insulin balance and/or insulin sensitivity are associated with changes in fattening. In contrast to obese mammals, fat chickens have low-plasma glucose and do not develop insulin resistance. Conversely, chickens from a low-glucose line are fatter than their counterparts. Only the corticosterone model behaves like obese mammals (showing higher plasma glucose and impaired insulin sensitivity). As discussed earlier, changes in insulin signaling are present in the models thus far investigated. Changes in glucose tolerance are not consistently associated with changes in body composition: in a commercial broiler cross, chickens exhibiting fast or slow plasma glucose regulation at 2 and 4 weeks of age following an oral glucose load did exhibit fast or slow glucose disposal at 8 weeks of age but did not differ in fasting or glucose-induced plasma insulin levels and body composition, which remains unexplained (Simon, 1980). One can hypothesize that, as in FL chickens, enhanced glucose-induced insulin levels are required to increase fattening without necessarily leading to insulin resistance. In vitro, perfused pancreas from fat chickens released less insulin during the first phase in response to glucose or arginine or acetylcholine in the presence of glucose than pancreas from lean chickens, which remains unexplained in (Rideau, 1988). In general, chickens appear to be controlled within a much narrower range for their body composition than mammals. Whether the endocrine pancreas of birds plays a part in this remains an open question and a challenge for the future.

34.8 Conclusion

Many results highlighted in this review point out further chicken peculiarities at the level of endocrine pancreatic physiology. Chickens (and birds in general) developed several species specificities during evolution. The most original ones concern: refractoriness's of glucose-induced insulin release and insulin signaling in muscle and adipose tissue. One unidentified inefficient metabolic step makes glucose a poor insulinotropic nutrient in chickens. Though several elements of insulin signaling pathways haven't been investigated yet, several steps of the IR cascade appear insensitive in muscle; the feature is even worse in adipose tissue. In contrast, IR signaling appears "normal" in chicken liver. Unrevealing mechanisms or steps accounting for these chicken peculiarities may provide important information, including for human diabetes pathology. Glucagon physiology appears more complex in chicken than in mammals: glucagon gene encodes several transcripts; it is expressed in adipose tissue; two types of glucagon receptors are present; an insulin-dependent paracrine glucagon regulation is suggested in adipose tissue. In the fed status, insulin is coordinating the endocrine balance to permit the development or the maintenance of an active anabolism. On a practical point of view, finding the way to favor pleiotropic anabolic actions of insulin in muscle and minimize liver lipogenic and adipogenic actions of insulin would be highly profitable for human and animal nutrition. This review also pointed out many lacks or new area to explore. In short, the secretory "machinery" of A- and B-islets needs to be fully characterized. Chicken is the unique model to provide such possibility in addition, very little information is known about the physiological actions of GLP-2, oxyntomodulin, miniglucagon, glicentin, or gastrin-releasing pancreatic peptide in chicken. Full characterization of IR signaling and subsequent steps up to the control of gene expression certainly also offer large area for research in future. Finally, chicken glucose transporters (presence and functionality) need to be characterized. Though, chicken has the inconvenient to require the development of technical tools for each area to explore, it remains an almost unexplored experimental animal model of large interest for comparative endocrinology and physiology.

Chapter 35

Reproduction in the female

Anna Hrabia

Department of Animal Physiology and Endocrinology, University of Agriculture in Krakow, Krakow, Poland

35.1 Introduction

The avian reproductive system is unique and differs from that of mammals. In majority of birds, only the left ovary and oviduct develop into the functional organs. The right primordial ovary and oviduct regress except in birds of prey. Herein the majority of information is based on studies derived from domesticated birds primarily chickens. The ovary and oviduct are dynamic organs undergoing diverse molecular, cellular, morphological, and functional changes over the course of the female reproductive cycle (development, laying, regression, and rejuvenation). Follicle development and ovulation depends on the coordinated action of hypothalamic, pituitary, and ovarian hormones and other factors. The oocyte released upon ovulation is engulfed by the oviduct where components of the laid egg are synthesized and secreted, including the egg albumen, eggshell membranes, and eggshell. In addition to the egg formation and transportation, the oviduct is the site of sperm storage and transport, fertilization, and early embryonic development. The oviduct development and function are orchestrated primarily by sex steroids. This chapter describes the current knowledge on development, morphology, and function of the female reproductive system. The cellular and molecular mechanisms underlying the regulation of follicle growth, selection, differentiation, ovulation, and regression as well as the molecular basis of egg formation are emphasized. In addition, the recent advances in molecular biology related to reproductive system development and function are included.

35.2 The ovary

In birds, gonads of ZW heterozygotes develop as asymmetric ovaries, whereas ZZ homozygotes develop as symmetric testes in processes regulated by genetic and hormonal pathways. In most female birds, only the left ovary and left Müllerian duct develop. The Müllerian duct later develops into the oviduct due to stimulatory action of estrogen and absence of anti-Müllerian factor. Those in the right side regress during embryonic life (reviewed in Shimada, 2002; Guioli et al., 2014; Kuroiwa, 2017; Hirst et al., 2018).

35.2.1 Embryonic and posthatch development of the ovary

The ovaries arise from the intermediate mesoderm, and are first evidenced at embryonic day 3−3.5, as a thickened coelomic epithelium ventral to the mesonephros. At the same time, the future ovaries are colonized by primordial germ cells (PGCs). In chickens, most of the PGCs originated from the central disc of the area pellucida (Ginsburg and Eyal-Giladi, 1987), occur in the dense accumulation in the germinal crescent at around 18−19 h of incubation, and then enter the vascular system at about 33 h of embryonic development. Thereafter, PGCs eventually migrate toward the future genital ridges. Until 72 h of incubation, most of PGCs accumulate at the genital ridges, preferentially colonize the left one, where, in female, differentiate into ova in response to different factors from surrounding somatic cells. By day five−six of incubation, PGCs are identified in higher number in the left then in the right ovary. Migration of PGCs to the genital ridge is mediated by chemokine, stromal cell-derived factor 1 and its receptor type 4 (SDF-1/CXCR4) signaling (Stebler et al., 2004) as well as stem-cell factor 1 and its receptor (Srihawong et al., 2015). As the left ovary proceeds development, the PGCs settle predominantly in the ovarian cortex and proliferate significantly, increasing in number about 25-fold between days 9 and 17 of incubation (Hughes, 1963). In the medulla of the left ovary and the right ovary, the PGCs undergo apoptosis until hatching or arrest in meiosis and do not undergo apoptosis until after hatching (Ukeshima, 1996; de Melo Bernardo et al., 2015). Meiosis is initiated by day 15.5 of incubation under influence of luteinizing hormone (LH) and retinoic acid (Smith et al., 2008a; reviewed in Tagami et al., 2017). As established in in vitro culture, PGC

Sturkie's Avian Physiology. https://doi.org/10.1016/B978-0-12-819770-7.00002-5

proliferation is regulated primarily by fibroblast growth factor 2 activating the signaling of mitogen-activated protein kinase (MAPK)/extracellular signal-regulated kinase (ERK) (Miyahara et al., 2016). Bone morphogenetic protein 4 (BMP4)- and activin-activated SMAD signaling (Whyte et al., 2015), insulin- and stem-cell factor 2-activated phosphoinositide 3 kinase/kinase Akt (protein kinase B) signaling as well as Wnt signaling via the stabilization of β-catenin and activation of its downstream genes are also proposed to be involved in enhancement of PGC proliferation (Lee et al., 2016; reviewed in Tagami et al., 2017). Recent results suggest that glycogen synthase kinase 3 is involved in cell renewal and apoptosis in chicken PGCs (Chen et al., 2020). In addition, growing evidence indicates that numerous microRNAs (miRNAs) regulate PGC biology. For example, gga-miR-181-5p, gga-miR-2127, and members of the gga-miR-302/367 cluster have a pivotal role in the regulation of avian PGC proliferation (Lázár et al., 2018).

Up to day 4.5 of incubation, the gonads are bipotential (able to differentiate into testes or ovaries) and morphologically indistinguishable until day 8−10 of incubation when are differentiated enough to be recognized upon necropsy. At this time anatomical asymmetry between the left and right ovary becomes evident due to gradual regression of the right ovary realized via apoptosis process. In contrary, the left ovary develops rapidly into a gonad with thickened an outer cortex overlying an inner medulla. The cortex differentiates into the tissue where the follicles develop, while the medulla differentiates into connective tissue, containing nerve and blood vessel systems. From day nine of embryonic development, the PGCs in the ovarian cortex begin to undergo folliculogenesis through synchronous rounds of mitosis and meiosis to form germ cell nests. Then, the germ cells are surrounded by the granulosa and thecal cells derived from somatic cells of the cortex or medulla, located just beneath the cortex. Development of the functional left ovary is completed after hatching with the formation of primordial follicles containing oocytes that are arrested in the diplotene phase of prophase I. The medullary cords, underlying the cortex of the ovary, become vacuolated and form structures called lacunae (reviewed in Cutting et al., 2012; Hirst et al., 2018).

Initial stages of gonadal differentiation is orchestrated by several genes (Guioli et al., 2014; Hirst et al., 2018). One of the earliest expressed gene is GATA4. Its expression occurs in the chicken bipotential gonad in both sexes prior gonadal differentiation at embryonic day four (Oreal et al., 2002). Steroidogenic factor-1 transcription also precedes gonadal differentiation in genetic male and female chickens and is detected at day 5.5 of incubation, then its expression increases in developing ovary (Smith et al., 1999). Differentiation of the bipotential gonad into the ovary occurs in chickens between days 6.5 and 8.5 of embryonic development and is characterized by the thickening of the outer cortex of the gonad. The proliferation and differentiation of both somatic cells and PGCs only in the cortex of the left ovary is controlled by transcription factor, paired-like homeodomain transcription factor 2, which in turn, regulates expression of the estrogen receptor α (ERα). This type of ER is predominantly involved in differentiation of the ovary and Müllerian duct/oviduct in birds (review in Guioli et al., 2014 and in Hirst et al., 2018; Mattsson and Brunström, 2017).

Although there are no ovary-determining genes linked to W sex chromosome identified, several autosomal genes were proposed to be implicated in the female sex differentiation in birds. Among them, forkhead box L2 (FOXL2) is an essential transcription factor involved in ovary development. Gene expression of FOXL2 and aromatase (CYP19A1), other critical player required for the ovary development, highly correlates in the developing gonad between days 4.7 and 12.7 of incubation (Govoroun et al., 2004). The aromatase protein (estrogen-synthesizing enzyme) is present in the medulla of female gonads from incubation day 6.5, and its expression increases during ovarian development. The proteins encoded both genes are co-expressed in the nuclei of medullar cord cells and the onset of FOXL2 expression slightly precedes aromatase expression. It is therefore thought that aromatase gene expression is under FOXL2 control (Hudson et al., 2005; reviewed in Hirst et al., 2018). R-spondin 1 (RSPO1) and wingless-type MMTV integration site family member 4 (WNT4) activation of β-catenin signaling also plays an important regulatory role in the ovary development. RSPO1 mRNA is expressed in the left and right gonads of ZW chicken embryos from day 4.5 of incubation, and increases greatly from embryonic day 8.5 onward (Smith et al., 2008b; Chue and Smith, 2011). WNT4 expression is observed in the bipotential gonads of male and female embryos at day 4.5 of incubation, and it is elevated in the left gonad of female embryo during sexual differentiation. RSPO1 and WNT4 are strongly expressed in the cortex of the developing ovary along with β-catenin (Ayers et al., 2013). Additional female-enriched candidate genes, Calpain-5 and G-protein coupled receptor 56 were recently identified in early chicken gonads, however, their precise roles in the ovary differentiation in not known yet (Ayers et al., 2015). Other studies have identified miRNAs with sexually dimorphic expression patterns in chicken embryonic gonads, implying that they are active during ovary development (review in Cutting et al., 2012; Feng et al., 2014).

35.2.2 The juvenile ovary

The age when female birds achieve sexual maturity depends on the species. For instance, quail are able to breed

within a few weeks after hatching, and domestic species within a few months. Chickens become sexually mature around 20 weeks of age. In most wild species, breeding occurs usually in the first breeding season after hatching. Larger birds may take several years to reach sexual activity (e.g., the Royal Albatross, fulmars) (Gilbert, 1979).

In period from hatching to just before the onset of egg lay, there are no key changes in the ovary. At hatching, the ovary is a small, roughly triangular in shape. During the first few weeks, the ovary grows very slowly; however, it becomes broader and more obviously triangular. Various folds develop and the cranial part is flexed laterally. The appearance of the ovary is a granular due to the numerous oocytes present. Then, a series of grooves which separate the cortical gyri develops, increase in number, and become deeper (Figure 35.1A). The medullary tissue occupies the gyri. At the time of sexual maturity, the distinction between the cortex and medulla is nearly eliminated (reviewed in Gilbert, 1979). Up to 4 week after hatching, primordial follicles in the ovary grow to the primary follicle stage (Gonzalez-Moran, 2011). During the 7 weeks preceding sexual maturity in the domestic hen, the weight of the ovary increases from about 0.34 to 35 g (Hrabia et al., 2011). Main increase in ovary weight occurs in the last week before the onset of egg lay and is due almost entirely to the growth of the yellow preovulatory follicles. Eight to five weeks before maturity, only primordial and primary follicles are seen in the ovary. White follicles appear about 4−3 weeks before the first ovulation, and 2 weeks before maturation yellowish follicles are present in the ovary (Hrabia et al., 2011; Hrabia, 2015) (Figure 35.1A−B).

The ovary lies in the cranial part of the body cavity, ventral to the aorta and the caudal vena cava, and adjacent to the cranial extremity of the left kidney and the caudal part of the left lung. It is hanged from the dorsal body wall by a peritoneal fold, the mesovarium. This fold is strengthened by connective tissue and forms the hilus containing blood vessels, nerves, and smooth muscle (Gilbert, 1979).

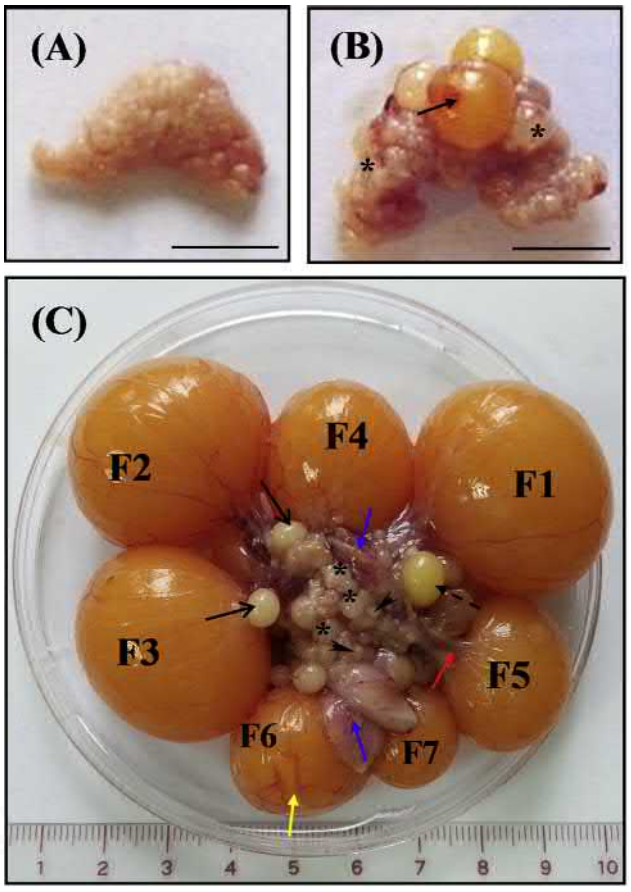

FIGURE 35.1 The hen ovary. (A) The ovary of growing chicken about 6 weeks before maturation with primordial and primary follicles. (B) The ovary of growing chickens about 2 weeks prior to the onset of egg lay, possessing white (*asterisks*) and small yellow (*arrow*) follicles. (C) The ovary of laying hen composed of prehierarchical white (*asterisks*) and yellowish (*black arrows*) follicles, small yellow follicles (*dashed arrow*), the seven largest hierarchical yellow preovulatory follicles (F7−F1), postovulatory follicles (*blue arrows*), and prehierarchical atretic follicles (*arrow heads*). *Red arrow* indicates the follicle stalk (pedicle). *Yellow arrow* indicates the follicle stigma. Bar = 1 cm.

35.2.3 The laying hen ovary

In the laying domestic hen, the ovary contains follicles of various size and stage of development (Figure 35.1C). There are numerous prehierarchical follicles (primordial and primary follicles embedded in the stroma with diameter <1 mm, white follicles >1−4 mm, and yellowish follicles >4−8 mm), the preovulatory yellow follicles (>8−36 mm; Fn-F1), which are arrange in a characteristic hierarchy (typically the largest five to eight follicles exist), and several postovulatory follicles (POFs) at different stage of regression (POF1-POFn). The largest follicle (F1) is the most developed and first to ovulate. After ovulation of the F1, less mature follicles are moved up one position in the hierarchy, and one follicle from the group of 6−8 mm follicles is recruited into the preovulatory hierarchy. Moreover, in the hen ovary several prehierarchical atretic follicles are present. The primordial follicles (up to 80 μm diameter) contain a large germinal vesicle (nucleus) and are surrounded by a single layer of flattened or cuboidal granulosa cells. Further, in primary follicles increasing in size to 1−2 mm, the basal lamina and a single layer of theca cells are addend (Figure 35.2A). These follicles exist in a quiescent phase of growth, lasting from a few weeks to several years. The next subpopulation of white follicles (numbering about 40−50 per ovary) is formed by further development of the granulosa layer into multilayer, and theca layer to the theca interna and externa layers (Figure 35.2B). Follicles become suspended from the ovarian surface by

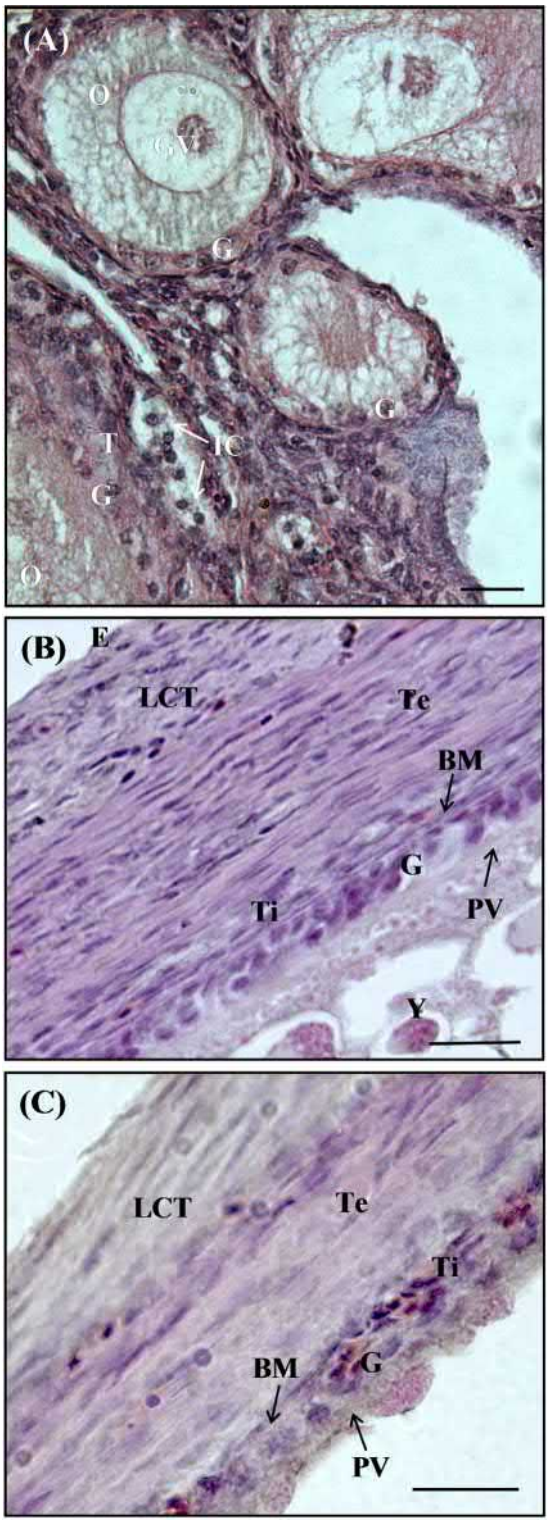

FIGURE 35.2 Histological structure of chicken ovarian follicles (hematoxylin and eosin staining). (A) Ovarian cortex with primordial and primary follicles. Primordial follicle consists of oocyte (O) with germinal vesicle (GV) and perivitelline membrane (PV) surrounded by one layer of granulosa cells (G). In further developed primary follicle, the basement membrane (BM), thin theca layer (T), and the interstitial cells (IC) in the outer area of the theca layer are additionally present. (B) The wall of prehierarchical follicles (5 mm diameter) with the multilayered granulosa. (C) The wall of the largest yellow follicle containing one layer of cuboidal granulosa cells. *E*, epithelium; *IC*, interstitial cells; *LCT*, loose connective tissue; *PV*, perivitelline layer; *Ti*, theca interna; *Te*, theca externa; *Y*, yolk. Bar = 20 μm.

a stalk. The germinal disc comprising germinal vesicle and cytoplasmic organelles is located at the animal pole of the oocyte. White follicles begin slow-growing stage, accumulate protein-rich white yolk and increase in diameter up to 4−6 mm within a few weeks. During slow-growing phase of development, the granulosa cells exhibit the highest proliferating rate, which in follicles 1−8 mm is five-, six-time greater than in the largest F3−F1 (Tilly et al., 1992). As follicle development progress through the stage of yellowish follicles (numbering 10−12 per ovary), the accumulation of lipid-rich yellow yolk starts. Approximately every 24−25 h, one 6−8 mm yellowish follicle enters into the rapid growth phase and in 5−9 days increases in size up to 36−40 mm. Fast-growing, yellow follicles contain oocyte with a large amount of yolk surrounded by the perivitelline layer, and the follicular wall including the granulosa layer, basal lamina, theca interna and externa layers, loose connective tissue, and epithelium (Figure 35.2C). Across this stage of development, there is a decrease in the rate of cell proliferation with concomitant reorganization of the granulosa layer from a multilayered to a single-cell layer, with cuboidal shape in the largest yellow follicles. In these follicles, the granulosa cells undergo intense differentiation, and their proliferation is limited to the region of the germinal disc (Tischkau et al., 1997; Yao and Bahr, 2001; Wojtysiak et al., 2011). Microvilli are well developed on lateral and apical surfaces of the granulosa cells, and they form interdigitations with adjacent cells. At the germinal disc area, the cell membrane of granulosa cells and oolemma form gap junctions (Yoshimura et al., 1993b). The basal lamina (basement membrane) separating the granulosa and theca interna layers is thick, approximately 1 μm in the largest follicle. It contains type IV collagen, noncollagenous extracellular proteins such as fibronectin, laminin, heparin sulfate proteoglycan, nidogen, and additional components that are not classified as extracellular matrix (ECM) proteins secreted by both the granulosa and theca layer cells (Asem et al., 2000). The theca interna comprises the interstitial cells, spindle-shaped fibroblasts, and relatively small amount of collagenous fibers. The interstitial (steroidogenic) cells are rich in mitochondria with tubular cristae, smooth endoplasmic reticulum, and lipid droplets. The theca externa contains fibroblast-like cells, aromatase cells, muscle fibers, and in large part is composed of ECM which contains dermatan sulfate, heparan sulfate, hyaluronic acid, and collagenous fibers. The loose connective tissue (superficial tissue) ambient the theca layers projects from the ovarian cortex and follicular stalk. Through this tissue the vascular and nervous systems enter the follicle. At the stigma region, this loose connective tissue becomes thin, while theca externa increases in thickness, and thus blood vessels except for capillaries in the theca interna are not developed here. The superficial epithelium consists of cuboidal or flattened cells (Yoshimura and Barua, 2017).

35.2.3.1 Follicle vasculature and blood flow

The blood contribution to the ovary comes through ovarian arteries originating from the left gonado-renal artery. Highly convoluted branches of the ovarian artery proceed across the medullary tissue giving off smaller branches to the cortex, and via the follicular stalk to the developing follicles. The venous efflux from the ovarian follicles collects in large veins within the medulla and leaves the organ via the cranial and caudal ovarian veins which join eventually the left suprarenal vein and the vena cava, respectively (Hodges, 1974). Prior to follicle selection, a limited number of blood vessels associated with the follicular wall is formed. The network of blood vessels increases along with the fast growth of follicle, achieving maximal development in the largest follicle (F1). The granulosa layer is lacking of vasculature, while the highly vascularized theca layer possesses an outer venous layer, a complex middle arterial and venous layers, and an inner capillary network. The progress in expansion of follicular vasculature along with follicle maturation to a final stage of development is accompanied by a gradual increase in the blood flow. Among the yellow preovulatory follicles, the blood flow is relatively constant. The five largest follicles receive about half of the ovarian blood flow (Scanes et al., 1982; Hrabia et al., 2005). Intensified angiogenesis and blood flow within the theca layer facilitate the rapid growth of preovulatory follicles by increase in incorporation of yellow yolk to the oocyte.

Increase in ovarian follicle vasculature is attributed to the enhanced level of gonadotropin-induced vascular endothelial growth factor (VEGF) expression within the granulosa cells at follicle recruitment, stimulating angiogenesis within the theca layer possessing VEGF receptors (Kim et al., 2016). Other angiogenic factor, i.e., metalloproteinase-9 (MMP-9), localized particularly around blood vessels, which expression and activity significantly increase in the theca layer of chicken preovulatory follicles, is also proposed as a regulator of ovarian vasculature development (Hrabia et al., 2019).

As an intraovarian regulator of blood flow, the most important are pituitary-derived gonadotropins and locally produced steroids, prostaglandins (PGs) or other factors such as biogenic amines. By way of example, the administration of PGF2 alpha was followed by a consistent decrease in blood flow to the largest preovulatory follicles (Scanes et al., 1982). In turn, histamine increased blood flow to chicken ovarian follicles (Hrabia et al., 2005).

35.2.3.2 Follicle innervations

The ovary possess an extrinsic and intrinsic neural system. The extrinsic innervation of the ovary consists of complex of many nerves and ganglia laying close to, or within the ovarian stalk. The intrinsic innervation of the ovarian medulla contains both large and small nerve bundles, some of which are associated with blood vessels and smooth muscles. The innervation within the ovarian cortex is predominantly associated with the follicles but also with blood vessels within stroma. With progressive growth and maturation of the follicle, the innervation increases (Gilbert, 1969). An extensive adrenergic and cholinergic innervation of the follicles is confined primarily to the theca layer. The granulosa layer possesses less than 5% of the total number of nerve fibers existing in the follicle (Gilbert, 1965, 1969). The ovarian neural system supplies numerous neurotransmitters (acetylcholine, catecholamines, serotonin, and histamine) and neuropeptides [vasoactive intestinal peptide (VIP), galanin, and brain-derived neurotropic factor] which mediate ovarian processes.

35.2.4 Follicle development, selection, and establishment of preovulatory hierarchy

Generally, in laying hen almost each day, the largest preovulatory follicle is ovulated, and the follicle number in the preovulatory hierarchy is kept essentially constant by the selection of one follicle from the pool of 6−8 mm diameter follicles. This process, occurring on a near-daily basis, is called as cyclic recruitment (Woods and Johnson, 2005) and seems to be independent of ovulation (Ghanem and Johnson, 2019a). The precise mechanisms that control a slowly growing follicle recruitment into a rapid growth phase are not fully elucidated. Nevertheless, follicle requirement is the result of well-synchronized interactions between oocyte and surrounding cells of the granulosa and theca layers, in response to a diverse endocrine, paracrine, and/or autocrine factors.

The most important event at the time of selection is that the granulosa cells becomes responsive to follicle-stimulating hormone (FSH) and VIP, which initiate G protein-coupled receptor-mediated cyclic adenosine monophosphate (cAMP) production. In turn, cAMP signaling within the granulosa cells upregulates the steroidogenic acute regulatory protein (StAR), cytochrome P450 side chain cleavage enzyme (CYP11A1), 17α-hydroxylase/17,20-lyase (CYP17A1), and LH receptor gene expression, resulting in initiation of steroidogenesis (Johnson and Bridgham, 2001; Johnson, 2015a; Ghanem and Johnson, 2018, 2019b). Prior to selection, the granulosa cells of up to 8 mm follicles remain undifferentiated and fail to initiate cAMP production in response to FSH compared to granulosa cells from the most recently recruited (9−12 mm) follicles (Tilly et al., 1991a; Johnson and Lee, 2016). Although FSH receptors (FSHR) are present at this stage of development, they fail to generate cAMP (remain in a desensitized state). Therefore, granulosa layer from follicles before selection is steroidogenically inactive. The inability of granulosa cells to generate cAMP synthesis in response to FSH is mediated through an inhibitory effect of the MAPK signaling via ESKs (ERK1,

ERK2) and/or protein kinase C pathways (Woods and Johnson, 2005; Woods et al., 2007; Johnson, 2014) as well as by β-arrestin (Kim and Johnson, 2018). There is also evidence that VIP signaling via its receptors (VPAC1 and VPAC2) in prehierarchical follicle granulosa cells is also suppressed, in vitro, by a β-arrestin-mediated event (Kim and Johnson, 2018). It was suggested that cyclic recruitment of follicle into preovulatory pool of follicles may result from a rapid decline in inhibitory cell signaling rather than the comparatively slower process of gene transcription and translation (Ghanem and Johnson, 2019b).

The FSH is a main hormone facilitating follicle selection into the preovulatory hierarchy. Treatment of hens with FSH (Palmer and Bahr, 1992) as well as with equine chorionic gonadotropin (Ghanem and Johnson, 2019b; Wolak et al., 2021), which possess mainly FSH-like properties, greatly increases the number of yellow follicles in the ovary (Figure 35.3). Even a single injection of FSH is capable of initiating FSH-responsiveness within the granulosa layer, resulting in the recruitment of multiple follicles to the preovulatory hierarchy within a single ovulatory cycle. Morphology and cellular characteristics of these follicles is the same as that following a spontaneous selection, including increased size, yellow yolk incorporation, and weight (Ghanem and Johnson, 2019b). FSHR are present in the granulosa and theca layer of growing follicles as early as 1−2 mm stage of development, and the expression of these receptors alters along follicular maturation. The highest FSHR mRNA levels noted in 6−8 and 9−12 mm follicles decrease progressively as the follicle develops to the preovulatory F1 stage (You et al., 1996; Zhang et al., 1997). An increase in FSHR expression in the granulosa cells and subsequent follicle recruitment is influenced by multiple paracrine and autocrine factors. One of them is anti-Müllerian hormone (AMH). In hens, the expression of AMH mRNA and protein, predominantly in the granulosa layer, is restricted to the growing population of follicles and is markedly decreased at around the time of follicle selection (Johnson et al., 2008; Johnson, 2012). Follicles larger than approximately 50 μm and smaller than 6 mm showed the most pronounced AMH expression, supporting the idea that the AMH signal must be reduced to promote FSH sensitivity in developing follicles (Johnson, 2012). As a regulator of AMH expression, vitamin D was proposed; it caused a decrease in the expression of AMH mRNA in the hen granulosa cells from 3−5 mm and 6−8 mm follicles concomitantly with increase in FSHR expression (Wojtusik and Johnson, 2012). Growth and differentiation factor 9 (GDF9) along with bone morphogenetic protein 15 (BMP15), oocyte-derived members of the transforming growth factor beta superfamily (TGFβ) have been identified in the ovary of hens as well, and their role was related to follicle selection (Johnson et al., 2005; Elis et al., 2007; Li et al., 2019). Expression of BMP15 receptor mRNA (BMPR1B and BMPR2) in granulosa cells increases with follicle development from 3 to 16 mm stage of development. Biological action of the GDF9 is associated with promotion of the granulosa cell proliferation (Johnson et al., 2005). BMP15 is found as a stimulator of FSHR expression and inhibitor of AMH and occludin expression in the granulosa cells from 3−5 mm and 6−8 mm follicles (Stephens and Johnson, 2016). In addition, BMP4 and BMP6 also enhance FSHR mRNA expression in granulosa cells from chicken prehierarchical follicles (Ocón-Grove et al., 2012; Kim et al., 2013). Further, Kit system containing Kit ligand (KL) and its tyrosine kinase receptor (cKit) is suggested to regulate the smaller prehierarchical follicle development and eventually recruitment. The highest KL mRNA abundances are noted in the primary <1 mm follicles and in the granulosa layer of 3 mm follicles as compared to expression in the granulosa layer of 6−12 mm follicles (Kundu et al., 2012). cKit protein is present in the theca layer and ovarian stroma but not in the granulosa cells (Kundu et al., 2012). Several potential factors involved in the regulation of KL synthesis are also proposed. For instance, treatment with heparin binding EGF-like growth factor, identified in the oocyte, resulted in a dose-dependent decrease in KL mRNA expression in the granulosa cell (Wang et al., 2007). Vitamin D3 increases, while FSH decreases expression of KL mRNA in the granulosa cells collected from 6−8 mm follicles (Kundu et al., 2012). Recently, the slit guidance ligands (SLIT1, SLIT2, and SLIT3) and their receptors

FIGURE 35.3 The hen ovary obtained after eCG treatment. Laying hens were injected subcutaneously with 75 IU eCG (PMSG)/kg of body weight for seven successive days. Treatment with eCG results in a higher number of yellowish and yellow follicles and disruption of the ovarian hierarchy.

(ROBO1, ROBO2, ROBO3, and ROBO4) have been revealed to mediate the prehierarchical follicles development in the hen ovary by an autocrine and/or paracrine fashion (Qin et al., 2015; Xu et al., 2018a, 2018b). SLIT2 and SLIT3 ligand overexpression reduces the granulosa cell proliferation as well as decreases the mRNA and protein expression levels of FSHR, GDF9, StAR protein, and CYP11A1 in the granulosa cells (Xu et al., 2018a). An inhibitory effect of SLIT ligands on granulosa cell proliferation, differentiation, and follicle selection involves primarily ROBO1 and ROBO2 receptors. In addition, SLIT2 effect in the prehierarchical follicles is mediated by the CDC42-PAKs-ERK1/2 MAPK signaling cascade (Xu et al., 2018a). Additionally, the present data based on high-throughput sequencing technology indicate that epigenetic and genetic mechanisms control ovarian follicles development and selection. Several miRNAs associated with follicle selection or growth were identified (Kang et al., 2013; Wang et al., 2018; Ocłoń and Hrabia, 2021). For example, mRNA and miRNA transcriptome profiling of the granulosa layer cells from geese ovarian follicles indicates that the genes related to junctional adhesion and lipid metabolism and interacting with the miRNAs play a key role in regulating follicle selection (Q. Li et al., 2019). Another numerous factors are identified in the prehierarchical follicles which may mediate follicle growth, differentiation, and selection by autocrine/paracrine fashion. Among them are PGs, growth factors, growth hormone (GH), inhibin, activin, and aquaporin 4.

Development of recruited follicle until ovulation is accompanied not only by enhancement of steroidogenesis process in the granulosa cells, but also by shift from FSHR-dominance to LHR-dominance, increase in the expression of antiapoptotic proteins (the follicle becomes resistant to atresia), and accumulation of huge amount of yolk in the follicle. These events are associated with morphological and functional changes attributed predominantly to the granulosa cells. Final follicle development and maturation are regulated by variety of factors such as pituitary hormones, metabolic status maintaining hormones, and locally produced growth factors (discussed in this chapter).

35.2.5 Vitellogenesis

In egg-laying hen, principal event responsible for the enormous growth of the ovarian follicle, initiated immediately after selection, involves the accumulation of hepatically derived plasma precursor yolk proteins into the oocyte. It is accomplished by increase in follicle vasculature and blood flow. In the domestic hen, within approximately nine days, the follicle weight increases from an average 0.28 g just after selection (pool of 8−12 mm follicles) to 13.5 g several hours before ovulation (34−36 mm F1).

The yolk precursor proteins such as lipoproteins, very low-density lipoprotein (VLDL), and vitellogenin (VTG) are synthesized in the liver in process of vitellogenesis, delivered to the oocyte through the vascular system, "filtered" via the basement membrane, and then moved between the granulosa cells to the perivitelline membrane to access the oocyte. Finally the yolk molecules are taken into the oocyte by receptor mediated endocytosis (Schneider, 2009, 2016) and enzymatically processed into yolk proteins that are deposited in yolk platelets or yolk spheres for future use (Ito et al., 2003). The LR8 yolk receptor, homolog of the mammalian low-density lipoprotein receptor with eight ligand binding domain repeats (Bujo et al., 1994) is an avian specific yolk receptor located on the oocyte plasma membrane. Functional absence of LR8 blocks oocytes from entering into the rapid growth phase (Schneider, 2016).

The rate of yolk molecules accumulation and thereby, facilitation of rapid growth of the preovulatory follicle is affected by communication between the oocyte and cells of the follicular wall. The size of intercellular space also selectively controls the uptake of specific plasma molecules. Prior to follicle selection, the granulosa cells lie close together and tight junctions between them prevent the smooth paracellular transport of yolk macromolecules to the oocyte. The relatively narrow intercellular space of the prehierarchical follicle allows only ferritin and other molecules of similar size to cross. At selection and through after, wide channels appear between the granulosa cells that enable dramatic increase in VTG and VLDL (containing mainly apovitellenin and apolipoprotein B) transportation to the oocyte (Ito et al., 2003). This event results, at least in part, from reduction in occludin, tight junction protein expression. In small white follicles, occludin is demonstrated at the apical region of granulosa cells, while no distinct localization of occludin is noted in larger follicles (Schuster et al., 2004). Expression of occludin mRNA is highest in small follicles, and decreases with increasing follicle size. Moreover, occludin mRNA abundance is higher in the germinal disc region of the granulosa layer than the nongerminal disc region. In granulosa cells of 3−5 mm follicles, occludin expression of ad libitum fed hens is lower compared to restricted fed broiler breeder hens concomitantly with no changes in LR8 mRNA abundance. As regulators of occludin expression, the FSH, epidermal growth factor, and activin A and B were found (Schuster et al., 2004; Stephens and Johnson, 2017).

After being taken into the oocytes, VTG and VLDL are cleaved into their constituents: lipovitellins and phosvitin, and triglycerides, cholesterol and phospholipids, respectively. This process is realized by the action of numerous proteases including cathepsin D and cathepsin E-A-like, as well as antiproteases (protease inhibitors) present in the egg yolk or the perivitelline membrane (Retzek et al., 1992;

Bourin et al., 2012; Zheng et al., 2018). In birds, three VTG genes are known: VTG1, VTG2, and VTG3, classified also as VTGAB1, VTGAB2, and VTGAB3, respectively (Finn, 2007). In the liver of the egg-laying hen, the ratio of RNA molecules per cell, encoding VTG1, VTG2, and VTG3 is 0.33:1:0.1, respectively (Evans et al., 1988).

Vitellogenesis (synthesis and deposition of the yolk precursors) is a hormone-dependent process. Of the stimulators of yolk synthesis, i.e., gonadotropins, estrogen, and androgen, the estrogen, mainly by its ERα, exerts the highest potency in transcription of egg yolk precursor genes. Other hormones may modify the response. GH is proposed as a modulator of the estrogen-potentiated vitellogenesis in the pigeon (Harvey et al., 1978) and the estrogen-induced VTG2 and very low-density apolipoprotein II (apoVLDLII) mRNA expression in the chicken liver (Socha and Hrabia, 2019). The plasma levels of VLDL and VTG increase dramatically at the onset of egg laying in hens, while decrease during a pause in laying. Examples of VTG2 and apoVLDLII mRNA expression in the laying hen liver affected by different factors are presented in Figure 35.4.

Interestingly, yolk of the large preovulatory yellow follicle of chicken contains approximately 48% of water, i.e., 9.2 g (Etches, 1996). Such huge accumulation of water requires its rapid movement. Recently, it was revealed that aquaporin 4 (integral plasma membrane protein) may facilitate water passage to the yolk in the interior of follicle (Nowak et al., 2017).

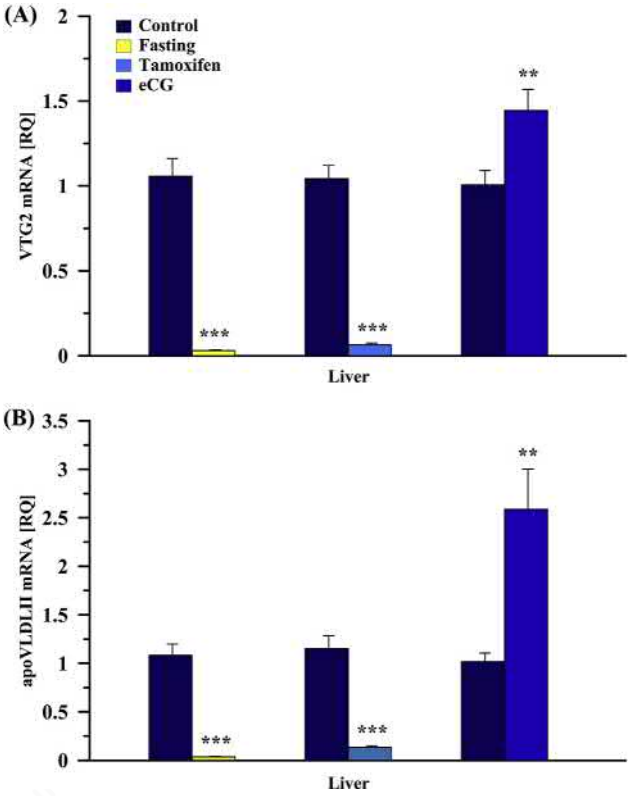

FIGURE 35.4 Expression of vitellogenin 2 (VTG2) (A) and very low-density apolipoprotein II (apoVLDLII) (B) mRNA in the chicken liver at different physiological states. The liver tissue was collected from egg laying hens and treated with a proper vehicle (Control), during a pause in laying induced by 5 days of food deprivation (Fasted), during a pause in laying induced by tamoxifen treatment for 8 days (6 mg/kg b.w.; Tamoxifen), or eCG-primed hens for 7 days (75 I.U./kg b.w.; eCG). Each value represents the mean of relative quantity (RQ) ± standard error of the mean from six or eight chickens normalized to 18S rRNA and standardized to control expression. $^{**}P < .01$, $^{***}P < .001$ - compared with the control.

35.2.6 Oocyte maturation and ovulation

The avian oocyte consists of a large amount of yolk and a structure called the germinal disc. The germinal disc is a white plaque (three to four mm in diameter) on the top of the oocyte and occupies about 1% of cell volume. It contains the nucleus and 99% of cytoplasmic organelles such as elongated membrane-bound vesicles, mitochondria, and glycogen granules. The oocyte is demarcated by the perivitelline membrane, and the overlying granulosa layer. Inside the oocyte, the perivitelline membrane is covered by extra-embryonic RNA. Several hours before ovulation, the junction between the oocyte surface and the granulosa cells projections dissociate with an accumulation of fluids in the perivitelline space. By 1 h before ovulation, the oocyte and the granulosa cells are disconnected. At this time, the oocyte maturation occurs, including the germinal vehicle break down, formation of the first and second maturation spindle just beneath the surface of the oocyte, and the release of the first polar body in the perivitelline space (Yoshimura et al., 1993b, 1993c).

The oocyte maturation is primarily under influence of LH that reaches the highest plasma concentration six–four h before ovulation. Its role has been confirmed in in vivo studies. Namely, injection of quail with LH induced the oocyte maturation (Yoshimura et al., 1993c) and premature ovulation of F1 follicle (Hrabia et al., 2003a). The preovulatory LH surge occurs coincidently with elevated secretion of progesterone mainly by F1 follicle. If the secretion of progesterone is insufficient, the LH surge with potency to induce ovulation does not occur. Participation of the maturation promoting factor and a homolog of fission yeast cdc2+ gene product (p34cdc2) was also suggested in quail oocyte maturation. Marked increase in kinase activity of p34cdc2 in the oocyte germinal disc at maturation was noted (Mori et al., 1991). More recently, overexpression of 250 genes in the germinal disc of the hen oocyte was revealed. Among them, 21 genes were suggested to be involved in different stages of final follicular maturation and eight genes (btg4, chkmos, wee, zpA, dazL, cvh, zar1, and ktfn) were indicated as a potential candidates driving maturation of the oocyte (Elis et al., 2008).

The process of ovulation includes a series of biochemical and morphological events occurring in parallel within the preovulatory F1 follicle, which lead to its rupture along stigma and release of the mature oocyte (Figure 35.5A-B). In the stigma area of follicle, the blood vessels except for capillaries are not supplied. Just before ovulation the theca externa, which comprises most of the follicular wall at the stigma region, becomes progressively thinner as a result of disintegration of the ECM elements, among others the collagenous fibers into individual fibrils and degradation of glycosaminoglycans. The granulosa layer and theca interna disappear completely in the middle part of the stigma (Yoshimura and Koga, 1982; Jackson et al., 1991). The stigma region becomes fragile and easy to be ruptured by the smooth muscle contraction of the follicle wall. The comprehensive alterations in the ECM, restricted to the stigma area, are realized by a cascade of proteolytic processes mediated by various proteases with different substrate specificities. Growing evidence has established that these events are largely controlled by the matrix metalloproteinases (MMPs). They can specifically degrade ECM components, including collagens, gelatins, elastin, laminin, and plasminogen, as well as activate other MMPs. First, Nakajo et al. (1973) suggested that proteolytic enzymes such as collagenase participate in follicular rupture in the chicken ovary. A marked increase in collagenase, acid and neutral protease activities was further observed immediately after ovulation in POF1 follicle (Tojo et al., 1982). The presence of several MMPs were demonstrated in the basal lamina of chicken preovulatory follicles indicating their involvement in the breakdown of this membrane required to release the oocyte during ovulation (Asem et al., 2000). More recently, increase in the expression of MMP-2, MMP-3, MMP-9, MMP-10, and MMP-13 mRNA and/or protein as well as increase in gelatinase (MMP-2 and MMP-9) activities in the chicken ovarian follicle along with follicular maturation has been revealed (Leśniak and Hrabia, 2012; Zhu et al., 2014; Hrabia et al., 2019; Wolak and Hrabia, 2020). Participation of gelatinases, demonstrated primarily in the theca layer of the follicular wall, in follicular rupture was further supported by the higher expression of both proteases 3 h compared to 22 h before ovulation as well as their markedly elevated activities in the F1 follicle (Hrabia et al., 2019). Plasminogen activators (PAs) have also been proposed to play an important role in the control of follicular rapture during the ovulation. An increase in PA activity and decrease in its inhibitor activity during follicular development, with the peak PA value in the largest preovulatory follicle (F1) 12−14 h before expected time of ovulation were observed (Politis et al., 1990). The dramatic increase in PA activity specifically in the stigma region of the F1 follicle, which remained high until ovulation, was additionally related to PA involvement in the ovulatory process (Jackson et al., 1993).

Ovulation is orchestrated by pituitary-derived LH and locally produced factors. It is well established that ovulation is induced by preovulatory release of LH, which achieves two−three fold increase of basal level 6−4 h before ovulation (Johnson and van Tienhoven, 1980; reviewed in Johnson, 1990; Rangel and Gutierrez, 2014). This gonadotropin might initiate follicular production of enzyme (s) capable of degrading the ECM components of the follicular wall, and that the progressive decomposition of the wall results in its rapture. Progesterone stimulates preovulatory surge of LH via positive feedback. Its increase prior to ovulation coincidently with LH peak is proceeded by plasma surges of estradiol and testosterone. Estradiol

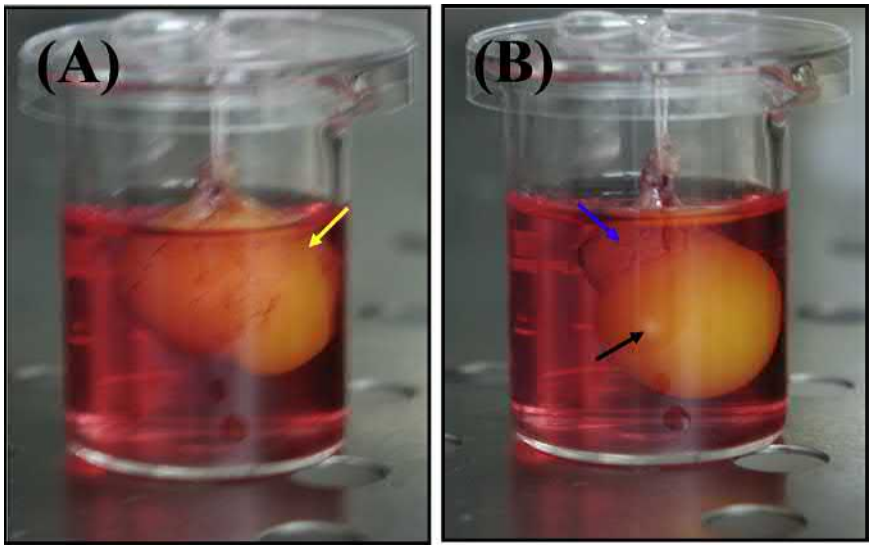

FIGURE 35.5 In vitro ovulation of F1 follicle. (A) Onset of ovulation process along stigma (*yellow arrow*). (B) Final stage of ovulation. *Blue arrow* indicates the postovulatory follicle, and *black arrow* indicates germinal disc.

"primes" the hypothalamo-pituitary axis and facilitates the progesterone-stimulated LH release. Testosterone which peak concentration occurs 10−6 h before ovulation promotes progesterone production needed for the occurrence of the preovulatory search of progesterone and LH. The stimulatory action of testosterone on progesterone synthesis by the largest preovulatory follicles is mediated by promotion of CYP11A1 and StAR mRNA expression as well as LH receptor mRNA expression (Rangel and Gutierrez, 2014). Treatment of laying hens with testosterone antagonist inhibits preovulatory surges of both progesterone and LH and ovulation (Rangel et al., 2006).

It is interesting to note that ovulation resembles the inflammatory process (Espey, 1980). Thus, inflammatory mediators such as biogenic amines and PGs also participate in the regulation of the ovulatory events. Histamine, which concentration gradually increases as follicle development progress toward ovulation (from F4 to F1), followed by a significant decrease in POF1 follicle, was suggested to play a role in the ovulatory process, as a mediator influencing the hemodynamics of blood vessels and consequently modifying blood flow through the follicle (Paczoska-Eliasiewicz and Rząsa, 1998; Hrabia et al., 2005). Moreover, histamine stimulates progesterone secretion by the granulosa cells of F1 follicle being just before ovulation (Paczoska-Eliasiewicz and Rzasa, 1999). Other biogenic amine, serotonin, exhibits similar profile of content to histamine, with the highest level 0.5 h prior to ovulation, however, it does not alter blood flow within the wall of the largest preovulatory follicle (Paczoska-Eliasiewicz and Rząsa, 1995; Rząsa et al., 2008). Catecholamines (dopamine, norepinephrine, and epinephrine) are localized primarily in the theca layer with only small amounts present in the granulosa layer. The increase in norepinephrine and epinephrine contents in the theca layer of the F1 follicle before ovulation serves them as the mediators of ovulation (Bahr et al., 1986). The granulosa cells of the largest preovulatory follicle are the major intraovarian source of PGs, and production of PGF2α is associated with the preovulatory surges of LH and steroid hormones (Etches et al., 1990). Thus, their role may be related to ovulatory processes mediation, including the increase in contraction of smooth muscles in the follicular wall to facilitate the rapture of the stigma as well as stimulation both cell-associated and secreted PA activity (Tilly and Johnson., 1987). Furthermore, PGs attract macrophages and stimulate MMP release by cells of the sow corpus luteum (Pitzel et al., 2000), therefore, similar role is plausible in the hen preovulatory follicle.

35.2.7 Postovulatory follicles

Unlike in mammals, the follicle in birds after ovulation rapidly terminates the metabolic activity and fails to form a functional corpus luteum. The structure remaining after release of the oocyte is a POF containing theca layers (internal and external) and a granulosa layer (Figure 35.6). The residual POF immediately shrinks and due to this, the wall becomes thickened, and the granulosa increases to several cells in thickness. Moreover, changes that occur in the wall of regressing POF involve cellular hypertrophy associated with accumulation of lipid, the disappearance of the basement membrane, and translocation of the theca interna and granulosa cells toward the follicle lumen. In POF3, the mass of cells contains both extra- and intracellular accumulation of lipids. During the later stages of regression, the luminal mass becomes invaded by capillaries and nerve fibers (for more details see Hodges, 1974; Gilbert, 1979; Lin et al., 2018). Regression of the granulosa layer begins immediately after F1 ovulation and is entirely completed in POF4. Degeneration of the theca layers progress slowly, and their complete resorption is observed in POF5-POF6 (Hrabia et al., 2018; Lin et al., 2018). In the chicken, the follicle undergoes tremendous regression within approximately 6−10 days after the extrusion of the oocyte.

To date it has been established that the regression of chicken POFs similarly to follicle atresia occur via the apoptotic cell death (Tilly et al., 1991b; Sundaresan et al., 2008a; Hrabia et al., 2018). Along with the progressive regression of POF, a gradual increase in the number of apoptotic cells is observed. It has been established that both the external and internal pathways of apoptosis are engaged in apoptotic cell death in POFs, involving the major mediators of these pathways, i.e., caspase 2 and 8 and caspase 9, respectively. In addition, proinflammatory caspase 1 and executive caspase 3 also mediate this process. The greatest activity of caspases is observed in POF3 (Sundaresan et al., 2008a; Hrabia et al., 2018). The intensity of cell apoptosis in POF correlated with the increase in the amount of nitric oxide (NO) and NO synthase, therefore, indicating the involvement of NO in the regulation of apoptosis (Sundaresan et al., 2007).

Recent report demonstrated that in POF regression, especially its theca cells, also autophagy is involved. A dramatic increase in the number of major autophagy markers, i.e., Beclin1 and microtubule-associated proteins 1A/1B light chain 3B (LC3B) was observed along with progressive regression of the theca layers (Lin et al., 2018).

Regression of POF tissues concerns not only changes in cell morphology and function but also turnover of the ECM architecture and components. Participation of MMPs and their tissue inhibitors (TIMPs) in this event was strongly suggested. Degree of follicle regression-dependent changes and tissue-dependent differences in the expression of selected MMPs and TIMPs, and an increase in MMP-2 and MMP-9 activity were observed concomitantly with the degeneration of POF through apoptosis (Hrabia et al., 2018).

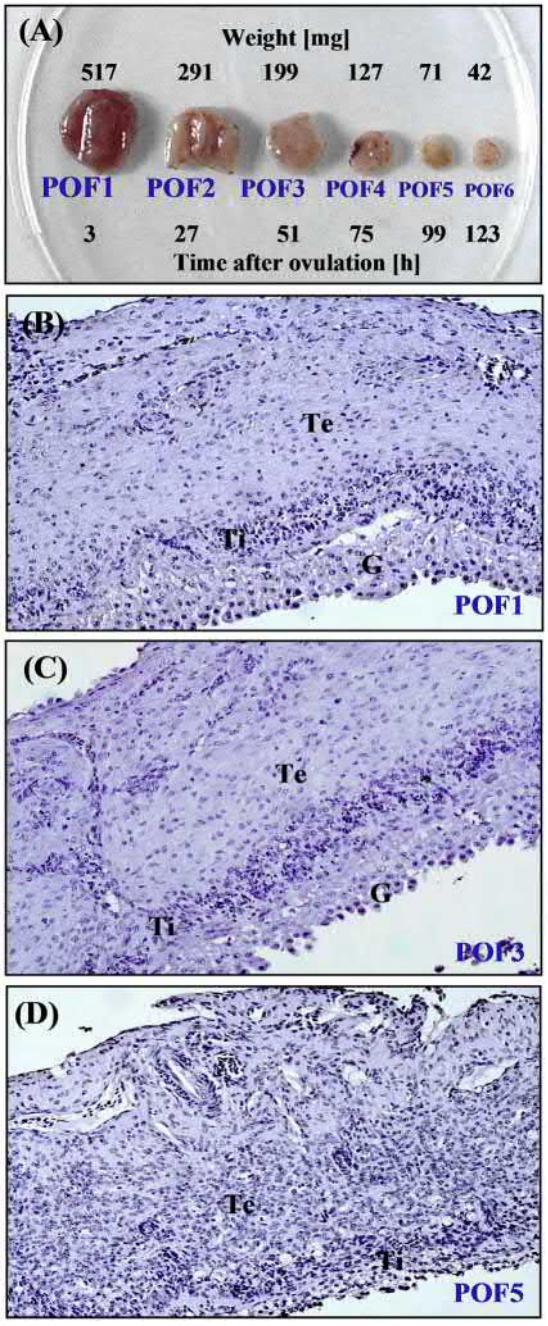

FIGURE 35.6 (A) Morphology and average weight of postovulatory follicles (POFs) in the hen ovary. (B–D) Histoarchitecture (hematoxylin staining) of the representative POFs. Note that the granulosa layer (G) in the POF1 increases to several cells in thickness due to immediate follicle wall shrink after ovulation. In the POF3, degeneration of the granulosa layer and basement membrane (BM) is advanced. In POF5, distinction among layers is very difficult due to the disappearance of the basement membrane, complete degeneration of granulosa layer, and translocation of the cells of theca interna layer toward the follicle lumen.

The contribution of the immune system to the degradation of POF is also important, as the regression of POFs resembles inflammation. POF regression is accompanied by the accumulation of macrophages, lymphocytes, and heterophiles compared to the F1 follicle (Barua et al., 1998; Sundaresan et al., 2008b). It was assumed that mainly macrophages may play a role in the POF regression by the removal of apoptotic cellular elements (Barua et al., 1998; Sundaresan et al., 2008b) and are a source of cytokines and chemokines. Increase in mRNA expression of selected cytokines (IL-1β, IL-6, IL-10, and TGF-β2) and chemokines (chCXCLi2, chCCLi2, chCCLi4, and chCCLi7) in POF as its regression progresses is observed (Sundaresan et al., 2008b). Cytokines are known activators of collagenases, gelatinase, and proteinases in various tissues. Macrophages are also a potential source of MMPs (Duncan, 2000). In turn, MMPs in addition to PG F2α may be factors enabling the influx of macrophages into POF tissues (Barua et al., 1998).

POF gradually loses steroidogenic activity. The greatest decrease in progesterone concentration in the POF is observed within the first 24 h after ovulation, which correlates with a decrease in the activity of 3β-hydroxysteroid dehydrogenase/Δ5-Δ4-isomerase (3β-HSD) (Dick et al., 1978; Lin et al., 2018). During the first 15 h after ovulation, the enzyme activity decreases drastically and then gradually. The concentration of estrogen in POF gradually decreases during its regression (Armstrong et al., 1977; Dick et al., 1978). In addition to the synthesis of steroid hormones, POFs are also a source of relaxin, whose precise role is unknown (Brackett et al., 1997), and are an important tissue for PG synthesis. The POF1 together with the F1 is the largest source of PGF2α in the chicken ovary (Saito et al., 1987; Hales et al., 2008). It has been observed that the secretory activity of POFs has an effect on egg laying time. Particularly important function was attributed to the granulosa layer of POF1. Damage or removal of this layer resulted in oviposition delay (Gilbert et al., 1978).

35.2.8 Ovarian steroidogenesis

Ovary is a main side of sex steroid synthesis (Figure 35.7). The cells involved in steroid production are the granulosa cells, thecal interstitial cells, and aromatase cells in the theca externa. The first step in steroid synthesis is transport of cholesterol from the outer to the inner mitochondrial membrane by the StAR protein, the rate-limiting factor in steroid production in all steroidogenic tissues. Expression of StAR protein in granulosa cells of prehierarchical follicles is very low. It elevates during follicular growth reaching the highest level in the F1 preovulatory follicle (Sechman et al., 2011, 2014; review in Johnson, 2015a, 2015b). Biosynthesis of steroids starts from conversion of cholesterol to pregnenolone catalyzed by the P450scc enzyme (CYP11A1) localized in the inner mitochondrial membrane. Subsequent synthesis of sex steroids can occur through two pathways: Δ4 and Δ5. In Δ4 pathway,

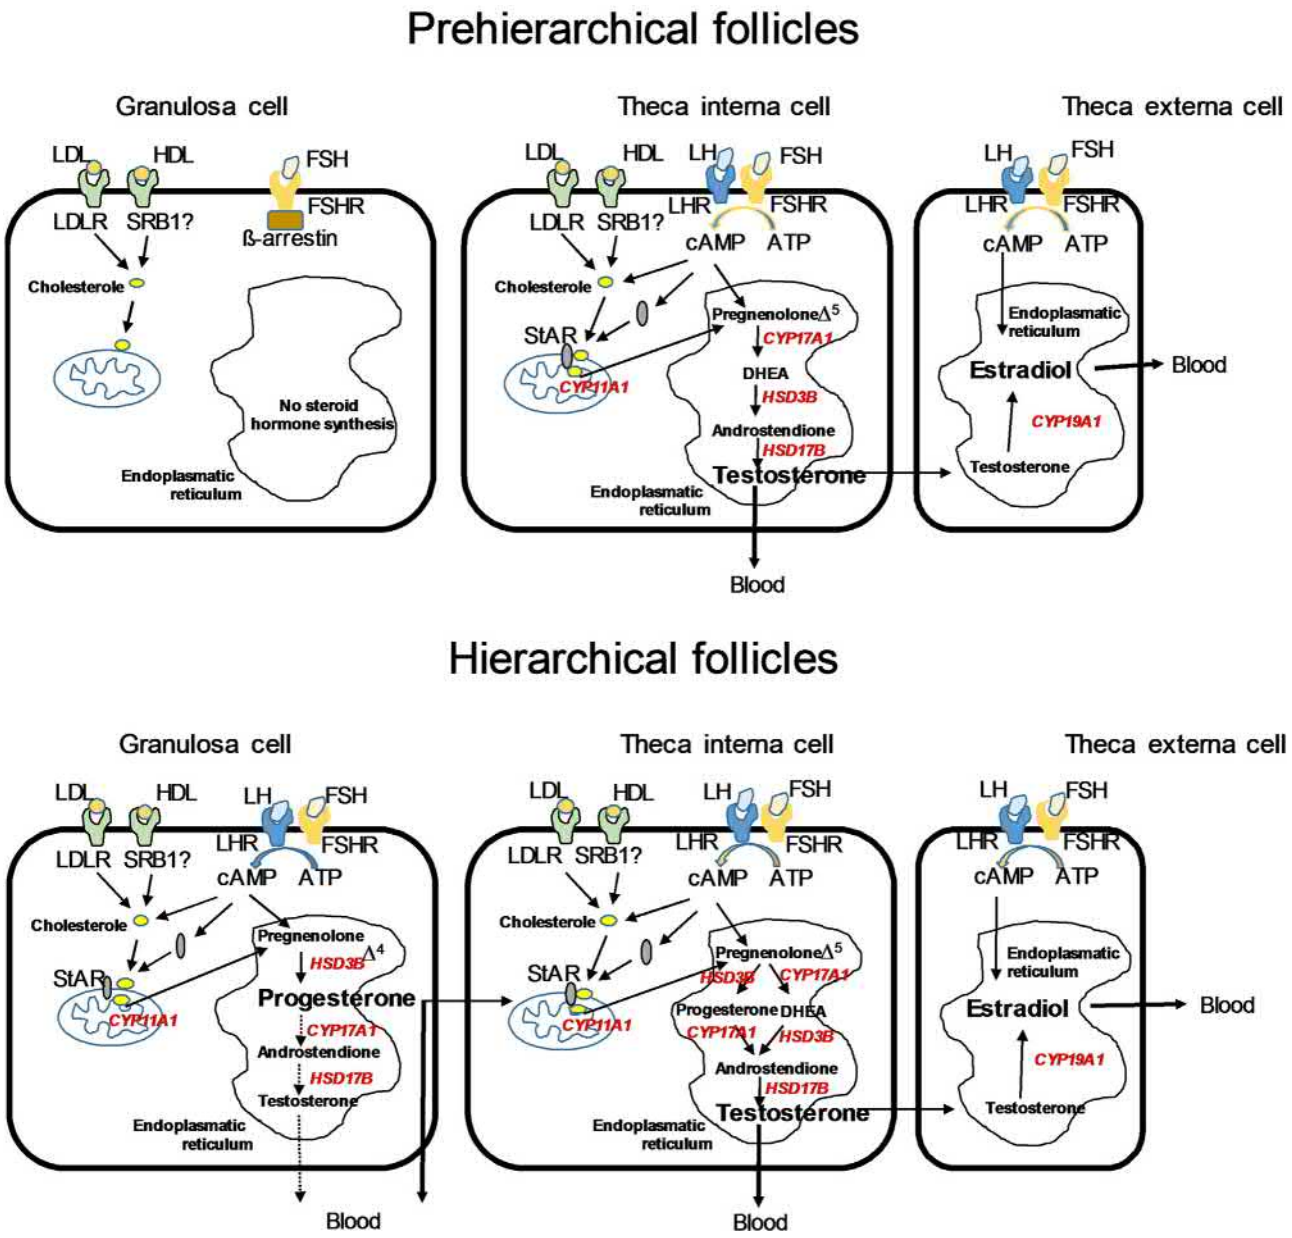

FIGURE 35.7 Diagrammatic summary of steroidogenesis in the avian ovary. Low-density lipoproteins (LDL) and high-density lipoproteins (HDL) deliver cholesterol. LDLR, LDL receptor; SRB1, receptor for HDL (it is not clear if the avian follicular cells express this receptor); StAR, steroidogenic acute regulatory protein; CYP11A1, mitochondrial cytochrome P450 cholesterol side-chain cleavage enzyme (P450scc) gene; CYP17A1, 17α-hydroxylase/17,20-lyase (P450c17) gene; HSD3β, 3β-hydroxysteroid dehydrogenase/Δ5-Δ4-isomerase (3β-HSD) gene; HSD17β, 17β-hydroxysteroid dehydrogenase (17β-HSD) gene; CYP19A1, aromatase (P450aroma) gene. LHR/FSHR, receptors for luteinizing hormone and follicular stimulating hormone, respectively. ATP, adenosine triphosphate; cAMP, cyclic adenosine monophosphate. *Thick arrow* indicates the predominant steroid released to the blood. See text for additional details. *Diagram prepared by Dr A. Sechman.*

pregnenolone is converted to progesterone and then to androstenedione. In Δ5 pathway, pregnenolone is changed to dehydroepiandrosterone (DHEA) and then to androstenedione. Androstenedione is next converted to testosterone which is aromatized to estradiol. Both pathways are functional in granulosa and theca cells of chicken ovarian follicles, but the granulosa layer preferentially metabolizes steroids by the Δ4 pathway, whereas the theca layer preferentially metabolizes steroids by the Δ5 pathway. Transformation of pregnenolone to progesterone or DHEA to androstenedione is catalyzed by 3β-hydroxysteroid dehydrogenase/Δ5-Δ4-isomerase (3β-HSD/HSD3β) bound to endoplasmic reticulum, which is the enzyme complex consisting of Δ5-3β-hydroxysteroid dehydrogenase and Δ5-3-oxosteroid isomerase. Change of pregnenolone to DHEA or progesterone to androstenedione is catalyzed

by17α-hydroxylase/17,20-lyase (P450c17/CYP17A1). In turn, conversion of androstenedione to testosterone and then testosterone to estradiol is catalyzed by 17β-hydroxysteroid dehydrogenase (17β-HSD/HSD17β) and aromatase (P450aroma/CYP19A1), respectively. Aromatase is an enzyme complex consisting of cytochrome P450 aromatase and NADPH-cytochrome P450 reductase (reviewed in Johnson, 1990, 2015b; Sechman, 2013).

Steroidogenesis in the avian ovary starts at early stage of embryogenesis. Androgens and estrogen are detected on measurable levels in undifferentiated gonads of both sexes (3−4 day of incubation). Progestins, androgens, and estrogens are further found in differentiating ovaries by days six to eight of embryogenesis. At this time of gonadal differentiation, androgen production by the right ovary is greater than that of the left ovary. By day 12 of incubation, the regressing right ovary synthesizes estradiol and testosterone in similar amounts to the left ovary, and then these steroids production decreases. Moreover, the ratio of estradiol-to-testosterone in the right ovary decreases concomitantly with its regression, while in the left ovary greatly increases throughout embryonic development. At 1 day posthatch, before the formation of primordial follicles, two types of steroidogenic cells producing testosterone and estradiol, respectively, are identified in the left ovary (reviewed in Johnson, 1990; Saito and Shimada, 2001). Steroid production occurs coincidently with gene expression of appropriate enzymes involved in synthesis of particular hormones, i.e., CYP11A1, HSD3β, CYP17A1, HSD17β, and CYP19A1. Expression of CYP17A1 mRNA in female gonad is first detected around day five of embryogenesis, CYP19A1 at day six, and CYP11A1 and HSD3β on day seven of incubation. P450c17 enzyme activity in the ovary increases from day 9 to 11 of incubation and remains unchanged between days 11 and 15 of incubation (reviewed in Saito and Shimada, 2001; Hirst et al., 2018).

Further development of the ovarian follicle is accompanied by gradual changes in their steroidogenic activity. The amount and type of steroid synthesized depends on the stage of follicle development, sensitivity to gonadotropins, and locally produced factors. In prehierarchical follicles (up to 6−8 mm), the granulosa layer cells are mitotically active, undifferentiated, and steroidogenically incompetent. In contrary, the theca of prehierarchical follicles is the source of ovarian estradiol, and in lesser extend androgen, produced predominantly by the Δ5 pathway (reviewed in Johnson, 1990, 2015b; Sechman, 2013). In hierarchical follicles, both granulosa and theca layers are steroidogenically active. At follicle selection into preovulatory hierarchy, the cells of the granulosa layer begin to express CYP11A1 mRNA and progesterone production under LH-stimulation. During preovulatory growth of the yellow follicles, the synthesis of progesterone gradually increases. The largest F1 follicle becomes the major source of progesterone in the circulation. Yellow hierarchical follicles are main source of testosterone in the avian ovary. Along with these follicles development, synthesis of testosterone in the theca interna gradually increases; the F3 follicle secretes its greatest amount, while the F1 loses ability to convert progesterone to testosterone. In contrary, the theca externa of the hierarchical follicles, due to a gradual decrease in aromatase activity, reduces estradiol synthesis and secretion (Bahr et al., 1984; Robinson and Etches, 1986; Porter et al., 1989; Kato et al., 1995; Lee et al., 1998; Sechman et al., 2014; review in Rangel and Gutierrez, 2014; Johnson, 1990, 2015b). Nevertheless, in laying hens, yellow hierarchical follicles are equally an important source of estradiol as stroma and prehierarchical follicles (Proszkowiec-Weglarz et al., 2005).

In chicken embryos, plasma testosterone and estradiol concentrations increase between days 9 and 15 of incubation. Progesterone concentration in blood plasma starts to elevate from day 10 toward the hatching (day 20) and reaches peak levels several days following hatch. Thereafter, progesterone levels decline and remain low until the prepubertal period. Plasma levels of testosterone and estradiol do not fluctuate significantly during the first month posthatch (reviewed in Johnson, 1990). During sexual maturation, a progressive increase in plasma concentrations of estradiol, produced by the ovarian stroma and the theca layer of white follicles, 3 to 1 week before puberty (onset of egg lay) is observed. Subsequently, the estradiol plasma levels decrease. Plasma testosterone concentration reaches peak at 3 week prior to puberty, and then decreases 1 week before the first oviposition, again increasing at sexual maturity. Progesterone, produced by the granulosa layer of large, yellow hierarchical follicles, increases sharply just prior to the first ovulation, afterward remains unchanged (Sechman et al., 2000; Paczoska-Eliasiewicz et al., 2006). In the laying hen, during the ovulatory cycle, lasting from 24 to 26 h in the domestic chicken, the plasma concentration of estradiol and testosterone increases between 9 and 8 h before ovulation, while the level of progesterone increases around 7 h before ovulation. Elevated levels of these hormones remain several hours (reviewed in Johnson, 1990, 2015b; Etches, 1996; Paczoska-Eliasiewicz et al., 1998; Rangel and Gutierrez, 2014).

35.2.9 Control of ovarian follicle development and functions

Ovarian development and functions are under control of coordinated actions of hypothalamic gonadotopin-releasing and -inhibiting hormones (GnRH and GnIH; Sharp et al., 1990; Tsutsui et al., 2000; Bentley et al., 2008; Maddineni et al., 2008; Bédécarrats et al., 2009, 2016), pituitary gonadotropins (LH and FSH), and other endocrine and locally

produced factors such as prolactin (PRL; Zadworny et al., 1989; Hrabia et al., 2004b; Hu and Zadworny, 2017; Hu et al., 2017a, 2017b), GH (Hrabia, 2015; Ahumada-Solórzano et al., 2016; Socha and Hrabia, 2019), thyroid hormones (Sechman, 2013), ghrelin (Sirotkin et al., 2006, 2016, 2017; Sirotkin and Grossmann, 2007a), growth factors (Onagbesan et al., 2009; Ahumada-Solórzano et al., 2016), adipokines (Ramachandran et al., 2013; Diot et al., 2015; Mellouk et al., 2018; Estienne et al., 2019; Hadley et al., 2020), calcitonin (Krzysik-Walker et al., 2007), retinoids (Pawłowska et al., 2008), leptin (Paczoska-Eliasiewicz et al., 2006; Sirotkin and Grossmann, 2007b), kisspeptin-10 (Xiao et al., 2011), PGs (Jin et al., 2006; Jia et al., 2010), parathyroid hormone-like hormone (Guo et al., 2019), and ovarian steroids (Camacho-Arroyo et al., 2007; Rząsa et al., 2009; Rangel and Gutierrez, 2014). Role of these factors is related primarily to direct or indirect regulation of ovarian cell proliferation, differentiation, apoptosis, and steroidogenesis. Some of the most important ovarian regulators are presented below.

35.2.9.1 Gonadotropin-inhibitory hormone

Gonadotropin-inhibitory hormone (GnIH) is a neuropeptide produced by and released from the hypothalamus. Its physiological effect is realized by specific receptor (GnIHR), a member of the G-protein coupled receptor family which couples to G(αi) and, upon activation inhibits adenylyl cyclase activity, consequently reducing intracellular cAMP levels. Main GnIH function is an inhibition of hypothalamic gonadotropin-releasing hormone (GnRH-I and GnRH-II) release and the synthesis and secretion of pituitary gonadotropins (Tsutsui et al., 2000; Bédécarrats et al., 2009, 2016). Presence of GnIH and its receptor in the ovary indicates that this neuropeptide influences ovarian follicle maturation, at least in part, in an autocrine/paracrine manner as well (Bentley et al., 2008). Within the chicken ovary, GnIHR mRNA is detected in both theca and granulosa cells. Greater GnIHR mRNA expression is in the theca layer of prehierarchical follicles compared with that of preovulatory follicles. GnIHR mRNA level is lower in the ovaries of sexually mature hens than in sexually immature chickens. Therefore, there is suggestion that GnIH exerts an inhibitory role in ovarian follicle development (Maddineni et al., 2008). The expression of GnIHR seems to be regulated by steroid hormones since treatment of sexually immature chickens with estradiol and/or progesterone caused a decrease in the GnIH mRNA abundance (Maddineni et al., 2008).

35.2.9.2 Gonadotropins (luteinizing hormone and follicle-stimulating hormone)

Key hormones driven ovarian follicle development and function are gonadotropins. Their release is under control of releasing and inhibitory hormones produced in the hypothalamus. The GnRH stimulates gonadotropin secretion (Sharp et al., 1990), while GnIH blocks LH an FSH release (Tsutsui et al., 2000). Both LH and FSH are responsible for follicular growth and development, while only LH induces ovulation.

In chickens, the LHβ subunit gene is expressed in the pituitary since day four of embryonic development, and LHβ immunoreactivity appears in the anterior pituitary gland on day eight of incubation (Maseki et al., 2004). In the female pituitary gland, the expression of LHβ mRNA increases on day one after hatching in comparison to embryonic day 11 or 17 (Grzegorzewska et al., 2009). The FSHβ gene is expressed in the chicken pituitary from day seven, and immunopositive reaction is detectable from day eight of incubation (Maseki et al., 2004). In the female embryo, the abundance of FSHβ transcript increases between days 11 and 17 of incubation (Grzegorzewska et al., 2009). Plasma LH in females is detected on day 10 of incubation (Tanabe et al., 1986) and increases across embryonic development reaching a plateau near hatching. Serum LH shows a maximum on day 19 of incubation (Gonzalez et al., 1987), while FSH remained low throughout the incubation period (Rombauts et al., 1993). In chickens, a prepubertal rise in plasma LH occurring 5−3 weeks prior to egg laying (Sharp, 1975; Wiliams and Sharp, 1977; Wiliams et al., 1986; Paczoska-Eliasiewicz et al., 2006) is suppressed by the increasing concentrations of estradiol 3−1 week before maturation. Then, progesterone, increasing sharply just prior to the first ovulation, triggers the preovulatory LH surge (Paczoska-Eliasiewicz et al., 2006). In addition, in immature hens, a pronounced increase in LH has been observed at the onset of darkness (Wilson et al., 1983). Comparatively less is known about circulating concentrations of FSH. In laying chickens, plasma FSH concentrations are relatively constant during ovulatory cycle, except an increase 15−12 h before ovulation (Scanes et al., 1977a; Krishnan et al., 1993). In turn, plasma LH concentrations peak 6−4 h before ovulation (Johnson and van Tienhoven, 1980; reviewed in Johnson, 1990; Rangel and Gutierrez, 2014). Role of this preovulatory LH surge is to induce ovulation (as discussed in this chapter). Less pronounced peak of LH is also noted 14−11 h prior to ovulation; however, its role is not elucidated. In addition to ovulation-related increase in LH levels, diurnal rhythm of LH secretion in the laying hen with increase in plasma concentration of LH occurring at the onset of darkness was revealed. This increase in LH may serve to time, but is not sufficient to initiate events that culminate in the preovulatory surge of LH (Wilson et al., 1983).

Gonadal expression of FSH and LH receptor mRNA (FSHR and LHR) is detected on day four of incubation in both sexes. Then, FSHR mRNA in the chicken ovary increases between days 11 and 17 of embryonic

development. There are no significant changes in LHR transcript levels in the second half of embryogenesis. Positive correlation between the ovarian FSHR mRNA expression and pituitary FSHβ transcript level indicates the crucial role of FSH in the ovarian development (Grzegorzewska et al., 2009). FSH stimulates cell proliferation and sex steroid synthesis in the left ovary (Pedernera et al., 1999; Velazquez et al., 1997) by stimulation of aromatase and 3β-HSD activity (Gómez et al., 2001). LH promotes estradiol synthesis and secretion from the left ovary in vivo (Teng et al., 1977, 1982; Woods et al., 1981) and in vitro (Gonzalez et al., 1987). LH treatment during embryonic development inhibits oogonia proliferation and induces meiotic prophase and follicle formation in the ovaries of newly hatched chicks (Gonzalez-Moran, 2007). Prepubertal changes of FSHR and LHR demonstrated in the duck ovary indicate that developing ovary is highly responsive to the FSH during the earlier stage, but when approaching the onset of sexual maturation, the ovary is likely more responsive to LH (Ni et al., 2007). The expression of FSHR and LHR genes changes according to the follicle development status. FSHR are present in both theca and granulosa layers of follicle at all developmental stages. The greatest abundance of FSHR around follicle recruitment to the preovulatory hierarchy, decreases along with follicle maturation, and is lowest in atretic follicles (You et al., 1996; Zhang et al., 1997). In contrast, LHR mRNA expression occurs in the theca cells of prehierarchical and hierarchical follicles, while within the granulosa layer is detected only after follicle selection in response to FSH and possibly VIP. Thus, revealed increase in steroid release by whole prehierarchical follicles in response to LH is attributed to the theca layer (Sechman et al., 2016, 2020). In fast growing preovulatory follicles, LHR expression in the theca layer decreases, while in the granulosa layer increases along with follicle maturation. The highest LHR expression is in the F1 follicle destined to ovulation (Zhang et al., 1997). Consequently, LHR mediates LH-stimulated progesterone, and to a lesser extent androgen, synthesis by granulosa cells in the preovulatory follicle.

35.2.9.3 Ovarian steroids

Ovarian steroids are involved in the regulation of variety of reproductive processes, including the local regulation of the ovarian development and function by autocrine/paracrine manner. Progesterone, androgen, and estrogen effects are mediated by their intracellular and membrane receptors. The first ones belong to a superfamily of ligand-activated transcription factors that control gene expression by interacting with DNA-specific sequences called hormone-responsive elements, while the latter ones are transmembrane proteins coupled to G proteins that induce changes in second messenger cascades.

35.2.9.3.1 Progesterone

Progesterone receptors (PRs) are present at all levels of the hypothalamo-pituitary-ovarian axis, in both the embryo and adult chickens. Two isoforms of nuclear PRs are expressed in birds as a product of one gene: PR-A and PR-B. They regulate different gene and exert different functions. Responsiveness to progesterone depends on the ration of PR-A and PR-B expression. Their abundance and ratio depends on the tissue and reproductive state, among others sexual maturity and ovulation-oviposition cycle (reviewed in Camacho-Arroyo et al., 2007). The role of progesterone is related primarily to ovulation process. Serum progesterone and LH preovulatory rises have a positive feedback (Lagüe et al., 1975). Progesterone stimulates preovulatory LH surge by induction of GnRH-I release from hypothalamus (Johnson, 1990, 2015b; Rangel et al., 2014). Moreover, progesterone is involved in the regulation of sexual and nesting behaviors, as well as oviduct development and its secretory activity (discussed further in this chapter).

Presence of PR protein, mainly PR-B isoform, in the female gonad is observed from day six of embryonic life. In the immature chicken ovary, PRs are detected in germinal epithelium, thecal, and stromal cells, but not in granulosa cells (Isola et al., 1987; González-Morán and Camacho-Arroyo, 2001). These results indicate that progesterone exerts its effects in the developing ovary by PR-B-mediated signaling. Differential expression of membrane PRγ was also reported in the ovaries of embryonic, newly hatched, and 1-month-old chickens suggesting participation of membrane PR in the progesterone-regulated growth and activity of the left ovary (González-Morán et al., 2013). In the laying hen ovary, PRs are localized in the granulosa layer, theca layers, and germinal epithelium including stigma region of follicles. The presence of PR in specific ovarian tissues strongly indicates that progesterone also locally regulates follicular maturation and ovulation (Yoshimura and Bahr, 1991a). Cell-specific changes in the total abundance PRs and the cellular ratio of PR-A and PR-B are under gonadotropins, estrogens, and progesterone itself control (reviewed in Camacho-Arroyo et al., 2007).

35.2.9.3.2 Androgens

Ovarian tissues are also targets for androgen actions. There is evidence that androgen by androgen receptor (AR)-mediated signaling may be involved in chicken ovarian morphogenesis (González-Morán et al., 2013). Further, AR is localized to the granulosa cells and theca cells at every stage of follicle development, except for the granulosa cells of the primordial and primary follicles (Yoshimura et al., 1993a). Testosterone plays a major role in the ovulatory process (as discussed in this chapter) and promotes progesterone production by the granulosa of the preovulatory follicles, even in absence of LH (Sasanami and Mori, 1999;

Rangel et al., 2006). As presented in vitro, the role of testosterone is related to stimulation of StAR, CYP11A1, and LHR mRNA expression when acts at physiological concentrations (Rangel et al., 2009). On the other hand, earlier results suggested that testosterone suppresses progesterone production by chicken granulosa cells of F1 follicle, acting as a competitive inhibitor of the P450scc (Johnson et al., 1988; Lee and Bahr, 1990).

35.2.9.3.3 Estrogens

The biological, multiple effects of estrogens are mediated mainly via two forms of estrogen receptors, alpha (ERα) and beta (ERβ). In birds, estrogens by ERα, but not ERβ, are thought to have a critical role in sex differentiation of gonads and development of the ovarian cortex in the left gonad. Estrogen receptor mRNA is expressed in both male and female gonads from day 4.5 of incubation; however, is more abundant in the left female gonad than in the right, from at least 7.5 day of chicken development. Moreover, ERα is present in a greater abundance in the ovarian cortex then in the medulla (Andrews et al., 1997; Guioli et al., 2014; González-Morán, 2014; Mattsson and Brunström, 2017; Hirst et al., 2018).

In the mature ovary, the roles of estrogen are related to the control of steroidogenesis, induction of PRs, cell proliferation, and protection against apoptosis. The wall of follicles at all developmental stages expresses ERα and ERβ mRNA, but in contrary to mammals, the main form of ER expressed in the avian ovary is ERα. Higher ER mRNA expression is detected in the granulosa layer then in the theca layer of preovulatory follicles (Hrabia et al., 2004a, 2008a). Immunohistochemically, ERs are localized to the interstitial cells of the theca layer of white follicles as well as to the granulosa cells and interstitial or aromatase cells in the theca layer of preovulatory follicles, suggesting involvement of estrogen in the regulation of steroidogenesis (Yoshimura et al., 1995). Such a role was evidenced. For instance, blockage of ERs by tamoxifen significantly modulates the chicken ovarian steroid production (Rząsa et al., 2009). Involvement of estradiol in mediation of LH-induced progesterone production in vitro by quail granulosa cells was also demonstrated (Sasanami and Mori, 1999). Injection of hypophysectomized birds with estrogen suppresses atresia in yellow follicles (Yoshimura and Tamura, 1986). Moreover, estradiol acts as an inducer of PRs at the hypothalamus, i.e., "primes" the hypothalamus and enhances the progesterone-stimulated LH release before ovulation (Etches, 1990).

In addition, estrogens are key hormones involved in the development of female secondary sexual characteristics, sexual differentiation of the nervous system, sexual behavior, and mobilization of calcium for eggshell formation. Synthesis of a group of egg yolk proteins, including apoVLDLII and VTG, in the liver and egg albumen proteins in the oviduct is also primarily estrogen-stimulated (as discussed in this chapter).

35.2.9.4 Growth hormone

The elevated GH concentration in chicken blood plasma at the onset of lay (Williams et al., 1986), around the time of ovulation (Harvey e al., 1979) as well as an attenuated concentrations of GH in chicken, turkey, and bantam hens with the cessation of egg laying (Scanes et al., 1979; Sharp et al., 1979; Bedrak et al., 1981) indicate the endocrine GH effects on the ovary function.

Growing evidence has demonstrated that the avian ovary is an extrapituitary site of GH synthesis and endocrine, paracrine, and/or autocrine actions. GH mRNA and protein expression occurs in the chicken ovarian follicles, with greater intensity in the granulosa layer and lower in the theca layer (Hrabia et al., 2008b; Ahumada-Solórzano et al., 2012; Luna et al., 2014). The GH receptors are also present in the chicken premature and mature ovary (Heck et al., 2003; Lebedeva et al., 2004; Hrabia et al., 2008b; Ahumada-Solórzano et al., 2012). The intraovarian role of GH is related to the regulation of steroidogenesis, cell apoptosis and proliferation, the modulation of LH action, and folliculogenesis in growing and sexually mature birds (Hrabia, 2015; Ahumada-Solórzano et al., 2016; Socha and Hrabia, 2019). The evidence of increased estradiol secretion by whole chicken prehierarchical ovarian follicles and decreased by yellow preovulatory follicles (Hrabia et al., 2012; Hrabia, 2015) as well as stimulation of progesterone production by whole (Hrabia et al., 2014a) or just the granulosa cells (Ahumada-Solórzano et al., 2012) of yellow follicles were demonstrated. The effect of recombinant chicken GH (chGH) on progesterone secretion is probably due to a direct up-regulation of CYP11A1 but not HSD3β enzyme expression (Ahumada-Solórzano et al., 2012). Moreover, an increase in both steroid contents in the ovary around the time of maturation in chickens treated with chGH during puberty as well as an increase in plasma progesterone, testosterone, and estradiol concentrations after chGH injections during a pause in laying have been reported (Hrabia et al., 2011; Socha et al., 2017).

The effects of GH observed in the avian ovary, reflect not only its direct impacts on cell functions but also indirect ones, mediated by insulin-like growth factors (IGF-1 and IGF-2). All members of the IGF system are identified in the chicken ovary, and IGFs are produced in ovarian follicles, at least in part, in response to GH (reviewed in Onagbesan et al., 1999; Hrabia, 2015). The proliferating and regulating steroidogenesis effects of the IGFs are well established (Onagbesan et al., 2009; Ahumada-Solórzano et al., 2016). In addition, an autocrine/paracrine proliferative effect of the locally

synthesized GH by granulosa cells from ovarian prehierarchical follicles, which is mediated via local IGF-1 was in vitro demonstrated (Ahumada-Solórzano et al., 2016).

35.2.9.5 Prolactin and prolactin-like protein

Apart from a fundamental role in the initiation and maintenance of incubation behavior in many species of birds (reviewed in Ohkubo, 2017), there is evidence that PRL has both pro- and antiovarian roles, acting at all levels of the hypothalamo-pituitary-ovarian axis. At the period of sexual maturation, the circulating PRL levels gradually increase at the onset of egg laying. During the ovulatory cycle of the chicken, its concentrations are highest around 10 h and lowest 6 h before ovulation (Scanes et al., 1977). An active immunization against PRL suppresses chicken egg production by reducing follicular recruitment into the hierarchy (Li et al., 2011). These observations indicate that PRL at lower concentrations appears to be progonadal. In turn, high and prolonged elevated PRL concentrations are associated with ovary regression and reduction in ovarian steroidogenesis (Hu et al., 2017a, 2017b). The direct suppression of hypothalamic GnRH levels in turkey (Rozenboim et al., 1993) and pituitary LHβ subunit mRNA expression by PRL in chicken (Kansaku et al., 1994) and turkey (You et al., 1995) is also observed.

Growing evidence has demonstrated that the avian ovary is a target site for direct PRL action. PRL gene expression occurs at very low level but PRL receptor mRNA is expressed richly in all follicle size classes, with the highest abundance found in the stroma and wall of follicles <2 mm. In the preovulatory follicles, the PRL receptor transcript is more abundant in granulosa than theca layers (Zhou et al., 1996; Hu et al., 2017a; Hrabia et al., unpublished data). It was proposed that changes in PRL receptor transcript levels during follicle development are related to changes in the process of follicular steroidogenesis and different responsiveness to gonadotropins and PRL variants (Hu et al., 2017a).

The action of PRL in the hen ovary is related to ovarian steroid synthesis. PRL suppresses both basal and gonadotropin-induced levels of progesterone and estradiol production by the ovary (Camper and Burke, 1977). In vitro, PRL inhibits both basal and LH-stimulated estrogen production by small ovarian follicles (Zadworny et al., 1989; Hrabia et al., 2004b). Effects of PRL on in vitro steroid secretion by preovulatory ovarian follicles are stimulatory or inhibitory dependant on the dose of PRL, the type of follicular wall layer, the stage of follicle maturation, and the stage of the ovulatory cycle (Hrabia et al., 2004b; Hu and Zadworny, 2017). Furthermore, glycosylation modulates the actions of PRL in basal and gonadotropin-stimulated follicular steroidogenesis depending on the concentration, the type of gonadotropin, and the stage of follicle development (Hu and Zadworny, 2017). The impact of PRL on steroid production by ovarian follicular cells of hens is mediated through modulation of the expression of steroidogenic enzyme (StAR, CYP11A1, CYP19A1, and HSD3β) expression (Tabibzadeh et al., 1995; Hu and Zadworny, 2017).

A novel prolactin-like protein (PRL-L) has been revealed in the chicken, and in contrast to PRL that is predominantly expressed in the pituitary, the PRL-L is expressed in extrapituitary tissues including the ovary, in both embryonic and adult chickens (Wang et al., 2010). Within the ovary, PRL-L mRNA levels are the highest in the wall of the smallest (<2 mm) follicles. As follicles grow and mature, the expression of PRL-L gradually declines. The transcription of PRL-L in undifferentiated granulosa cells appears to be regulated by FSH or PRL variants independently, or in combination. The stimulatory action of FSH on PRL-L expression is mediated by multiple signaling pathways including the adenylyl cyclase/cAMP/protein kinase A and the inositol phospholipid signaling pathways (Hu et al., 2017b). However, the physiological significance of PRL-L in the avian ovary remains unknown.

35.2.9.6 Ghrelin

Ghrelin is a hormone produced primarily by the proventriculus. There is also evidence for the ovarian expression of ghrelin and its receptor and involvement of ghrelin in the modulation of chicken ovarian cell proliferation, apoptosis, and hormone secretion (Sirotkin et al., 2006, 2016). Increase in testosterone secretion and decrease in estradiol release in vitro by the chicken preovulatory follicle wall in response to ghrelin was shown as well (Sirotkin and Grossmann, 2007a). Moreover, treatment of hens with ghrelin 1-18 prevents the food restriction-induced decrease in ovarian testosterone, estradiol, and arginine vasotocin (AVT), but it do not change progesterone output or egg laying (Sirotkin and Grossmann, 2015). Ghrelin can also mediate the effect of metabolic state on hormones involved in the control of reproduction (Sirotkin et al., 2017). The action of ghrelin in the ovary was proposed to be mediated by MAPK-and PKA-dependent mechanisms (Sirotkin and Grossmann, 2007a).

35.2.9.7 Thyroid hormones

It is well established that thyroid hormones, thyroxine (T4) and triiodothyronine (T3), are involved in the regulation of avian reproduction. The disturbed thyroid gland function is frequently accompanied by abnormalities in the reproductive system. In several species of birds, thyroid hormones are required for the onset of the seasonal reproductive cycle as well as for development of photorefractoriness and the

resulting cessation of reproduction, and also in the expression of incubation behavior in birds (Sharp, 2005; Nakao et al., 2008a,b; Siopes et al., 2010; reviewed in Yoshimura, 2010). They are also involved in the last phase of sexual maturation, as indicated by a negative relationship between thyroid hormones and ovarian steroids concentrations in blood plasma, during chicken sexual maturation (Peczely, 1985; Sechman et al., 2000).

Treatment of hens with single or multiple injection of T3 reduces in a dose-dependent manner the egg laying rate, ovarian weight, and decreases plasma LH and sex steroid concentrations (Sechman et al., 2009). Moreover, dose-dependent changes in the ovarian morphology, i.e., an atresia of the hierarchical follicles, are observed (Sechman, 2013). In the ovarian follicles, T3 decreases estradiol and progesterone synthesis with simultaneous reduction in CYP19A1 and HSD3β mRNA expression. These results suggest that in the laying chickens, thyroid hormone act at the hypothalamo-pituitary level, diminishing production and/or secretion of LH which in turn negatively affects ovarian steroidogenesis and/or at the ovarian level, directly influencing this process (reviewed in Sechman, 2013).

In the chicken ovarian follicles, both granulosa and theca layers express mRNA encoding the nuclear thyroid hormone receptors (TRα and TRβ0 isoforms) as well as the plasma membrane receptor, ITGAV and ITGB3 (encoding αV and β3 subunits of the integrin receptor), indicating genomic and nongenomic action of iodothyronines in the chicken ovary (Sechman et al., 2009; Sechman, 2013). In vitro studies revealed that T3 increases progesterone secretion by the granulosa layer of the largest preovulatory follicles (F3−F1), and decreases estradiol secretion by the white prehierarchical follicles and the theca layer of preovulatory F3−F1. These effects were attributed to expression of StAR protein and steroidogenic enzymes as well as to modulation of the cAMP signaling pathway in steroidogenic cells of ovarian follicles. Results to date indicate that the iodothyronines by affecting ovarian steroidogenesis may participate in the processes occurring during the recruitment of yellowish follicles into preovulatory hierarchy, and during growth and maturation of the yellow hierarchical follicles in the laying chicken (Sechman et al., 2011; Sechman, 2013).

35.2.9.8 Adipokines

Evidence is accumulating that adipokines may also play a role in the follicular development and function. In laying hens, adiponectin and two adiponectin receptor (AdipoR1 and AdipoR2) are present in both granulosa and theca cells. Systemic and/or mainly theca-derived adiponectin may affect proliferation, metabolism, and steroidogenesis in the avian ovary (Chabrolle et al., 2007; Hadley et al., 2020). Other adipokines such as chemerin and visfatin have also been identified in the avian (chicken or turkey) ovary, and their roles were related to steroid synthesis, at least in part, by influencing StAR and HSD3β expression or modulation of IGF-I effect (reviewed in Mellouk et al., 2018; Estienne et al., 2019).

35.2.10 Ovarian tissue remodeling

Follicle growth, development, ovulation, and atresia in the avian ovary are accompanied not only by changes in cell physiology but also by extensive reorganization of the ECM. The ECM components influence basic cellular processes such as proliferation, differentiation, apoptosis, and adhesion. Thus, the ECM is crucial for proper follicular development, function, and atresia/regression. The comprehensive changes in ECM across follicle development require a cascade of proteolytic processes. Former studies suggested participation of PAs that catalyze the conversion of the proenzyme plasminogen to plasmin in these events. Observed high PA activity in the nonstigma region of growing follicles or granulosa cells of the mitotically active germinal disc region of the F1 indicated possible role of PA in remodeling of the ECM of the follicular wall during follicular growth and maturation (Jackson et al., 1993). Involvement of PA in follicle cell proliferation, especially the granulosa cells, was postulated as well (Tilly et al., 1992). More recently it has been indicated that ECM turnover during follicle development/atresia is largely controlled by the MMPs (Hrabia et al., 2019; Wolak and Hrabia, 2020). Besides specific degradation of ECM constituents and activation of other MMPs, they can affect diverse signaling pathways that modulate cell biology in normal physiological and pathological processes by releasing numerous signaling proteins. Among these are growth factors, cytokines, E-cadherin, Fas ligand, and tumor necrosis factor. Recent studies have provided evidence for the hen ovary as a side of MMPs synthesis and action. The presence and changes in activity of several MMPs and alterations in expression of their tissue inhibitors in chicken ovarian follicles across the period of development, suggest that these molecules participate in the regulation of follicle growth and maturation (Leśniak and Hrabia, 2012; Zhu et al., 2014; Hrabia et al., 2019). Since localization of MMPs, mainly in the theca layers, correlated with macrophages localization and frequency (Barua et al., 1998), these cells in addition to fibroblasts were suggested to be a significant source of MMPs in the follicular wall. A role for ovarian steroids, mainly estrogen, in regulating the transcription, translation, and/or posttranslational activity of MMPs was also demonstrated (Ogawa and Goto, 1984; Zhu et al., 2014; Wolak and Hrabia, 2020).

35.2.11 Follicle atresia

Ovarian follicle atresia is a normal physiological phenomenon that eliminates unnecessary ovarian follicles by a noninflammatory process and can occur at any stage of follicular development, from primordial to ovulatory. In birds, atresia is a common destiny in the pool of small follicles that are not selected to complete follicle development (Johnson and Woods, 2007). Only 5% of white follicles reach a diameter of 6–8 mm and enter the follicular hierarchy. In normal physiological conditions, there is little atresia associated with follicles as they advance toward ovulation. In the pool of hierarchical follicles, atresia can only be induced by metabolic or environmental disturbance such decrease in gonadotropin availability, ovarian steroid imbalance, disease, fasting, or the light day shortening (Figure 35.8A). Interestingly, during the induced pause in laying the chicken hierarchical follicles undergo atresia, and the prehierarchical follicles are resistant to this event (Proszkowiec-Weglarz et al., 2005; Socha and Hrabia, 2019).

The atretic follicles differ morphologically and functionally from that of healthy, properly developing follicles. The yellow atretic follicles are shrunken and often hemorrhagic (Figure 35.8A). The wall of atretic follicle (Figure 35.8B–D) is characterized by hypertrophy of the connective tissue, loosening of the theca layers, disintegration of the granulosa layer, and displacement of the granulosa and theca cells into the lumen of the follicle (Hodges, 1974). Moreover, late atresia is associated with

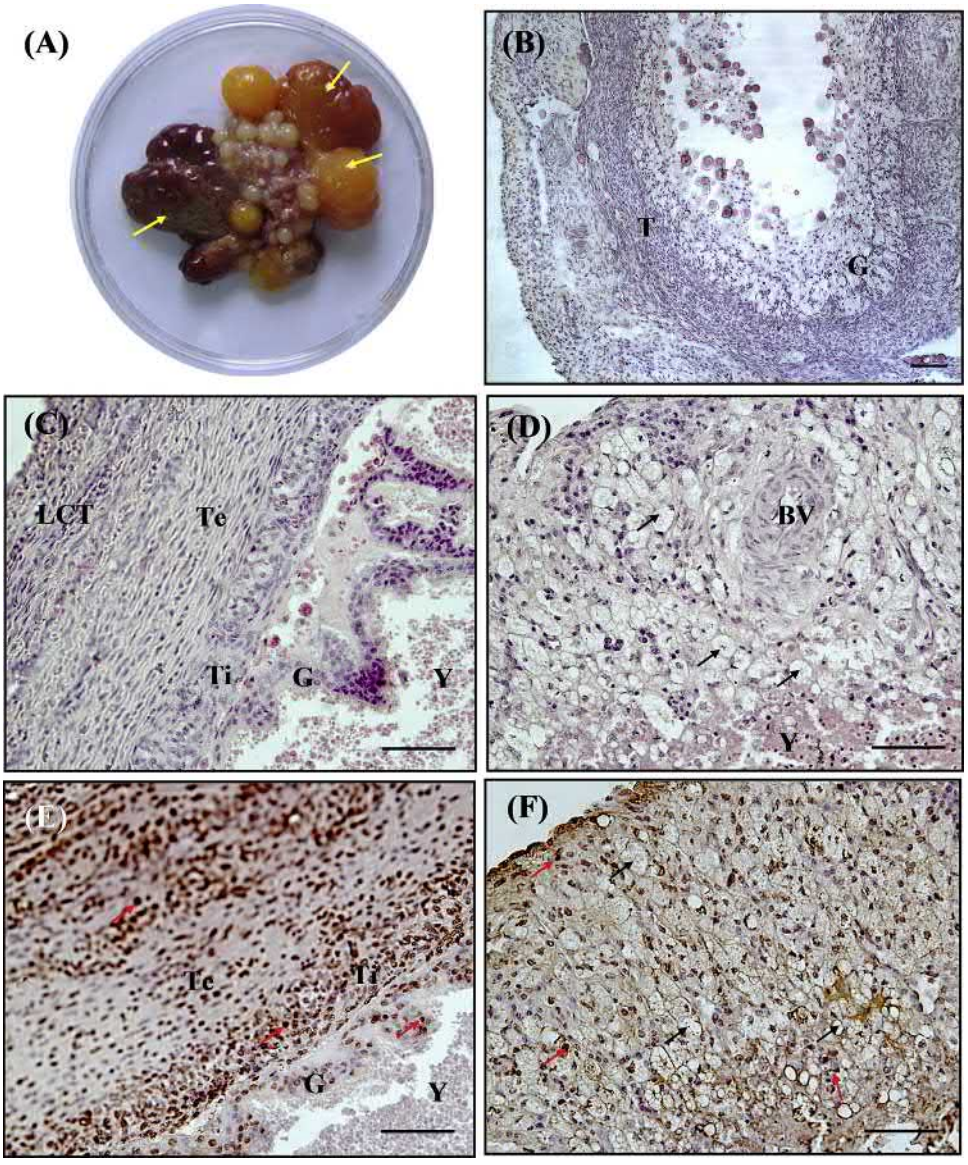

FIGURE 35.8 (A) The ovary with atretic large yellow follicles (*arrows*). The largest follicles are shrunken, grossly regressed, and often hemorrhagic. (B) Histological structure of the atretic primary follicle localized in the ovarian stroma. (C) Histological structure of the atretic yellow follicle at early stage of atresia. Detached granulosa layer (G), disappearance of the basement membrane, and disintegration of the theca interna (Ti) are observed. (D) Histological structure of the large yellow follicle at advanced stage of atresia. Disintegration of entire follicular wall and lipid accumulation (*black arrows*) are recognized. (E) and (F) Localization of apoptotic (TUNEL-positive) cells displaying brown nuclear staining (*red arrows*) in the wall of yellow follicle at early and advanced stage of atresia, respectively. *BV*, blood vessel; *LCT*, loose connective tissue; *Te*, theca externa; *Y*, yolk. Bar = 50 μm.

accumulation of huge amount of lipids. The steroidogenic activity of atretic follicles is significantly reduced. Although aromatase and 3β-HSD enzyme activities are detected at early stage of follicle atresia, the activities and accompanied estradiol and progesterone synthesis are dramatically decreased as degeneration progresses (Proszkowiec-Weglarz et al., 2005).

The follicle atresia in the avian ovary is realized mainly via apoptotic cell death initiated within the granulosa layer. As atresia continues, apoptosis progresses across the theca layers (reviewed in Johnson and Woods, 2007) (Figure 35.8E and F). Involvement of autophagy and necrosis in follicle atresia is additionally proposed (D'Herde et al., 1996). Apoptosis is a form of cell death allowing the controlled removal of unwanted, damaged, or aged cells. The control of cell death is dependent on competing pro- and antiapoptotic molecules. Among them are proteins from the B-cell lymphoma-2 (Bcl-2) family, survivin, an inhibitor of T-cell apoptosis, and the apoptosis-inducing factor FasL. In this event, two essential signaling pathways are engaged: extrinsic (initiating by the binding of a ligand to a transmembrane death receptor) and intrinsic (mediated by factors released from the mitochondria). Each of these pathways has its own initiator caspases which in turn activate effector caspases leading to the cleavage of numerous cellular proteins and finally cell death (Elmore, 2007). Most of mentioned signals are expressed in the chicken developing follicles and correspond to resistance or susceptibility of granulosa cells to apoptosis (Johnson and Woods, 2007; Socha and Hrabia, 2019).

A dramatically reduced susceptibility to atresia of the yellow preovulatory follicles is attributed to considerably increased resistance to apoptosis and elevated viability of granulosa cells after transition from a prehierarchical to preovulatory stage of development. The resistance to apoptosis is coordinated, at least in part, by numerous antiapoptotic proteins, products of genes expressed in response to cAMP signaling activation. Among them is inhibitor of apoptosis proteins, B-cell lymphoma-extra large (Bcl-xL), and Bcl-2 (Johnson, 2015a). In turn, decrease in mRNA abundance of the cell survival protein, Bcl-xL, and in addition significant reduction in expression of VEGF together with their receptors (VEGFR1 and VEGFR2) within the granulosa and theca layers, lead to follicle atresia (Kim et al., 2016). Recent study (Hrabia et al., 2019) suggests the engagement of MMPs, including MMP-2 and -9, in the atresia of chicken prehierarchical follicles. A markedly higher activity of both gelatinases in small atretic follicles in comparison with white healthy follicles was observed. This proposal may not apply to the atresia of the yellow preovulatory follicles because within them, in advanced stage of atresia, the activity or abundance of several MMPs were significantly lower than in the normal yellow hierarchical follicles (Wolak and Hrabia, 2021). Other factors such as aquaporins (AQPs) may also control follicular atresia by mediation of water loss needed for downstream apoptotic events in granulosa cells. A strong immunoreactivity for AQP4 is observed in prehierarchical atretic follicles (Nowak et al., 2017).

35.2.12 Chicken ovary as a model for human ovarian cancerogenesis

The egg production by commercial laying hens is highly efficient. They lay more than 300 eggs per year and ovulate at near 24 h intervals. As a consequence of this high-repetitive ovulation or events associated with ovulation, the development of ovarian tumors is postulated (Johnson et al., 2015). Like humans, the spontaneous occurrence of ovarian cancers in the domestic hens increases with age; up to 35% of hens develop adenocarcinoma after 2.5 year of age (Fredrickson, 1987). Repeated cycles of rupture and repair of the ovarian epithelium probably promote DNA damage and mutation of ovarian epithelium cells lading to subsequent development of an epithelial-derived cancer (Hakim et al., 2009). Oviduct may be an alternative site of ovarian tumor origin. Some oviduct-related genes including ovalbumin are identified and upregulated in hen ovarian tumors (Treviño et al., 2010). In addition, numerous proteins involved in the regulation of the oviduct function were found as a potential diagnostic biomarker of ovarian cancer in laying hens. Among them are vitelline membrane outer layer protein 1 (VMO1) (Lim and Song, 2015), apolipoprotein D (Jeong et al., 2015), alpha 2 macroglobulin (Lim et al., 2011), WNT4 (Lim et al., 2013), beta-catenin (CTNNB1) (Bae et al., 2014b), and cell cycle-related cyclins, cyclin-dependent kinases, and cyclin-dependent kinase inhibitors (Lee et al., 2012). Involvement of estrogen and specific miRNAs in these gene regulation was also indicated.

Moreover, participation of AQP3 and AQP5 in the avian ovarian tumorigenesis was suggested (Tiwari et al., 2014; Yang et al., 2016). Increased protein abundance of both AQPs was found in the chicken cancerous ovary. Similar histological subtypes and cellular marker expression (cytokeratin, proliferating cell nuclear antigen (PCNA), cyclooxygenase 1 and 2, p53 tumor suppressor gene, and HER-2/neu oncogene) in hen and human ovarian tumors, serve the avian ovary as a unique model for the human ovarian cancer investigation (Rodriguez-Burford et al., 2001; Urick and Johnson, 2006; Barua et al., 2009; Hakim et al., 2009; Treviño et al., 2012; reviewed in Johnson and Giles, 2013; Johnson et al., 2015; Yoshimura and Barua, 2017).

In addition, chicken is also an excellent model for research involving the molecular basis underlying the development of human uterine fibroid. Laying hens develop fibroids in the oviduct (magnum and shell gland)

spontaneously, with large similarities to fibroids in women. Among them is the expression of TGF, ER, PR, Bcl-2, PCNA, alpha-smooth muscle actin, and desmin (Berry et al., 2006; Machado et al., 2012).

35.3 The oviduct

The oviduct develops from the Mullerian (paramesonephric) duct, originally derived from the urogenital ridge. The tubal ridges appear on both sides on embryonic day 4 as a groove-like invagination of the coelomic epithelium at the cranial end of the mesonephros. The left Mullerian duct continues to develop, growing caudally and by day 11 it reaches the cloaca. Differentiation of the various regions of the duct becomes apparent between days 12 and 13. The right duct similarly develops for a time but its regression occurs from about embryonic day 11. It disappears completely by the time of hatching (reviewed in Gilbert, 1979).

Rapid development of the left oviduct to the fully functional organ occurs in the domestic hen during several weeks prior to the first egg lay (Figure 35.9A and B). Over a period of 7 weeks before sexual maturity, the oviduct weight increases from about 0.12 to 50.5 g and is accompanied by a remarkable capacity to secrete egg components (Hrabia et al., 2016).

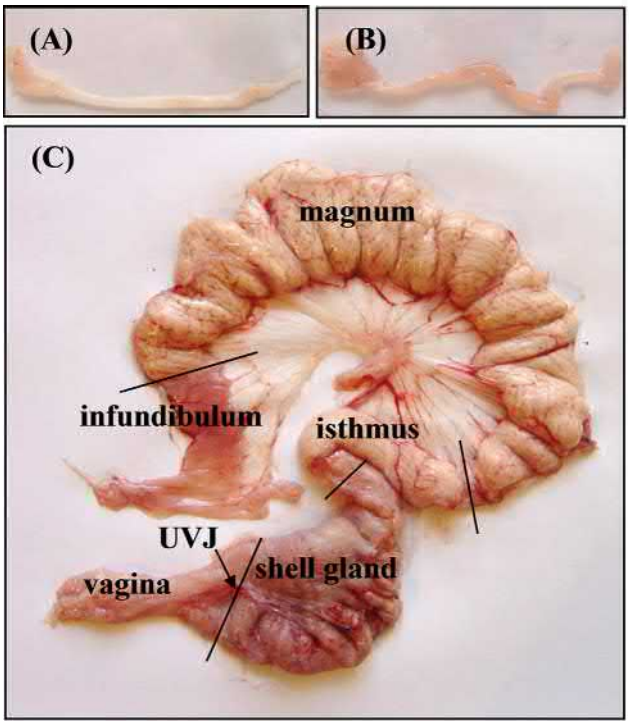

FIGURE 35.9 The hen oviduct. (A) The oviduct of growing chicken about 7 weeks before maturation. (B) The oviduct of growing chicken about 3 weeks prior to the onset of egg lay. (C) The oviduct of laying hen composed of the infundibulum, magnum, isthmus, shell gland (uterus), and vagina. *UVJ*, uterovaginal junction.

The oviduct is suspended within the abdominal cavity by dorsal and ventral ligaments, by which the blood vessels and nerves supply the particular oviductal parts. The laying hen oviduct includes five morphologically and functionally specific segments: the infundibulum, magnum, isthmus, shell gland (uterus), and vagina (Figure 35.9C).

The wall of the oviduct is composed of: (1) an outer epithelium, (2) a double layer of smooth muscles (outer longitudinal and inner circular) with an interspersed connective tissue layer in which lie blood vessels, (3) a layer of connective tissue, (4) a lamina propria including tubular glands lined by secretory cells, and (5) an inner surface (luminal) epithelium lined by ciliated nonsecretory and nonciliated secretory cells. The last two layers constitute the mucosa which possess complexity and is formed into folds. In the magnum, isthmus, and shell gland, the tubular glands are well developed to synthesize constituents of the albumen, eggshell membranes, and eggshell, respectively. The products of the tubular gland cells are delivered to the lumen via a short duct. The ultrastructural appearance and secretory activity of the mucosal cells change during the formation of the egg as it passes through the oviduct (for more details regarding oviduct histology and function see: Hodges, 1974; Etches, 1996; Chousalkar and Roberts, 2008).

The oviduct is innervated by sympathetic and parasympathetic nerves. The sympathetic innervation arises from following abdominal plexuses: the ovarian plexus innervating the infundibulum, the renal and aortic plexuses innervating the magnum, the posterior mesenteric plexus innervating the isthmus, and the hypogastric plexus innervating the shell gland and vagina. Parasympathetic pelvic plexus contains fibers from the pelvic nerve. The nerve fibers in the avian oviduct are often associated with the large blood vessels and muscle (Gilbert and Lake, 1963; Liu et al., 2007). The blood supply to the oviduct is well developed and comes from an anterior oviductal artery, middle oviductal artery, hypogastric artery, and left internal iliac artery. The venous drainage occurs through the anterior oviductal veins, middle oviductal veins, and left internal iliac vein (for more details see Hodges, 1974). Oviductal blood flow significantly changes according to oviductal activity, and 15% of cardiac output perfuses the oviduct of the laying hen, that indicates a high rate of metabolic processes in this organ (Moynihan and Edwards, 1975; Niezgoda et al., 1979). During each ovulation-oviposition cycle of 24 h, the hen lays an egg weighing 50–70 g, which is composed of 25–35 g egg white and 5–6 g eggshell produced in the oviduct. The presence of the egg in a given oviductal segment significantly (three to four times) increases blood flow to this part (Boelkins et al., 1973).

35.3.1 Infundibulum

The infundibulum consists of a thin-walled funnel and a narrow thin-walled neck (tubular region) which increases in

size and thickness to form the next oviductal segment, the magnum. Muscle fibers surrounding the infundibulum are sparse. The mucosal folds in the infundibulum are relatively thin but tall (Figure 35.10A and B). Surface epithelium in the anterior part of this segment predominantly contains ciliated cells. Cuboidal nonciliated cells are localized in groups at the base of the grooves between the epithelial ridges. The tubular glands are present in the distal parts of the infundibulum, and their function is attributed to formation of chalaze.

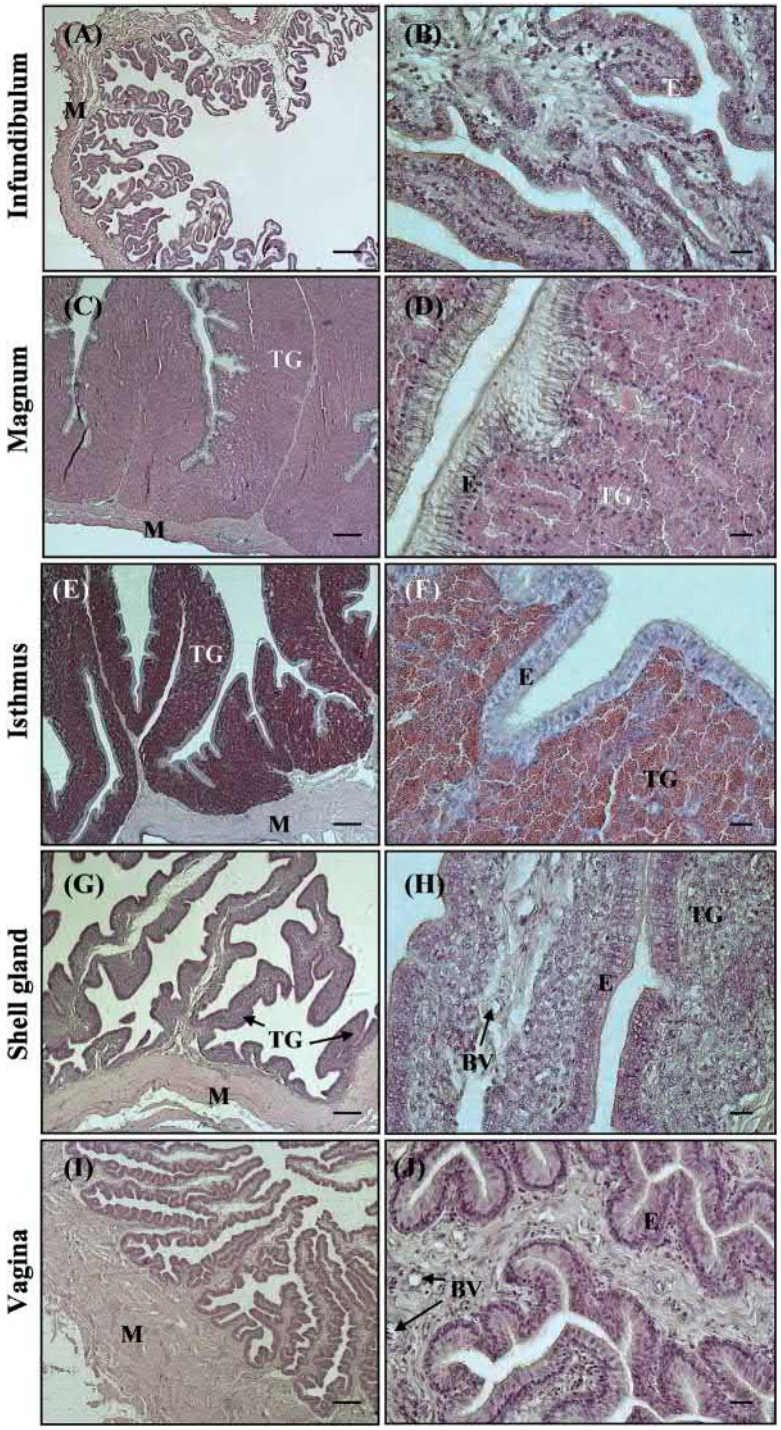

FIGURE 35.10 Histological structure of the laying hen oviduct segments (hematoxylin and eosin staining). (A) Infundibulum. (C) Magnum. (E) Isthmus. (G) Shell gland. (I) Vagina. (B, D, F, H, J) Higher magnification of mucosal tissues of a given oviduct segment. *BV*, blood vessels; *E*, surface epithelium; *M*, muscles and connective tissue; *TG*, tubular glands in the lamina propria. Bar = 200 μm (A, C, E, G, I) and 20 μm (B, D, F, H, J).

The infundibulum engulfs the ovum, which is released upon ovulation. During approximately 18 min (range: 15−30 min) of egg residence in this part, the fertilization occurs and the first layer of egg white is secreted. Fertilization must occur before the outer layer of the vitelline membrane (extravitelline layer) is laid down on the ovum since spermatozoa are not able to penetrate this layer (Bakst and Howarth, 1977; Howarth, 1984) and bind to sperm receptors in the inner perivitelline layer (Kuroki and Mori, 1997). Birds exhibit physiological polyspermy. Many sperm pass through the perivitelline layer into the germinal disc of an oocyte, where the nuclei undergo decondensation and form male pronuclei, although only one sperm successfully fertilizes the oocyte (Bakst and Howarth, 1977; Okamura and Nishiyama, 1978; Perry, 1987; Waddington et al., 1998). The supernumerary pronuclei degenerate at the very early stage of embryo development (Perry, 1987; Waddington et al., 1998), probably as a result of DNase activities (Stepińska and Olszańska, 2003). Evidence was provided that intracytoplasmic injection of a single sperm (ICSI) into quail oocyte can activate the oocyte and lead to fertilization (Hrabia et al., 2003b), although polyspermy naturally occurs in birds. However, the embryonic development after ICSI as well as after conventional in vitro fertilization (Olszańska et al., 2002) was delayed compared to that achieved naturally.

35.3.2 Magnum

The magnum is the largest region of the oviduct. Its length in the chicken is approximately 33 cm. The wall of the magnum possesses well developed muscle layers (although much less developed than in the more posterior segments of the oviduct) and the mucosa. Compared to the tubular region of the infundibulum, the mucosal ridges in the magnum increase in number, height, and thickness, mainly due to intense development of the tubular glands (Figure 35.10C and D). There are three types of tubular glands. Glands A and C are composed of one cell type but with different phases of secretory activity, whereas gland B is of a different cell type. The A cells seems to produce ovalbumin, while the C cells are assumed to be a recovery phase of the A cells. The B cells are engaged in the synthesis of lysozyme. The surface epithelium of the magnum is lined by ciliated and goblet (granular) cells.

The goblet cells synthesize avidin mainly under progesterone and its receptor control, and in less extend other steroids (Hora et al., 1986; Isola, 1990; Kunnas et al., 1992; González-Morán, 2016). Tubular gland cells are responsible for the production of ovalbumin, lysozyme, ovotranferrin, conalbumin, and antimicrobial peptides primarily under the stimulatory control of estrogen (Palmiter, 1972; Tuohimaa et al., 1989; Jung et al., 2011; Socha and Hrabia, 2018). As the ovum traverses through the magnum in approximately 2.5−3 h, most (∼15 g) of the egg white is secreted.

35.3.3 Isthmus

The isthmus is a short section of the oviduct (in chickens ∼8 cm in length), separated from the magnum by a narrow translucent line of demarcation, which is a nonglandular region. The muscular layers of the wall (especially the circular layer) are thicker than in the magnum, while tubular glands in the mucosa are less developed (Figure 35.10E and F). They contain two cell types. The surface epithelium is lined by ciliated, nonciliated, and mitochondrial (the third cell type) cells. The ridges of the isthmus are angular in a shape, and the crypts between the ridges are open.

Both inner and outer eggshell membranes, that enclose the egg albumen, are created during about 1 h and 15 min (range: 1−2 h) passage through the isthmus. There is evidence that eggshell membrane formation is accompanied by differential expression of 107 unique genes in the isthmus tissue. Highly expressed genes include membrane structural proteins such as collagens, collagen processing enzymes, and protein regulating disulfide cross-linking (Du et al., 2015). In the distal part of the isthmus, the mammillary cones of the eggshell are formed by mineralization of the outer shell membrane fibers (Hincke et al., 2012).

35.3.4 Shell gland

The shell gland is subdivided into the initial short (∼2 cm in length) tubular shell gland and the sac-like shell gland pouch (∼7 cm in length and ∼3 cm in width). The shell gland wall musculature, mainly the outer layer, is more prominently developed than in other segments of the oviduct. Mucosa is formed into numerous leaf-shaped folds, with some secondary folding on the surface and less expanded by the branched tubular gland layer (Figure 35.10G and H). The surface epithelium consists of equal numbers of apical ciliated and basal nonciliated cells. Function of the basal cells is linked to production of cuticle, and ciliated epithelial cells to calcium transport, secretion of eggshell pigment, and production of some shell matrix proteins. Tubular gland cells produce most of eggshell constituents.

During approximately 19−20 h which the egg remains in the shell gland, it takes up 15 g of fluid into albumen in process termed “plumping,” and the eggshell is deposited on the eggshell membranes. The volume of the shell gland acellular fluid significantly changes during eggshell formation. It increases during the first 6 h after entry of the egg into the shell gland, being maintained at a high level for about 6 h, and decreases during the last 6 h of eggshell

calcification. During the first 5 h of egg stay in the shell gland, 8 mL of water containing electrolytes, including Na^+, K^+, and Cl^-, accumulates in the egg. When the rate of eggshell calcification increases after this initial stage, the rate of fluid uptake decreases to 0.15 mL per 8 h or less (reviewed in Etches, 1996). The biochemical composition of the shell gland fluid also changes with stage of the shell formation (Nys et al., 2001). For instance, the K^+ and glucose concentrations increase, and Na^+ and Cl^- decrease (Etches, 1996). In addition to mentioned ions, the uterine fluid contains Ca^{2+}, Mg^{2+}, HCO_3^-, CO_2, enzymes (carbonic anhydrase, acid phosphatase, esterase, and proteases), protease inhibitors, and a variety of organic matrix protein precursors which show differential abundance according to the eggshell mineralization stage (Marie et al., 2014, 2015). These proteins are gradually incorporated into the calcifying eggshell resulting in their differential distribution throughout the eggshell regions (Hincke et al., 2012). More than 600 proteins are reported to be present in the chicken uterine fluid. Among the most abundant uterine fluid proteins are ovalbumin, ovotransferrin, ovocleidin-17, EGF-like repeats and discoidin I-like domains 3 (EDIL3), milk fat globule-EGF factor 8, and ovocalyxin-21 (Marie et al., 2015; Stapane et al., 2019). Evidence suggest that in the shell gland fluid, the elements needed for eggshell mineralization (i.e., Ca^{2+} and HCO_3^- ions) are transported in extracellular vesicles targeting the mineralization site (Stapane et al., 2019).

35.3.4.1 Eggshell calcification

The eggshell is composed of 95% calcium carbonate ($CaCO_3$), 3.5% organic matrix (proteins, polysaccharides, and proteoglycans), and 1.5% water (Hincke et al., 2012). The eggshell is formed by mineralization of ionized calcium (Ca^{2+}) and bicarbonate (HCO_3^-) in the uterine fluid. Shell formation is the fastest biomineralization process known in biology (Arias et al., 1993). The complete chicken eggshell contains about 6 g of mineral. The $CaCO_3$ precursors are supplied by the blood through transepithelial transport. As a main calcium-binding and intracellular transporting protein, calbindin D28K is accepted (Jonchčre et al., 2012). Its expression in the tubular gland cells is under the direct control of $1,25(OH)_2$ vitamin D_3 and co-regulatory action of sex steroids (Corradino, 1993). In turn Ca^{2+} pumps and Na^+/Ca^{2+} exchangers are involved in the Ca^{2+} secretion from epithelial cells into uterine fluid (Jonchčre et al., 2012). Additional several novel genes and biological pathways involved in the Ca^{2+} transportation in the shell gland of hen and their potential functions in the eggshell biomineralization have been recently proposed (Sah et al., 2018). Synthesis of HCO_3^- from CO_2 and H_2O is catalyzed by the carbonic anhydrase 2 in the tubular gland cells (Jonchčre et al., 2012). $CaCO_3$ is initially deposited as an amorphous phase, which is progressively converted into calcite. The organic components of the shell gland fluid promote the formation of calcite. In addition, the matrix-mineral interactions determine the orientation of calcite crystals, which results in the complex ultrastructure of the eggshell, its texture, and consequently its mechanical properties (Stapane et al., 2019).

Eggshell calcification occurs in three phases. The first stage lasting about 5 h corresponds to the initiation of mineralization on the surface of the outer shell membrane. This slowly occurring stage results in calcified mammillary cones formation, which then grow outwards to form the base of the palisade layer. During the second, active stage of calcification, the palisade layer formation occurs rapidly for about 10 h. During this time, about 0.33 g per hour of $CaCO_3$ is deposited. Hardness (texture) of the palisade layer as well as termination of shell calcification are, at least in part, controlled by osteopontin, a phosphoprotein secreted from nonciliated epithelial cells and deposited within the developing eggshell. The final stage of calcification lasts approximately 1.5 h and is related to termination of $CaCO_3$ deposition due to inhibitory action of inorganic phosphate and phosphoproteins (e.g., ovocalyxin-32) action; phosphate anions are able to inhibit $CaCO_3$ precipitation. For more details see Nys et al. (2001), (2004); Bar (2009); Hincke et al. (2012).

35.3.4.2 Eggshell cuticle and pigment deposition

Once calcification is completed, the cuticle is deposited on the shell surface during the final hour before oviposition. The cuticle protects avian egg from microbial invasion into the eggs. It contains proteins with antibacterial properties such as ovocalyxin-25, ovocalyxin-32, ovocalyxin-36, ovocleidin-116, ovocleidin-17, and clusterin, as well as lipids and polysaccharides related to the glycosylation of the proteins (Rose-Martel et al., 2012; Mikšik et al., 2014; Wilson et al., 2017). The hormonal factors that regulate of a given protein expression in the shell gland are unknown, although estrogen and GH involvement has been suggested, at least in regards to ovocleidin-116 and ovocalyxin-36 (Socha et al., 2017; Socha and Hrabia, 2018). In colored eggshell, pigments (porphyrin derivatives) secreted from surface epithelial cells of the shell gland are deposited during the last 3 to 0.5 h before oviposition (reviewed in Samiullah et al., 2015). Avian eggshell color is mainly determined by three kinds of pigments, i.e., protoporphyrin-IX (brown-shelled egg), biliverdin-IX (blue-shelled egg), and biliverdin zinc chelate. The molecular mechanism of pigmented eggshell formation remains still unclear. However, there is growing evidence for expression of numerous genes involved in the pathway of biliverdin (or other porphyrin derivatives) synthesis in the shell gland epithelial cells (Zhang et al., 2019).

35.3.5 Vagina

The vagina is a narrow duct (in chickens ~10 cm in length), separated from the shell gland by the uterovaginal sphincter muscle and opens at the urodeum of the cloaca. The large part of the vaginal wall is composed of the muscles. The longitudinal muscle layer consists of bundles of muscle fibers scattered within a connective tissue, and the circular one is strongly developed. The mucosa possesses numerous folds with surface epithelium thrown into many secondary folds, which are lined by ciliated and nonciliated cells. There are no tubular glands present in the lamina propria, except the sperm storage tubules (SSTs) (sperm-host glands) located in the uterovaginal junction (UVJ) (Figure 35.10I and J).

The vagina does not play any distinct roles in egg formation, but in coordination with the shell gland, takes part in the expulsion of the egg. The well-developed immune system in the vagina prevents invasion of the pathogens from the cloaca. In addition, mucin produced by epithelial cells of the lower oviductal segments (isthmus, shell gland, and vagina) provides a barrier against invasion by microbes.

35.3.6 Sperm storage in birds

In birds, the oviduct is able to store spermatozoa for a prolonged period within SSTs located in a narrow band, approximately 2−3 mm wide, at the UVJ. The UVJ is the primary site for the sperm storage, from which spermatozoa are transported to the infundibulum (site of fertilization) where additional SSTs exist (Bakst, 1981). It was estimated in turkey hens that less than 1% of the sperm inseminated into the vagina enter the SSTs (Bakst, 1994). The surface epithelium in the UVJ is lined by cells with well-developed cilia which facilitate the sperm transport to the SSTs. In addition, it is suggested that sperm motility and the seminal plasma constituents such as PGF2α, contribute to sperm entrance to the SSTs (Sasanami et al., 2015). Spermatozoa can be stored (immotile) and survive in the SSTs for a few weeks after insemination or natural mating; up to 10 days in Japanese quail, 2−3 weeks in chickens, and 10 weeks in the turkey hen. Organization of the SSTs is similar to tubular glands in other regions of the oviduct; their epithelium is a single layer of nonciliated cells with microvilli on their apical surface. There is evidence that SST cells synthesize and secrete exosomes, however their role needs to be elucidate (Huang et al., 2017).

The mechanism by which sperm can remain viable in the SSTs is not fully established, but potential roles for alkaline phosphatase (Bakst and Akuffo, 2007), carbonic anhydrase (Holm et al., 1996), avidin (Foye-Jackson et al., 2011), AQPs (Zaniboni and Bakst, 2004; Socha et al., 2018; Hrabia et al., 2020), fatty acids (Huang et al., 2016), some eggshell matrix proteins (Riou et al., 2017), albumin, and transferrin (Matsuzaki et al., 2020) in maintenance of proper microenvironment and nutrients supply for spermatozoa in SSTs are suggested. Recent report demonstrated changes in expression of numerous genes related to fatty acid metabolism, regulation of cell differentiation, regulation of transport, immune response, and pH-regulatory functions in UVJ. These alterations are attributed to sperm storage in the SSTs (Han et al., 2019). A high concentration of lactic acid in SSTs is proposed as a key factor making resident spermatozoa quiescent in the SSTs (Matsuzaki and Sasanami, 2017). Another important factor supporting spermatozoa viability in SSTs is the protection of resident spermatozoa from immune response by the TGFβ system (Das et al., 2008).

Following oviposition, spermatozoa are released from the SSTs and migrate to the infundibulum for fertilization. This event is in accordance with the ovulation timing. Progesterone which plasma concentration increases before ovulation is considered as a sperm-releasing factor. It elicits morphological changes in the SSTs, which squeeze out the stored spermatozoa. Progesterone also stimulates secretion of cuticle components from the epithelial cells of the UVJ and shell gland that support the spermatozoa migration toward the infundibulum. In addition, evidence suggests that HSP70 protein secreted from the surface epithelium of the UVJ, bound to the sperm and reactivates its motility. This help sperm movement to the fertilization site (Hiyama et al., 2013). For more details regarding unique phenomenon of sperm storage in birds, see Matsuzaki and Sasanami (2017).

35.3.7 Hormonal and physiological regulation of oviduct development and function

35.3.7.1 Ovarian steroids

The series of events related to egg formation in the avian oviduct are regulated by numerous hormones and factors, primarily by the ovarian steroids. Estrogen is the main steroid that controls the growth and function of the oviduct, but progesterone and androgens are required for development and maintenance of full secretory activity (Mika et al., 1987). Progesterone and androgens alone have little effect on the development of the oviduct (Palmiter and Wren, 1971). ERα is expressed in the avian oviduct before and after hatching, indicating participation of this form of ER in the estrogen-regulated growth of the left Müllerian duct (Kiell et al., 1982; González-Morán and Camacho-Arroyo, 1998). High abundance of ERs is also noticed in growing and laying hen oviduct, and their expression changes according to reproductive function of the oviduct (Jung et al., 2011; Hrabia et al., 2004a; Socha et al., 2017). Within the wall of the magnum and shell gland, ERs are localized in

the surface epithelium and in the tubular gland cells (Hansen et al., 2003; Jung et al., 2011). The roles of estrogen in the oviduct of growing and laying hens are attributed to growth and maintenance of mucosal cell proliferation and differentiation. Gene expression of numerous proteins related to cell functions and egg constituents is under estrogen control as well (reviewed in Dougherty and Sanders, 2005; Jung et al., 2011; Yang et al., 2016; Jeong et al., 2017a, 2018). Estrogen is also required for regulation of proteins participating in calcium metabolism for calcification of the eggshell include calbindin and epithelial calcium channels (TRPVs) (Corradino, 1993; Bar, 2009). In addition, estrogen orchestrates the remodeling of the reproductive system to increase the subsequent rate of egg production, following molting in laying hens (Socha et al., 2017; Socha and Hrabia, 2018). There is a great number of evidence regarding the response of avian oviduct to estrogen. By way of example, exposure of immature chickens to synthetic estrogen, diethylstilbestrol increases growth, development, and differentiation of the oviduct and changes expression of genes related to tubular gland formation, epithelial cell differentiation, hormone interactions, nerve development, and tissue remodeling (Song et al., 2011). In turn, treatment of chickens with estrogen receptor blocker (e.g., tamoxifen) induces regression of the oviduct via stimulation of cell apoptosis and causes decrease in expression of genes coding the egg albumen and eggshell matrix proteins (Socha and Hrabia, 2018). Similar effects are noticed in hens exhibiting low-plasma levels of estradiol and other sex steroids (progesterone and testosterone) during a pause in laying induced by fasting or high dietary Zn treatment (Heryanto et al., 1997; Anish et al., 2008; Jeong et al., 2013; Socha et al., 2017). Estrogen also induces progesterone and AR synthesis in the oviduct of immature and laying chickens (Toft and O'Malley, 1972; Hora et al., 1986; Joensuu, 1990). Co-expression of PR and ERα in all cell types of the oviductal magnum as observed in one-week and one-month-old chickens suggests that progesterone in cooperation with estradiol participates in the regulation of growth and cell differentiation at the posthatch stages of the magnum development (González-Morán, 2015). Such a role for progesterone is well established.

PRs were examined deeply in the oviductal magnum, and in a less extend, in the shell gland (Yoshimura and Bahr, 1991b; González-Morán, 2015, 2016; Socha et al., 2017). In the magnum, PRs appear at the age of one week and thereafter, concomitantly with histological changes in this oviductal segment. Within the oviductal wall of mature laying and nonlaying hens, PRs are present in the surface epithelial cells, tubular gland cells, stromal fibroblasts, and muscle cells (Yoshimura and Bahr, 1991b; González-Morán, 2016). Thus, progesterone acting through its receptor regulates the secretory activity of the surface epithelium and tubular gland cells for egg formation and the contractile activity of the myometrium. The mRNA and protein expression as well as density of PR-positive cells are greater in nonlaying hens, with atrophied oviductal tissues, than in laying hens. Therefore, it is suggested that once the cells differentiate and become responsive to progesterone, these cells maintain this responsiveness even during the nonlaying period (Yoshimura and Bahr, 1991b; Socha et al., 2017). The ratio of PR-A and PR-B changes in the oviduct according to the cell type, the age, and reproductive activity. In the laying hen oviduct, a similar expression of PR-A and PR-B is observed, but in the nonlaying or estrogen-withdrawn chickens, PR-A is a predominant isoform (Schrader and O'Malley, 1972; Syvala et al., 1997; González-Morán, 2016). It seems that in the responsiveness of the oviduct to progesterone, the ratio of PR-A and PR-B isoform abundance is important because they control expression of different genes and exert distinct functions (Tora et al., 1988).

ARs are also expressed in the avian oviduct. Androgens act synergistically with estrogen to stimulate the oviduct growth and to maintain oviductal functions (Palmiter and Haines, 1973; Kawashima et al., 1999; Socha et al., 2017).

35.3.7.2 Other factors

In recent years, an ever-increasing number of factors have been implicated in modulation of the oviduct development and function. For instance, GH is produced by oviductal tissues, and its receptors are present primarily in the mucosal cells (Ni et al., 2007; Hrabia et al., 2013, 2014b; Luna et al., 2014; Hrabia, 2015). Along with oviduct length, the GH concentration is consistent, but it progressively declines from puberty to the late laying period. The role of GH in the chicken oviduct is linked to synthesis of egg constituents. Treatment of chickens with chGH during sexual maturation results in an increase in mRNA expression of ovalbumin in the magnum as well as ovocalyxins 32 and 36 in the shell gland. Improved eggshell quality in older hens is observed after GH injections (Donoghue et al., 1990). The action of GH in the chicken oviduct is additionally related to the regulation of oviductal cell apoptosis and proliferation (Hrabia et al., 2014b). Mediation of some GH actions by IGFs in the avian oviduct is also possible since IGF-1, IGF receptor, and IGF binding protein-2 are evidenced, and paracrine and/or autocrine actions of IGF-1 in the quail oviduct during its development is suggested (Fu et al., 2001; Kida et al., 1994; Ni et al., 2007). In primary cultures of quail oviduct cells, elevation of ovalbumin synthesis by IGF-1 in cooperation with estrogen was shown (Kida et al., 1995). Ghrelin-immunopositive cells are demonstrated in the mature Japanese quail oviduct, but not in immature quail. This finding indicates that ghrelin synthesis is associated with development and differentiation of

the oviduct (Yoshimura et al., 2005). PRL protein was localized on the surface of UVJ of Japanese quail oviduct, and its role has been implicated in the maintenance of the fertilizability of the spermatozoa through the prevention of the spontaneous acrosome reaction (Hiyama et al., 2016).

To provide an appropriate environment for fertilization, early embryo development, movement of the egg during its formation, and sperm storage and transportation in the avian oviduct, the balance of water and fluid secretion is essential. In recent years, the AQPs have been implicated in regulation of the oviduct development and oviductal fluid secretion. AQP3 was proposed to be involved in the estrogen-induced development of the chicken oviduct (Yang et al., 2016). Other results provide evidence that the AQP4 mRNA and protein are present in all segments of the chicken oviduct. The expression of AQP4 depends on the segment, the cells of the wall, and reproductive activity of the oviduct. Generally, its expression is reduced during a pause in laying induced by tamoxifen treatment or starvation. The role of this channel protein is linked primarily to the regulation of water movement required for egg formation, especially for secretory processes in the infundibulum and the "plumping" of fluid into the albumen in the shell gland (Socha et al., 2018; Hrabia et al., 2020). Moreover, localization of AQP2, 3, and 9 within the apical side of the epithelial cells that form the SST in the turkey vagina implies these AQPs in water exchange that may interact with sperm residing within the SST (Zaniboni and Bakst, 2004).

It has been demonstrated that circadian clock-related genes (e.g., Bmal1, Clock, Per2, Per3, and Cry2) are expressed in four segments of the chicken oviduct (infundibulum, magnum, isthmus, and shell gland). The expression of these genes shows significant rhythmicity in a daily light-dark cycle, in the infundibulum and shell gland but not in the magnum and isthmus. These results provide evidence for a functional clock within the avian oviduct, as well as for the role of this local clock in the regulation of the infundibulum and shell gland activities related to the capture of the ovum and eggshell formation/oviposition, respectively (Zhang et al., 2016).

There is also evidence for implication of a large number of differentially expressed genes in the regulation of avian oviduct development (Dunn et al., 2009; Jung et al., 2011; Song et al., 2011; Yin et al., 2019) and function of a given oviduct segment (Lim et al., 2012; Jeong et al., 2013; Khan et al., 2019; Yin et al., 2020). In turn, gene expression can be modified by miRNAs acting at a posttranscriptional level (Lim et al., 2012; Bae et al., 2014a, 2014b; Lim and Song, 2014). There is evidence that numerous miRNAs regulate gene expression (often estrogen-induced genes) in the oviduct during developmental (Jeong et al., 2017b) and in different stage of reproductive activity (Kim et al., 2017; Jeong et al., 2013, 2018).

Changes occurring in the structural architecture of the oviductal tissues during its development, regression, and rejuvenation required the controlled turnover of the stromal ECM. This process is regulated, at least in part, by proteolytic enzymes including the MMPs and their inhibitors such as TIMPs and α2-macroglobulin, which expression is especially high in the epithelial and tubular gland cells (Lim et al., 2011). Recent studies have provided evidence for synthesis and activity of some MMPs within the domestic hen oviduct as well as changes in MMP activities in relation to oviduct development and reproductive state (Ha et al., 2004; Leśniak-Walentyn and Hrabia, 2016a, 2016b, 2017). In addition, involvement of estrogen in the regulation of MMP expression and activity was proposed (Leśniak-Walentyn and Hrabia, 2017).

35.4 The ovulatory cycle

The ovulatory cycle of the hen spans the time from one ovulation to the next ovulation. The ovulation−oviposition cycle covers the period from ovulation of an ovum to the oviposition of the fully formed egg. In the domestic hen, ovulation is followed by oviposition approximately 24−26 h later. Ovulation of the F1 (most advanced in the development) follicle occurs within 15−45 min after oviposition, or even within 5 min in commercial layer strain hens, producing more than 300 eggs per year. Ovulations happen uninterrupted for several consecutive days, after which a pause in laying, lasting one or more days, occurs. The number of eggs laid on successive days is called a sequence or clutch. The first event in a sequence is the preovulatory release of LH, second the occurrence of ovulation, and third oviposition. Laying is restricted to a 4 to 8 h period of the day, and this restriction is the result of a circardian rhythm in some components of the physiological system controlling ovulation. Each successive egg within a sequence is laid at a slightly later time each day. The differences in lag time within a sequence represent mainly variation in the amount of time between oviposition and the subsequent ovulation (reviewed in Etches, 1990; Johnson, 2015b).

Under 24 h of photoschedule cues (14 h light and 10 h dark), the preovulatory surge of LH in the domestic hen is restricted to an 4 to 11 h "open period" beginning at the onset of dark phase (the scotophase). In chickens, ovulation of the first egg of a sequence usually occurs early in the photophase. For comparison, Japanese quail ovulate the first egg of the sequence 8−9 h after the onset of the photophase. Consequently, most eggs are laid by the domestic hens in the morning, and by quail in the afternoon (Fraps, 1955; reviewed in Etches, 1990; Johnson, 2015b).

The timing of ovulation is controlled by the neuroendocrine and ovarian clock systems. At a central level, avian

circadian timing is regulated at multiple oscillatory sites, including the retina, pineal gland, and hypothalamus. A signal from the central clock is crucial for the initiation of the LH surge capable to induce ovulation. At an ovarian level, clock genes such as Bmal1, Clock, Cry1, Cry2, Per2, and Per3 are rhythmically expressed in the theca and/or granulosa layers of preovulatory F1 follicle as revealed in Japanese quail and chicken (Nakao et al., 2007; Tischkau et al., 2011; Li et al., 2014; Zhang et al., 2017). Clock gene rhythmicity is absent in the granulosa layer of prehierarchical follicles (Nakao et al., 2007) or less mature F6−F5 follicles (Zhang et al., 2017). The function of the ovarian clock is related to the timing of gene expression involved in steroidogenesis, gonadotropin responsiveness, and ovulation primarily in granulosa cells of the largest preovulatory follicle. The expression of clock genes in the ovary is regulated by the LH signaling cascades mediated by the cAMP pathway and, in lesser extent, the p38MAPK and ERK1/2 pathways (Li et al., 2014). In both theca and granulosa cells of F1 follicle, LH-regulated production of StAR changes over the course of 24 h, coincidently with changes in the abundance of the clock gene, Per2. The chicken StAR gene has the functional capacity for clock-driven expression (Nakao et al., 2007; Zhang et al., 2017). In addition, it has been evidenced that FSH provides a cue for the development of the functional cellular clock in granulosa cells of less mature hierarchical follicles, and that LH synchronizes the cellular clock of granulosa cells of the most mature follicle (Zhang et al., 2017). The data indicate that local clock system plays an important part in the regulation of ovarian follicle maturation, the timing of ovulation, and the rate of lay.

35.5 Egg transportation and oviposition

The ovum captured by the infundibulum is moved with variable speed through individual segments of the oviduct showing a different type of mobility, i.e., different frequencies and amplitude of contractions (Rząsa, 1972; Hrabia, 2000). The electrical activity and motility of the oviductal parts change during the ovulatory cycle. The highest frequency of electrical activity occurs in the shell gland at the time of oviposition (Shimada and Asai, 1978). Moreover, the ovum promotes its own transport in the oviduct, which muscles function like a stretch receptors. When the egg travels through the oviduct, the electrical activity of the musculature behind the egg is much higher than in its front. Thus, the egg stretching the wall of the oviduct, increases the contraction activity of smooth muscles, which causes the egg to move (Arjamaa and Talo, 1983).

Significant role in the egg transportation through the oviduct plays adrenergic innervation. Both adrenergic receptors (α and β) are present in the oviduct. Stimulation of α receptors contracts and stimulation of β receptors relaxes oviductal smooth muscles. In vitro and in vivo epinephrine and norepinephrine contract all oviductal segments except for the shell gland, which relax (Rząsa, 1977; Verma et al., 1977; Crossley et al., 1980). Histamine, which concentrations change throughout the length of the oviduct and depends on oviductal activity (Paczoska-Eliasiewicz et al., 1998) has also been suggested as a local regulator of the chicken oviduct contractility (Hrabia, 2000). Other results implied participation of PGs and AVT in the regulation of oviduct activity. Both PGF2α and PGE2 contract all oviductal segments except for the vagina, which is relaxed by PGE2 (Wechsung and Houvenaghel, 1976). AVT provokes a contraction of the magnum, isthmus, and shell gland, and sensitivity of the oviduct to AVT increases from infundibulum to shell gland (Rząsa, 1972).

Oviposition, i.e., expulsion of the fully formed egg from the oviduct involves the relaxation of abdominal muscles and sphincter between the shell gland and vagina as well as the vigorous contractions of smooth muscles of the shell gland. This event is controlled by AVT, PGs, acetylcholine, and galanin.

AVT is released from the posterior pituitary gland as well as is expressed in the shell gland, suggesting its paracrine effect (Srivastava et al., 2010). In laying hen, AVT plasma concentration is found to be highest at the time of oviposition (Niezgoda et al., 1973) concomitantly with the lowest plasma activity of oxytocinase (aminopeptidase), enzyme inactivating AVT (Brzezińska et al., 1967). AVT has well-documented stimulatory effects on the shell gland contractility and oviposition, acting by its receptor VT3, members of G-protein coupled receptor family. Injection of AVT or oxytocin can induce premature oviposition in laying hens (Rząsa and Ewy, 1970; reviewed in Srivastava et al., 2018). The action of AVT is mediated by locally produced PGs. Treatment with PGF2α or acetylcholine causes a marked increase in plasma AVT levels and premature oviposition (Shimada et al., 1987). Administration of indomethacin (PG synthetase inhibitor) blocks AVT-induced premature oviposition (Rząsa and Paczoska-Eliasiewicz, 1989). PGs and AVT are reported to intensify their actions. PGF2α released in the shell gland at the time of oviposition stimulates tissue contractility, which in turn increases the release of AVT (Saito et al., 1987b; Shimada et al., 1987). Moreover, AVT causes uterus contractions as well as PG release from the shell gland tissue (Rząsa, 1978, 1984; Takahashi et al., 2004). Local synthesis of AVT and the expression of its VT3 receptors in the shell gland is, at least in part, estrogen dependent (Srivastava et al., 2010).

It is well established that PGs (PGE2 and PGF2α) produced in the hen shell gland directly stimulate contractions of this oviductal segment, acting by specific receptors (Asbóth et al., 1985; Takahashi et al., 2004, 2011).

Local synthesis of PGs in the hen uterus has been confirmed recently, by presence of cyclooxygenases (COX-1 and COX-2), the rate-limiting enzymes of PG synthesis. The highest expression of COX-2 in the shell gland just prior to oviposition implies its important role in the production of PG necessary for oviposition event (Elhamouly et al., 2017). Released PGs into the blood serum are rapidly metabolized. Treatment with exogenous PGs (PGF2α or PGE1) stimulates the shell gland contractility, relaxes the vagina, and evokes premature oviposition in chickens and Japanese quail. Blocking of PG synthesis, by treatment with indomethacin, decreases the occurrence of the oviposition peak of uterine contraction and delays oviposition (Shimada and Asai, 1979; Rząsa, 1978; Rząsa and Paczoska-Eliasiewicz, 1989; Takahashi et al., 2004). There is also evidence suggesting that PGs E and F produced in the highest amount around the time of oviposition by ovarian preovulatory follicle (F1) and most recent postovulatory follicle (POF1) play an important role in the control of egg expulsion (Saito et al., 1987a; Hales et al., 2008). Removal of either the POF1 or the F1 follicle results in a 1−7 day delay in oviposition (Rothchild and Fraps, 1944).

Avian galanin is identified in the Japanese quail oviduct extract, and galanin immunoreactive fibers are localized in the muscle layers of the shell gland and vagina. The synthetic peptide enhances in vitro contractions of both the vagina and the shell gland tissues in a similar manner to the native peptide. Administration of the synthetic peptide induces quail oviposition during 5 min after injection. The direct galanin action on the oviductal shell gland and vagina is evidenced by presence of galanin binding sites. Their abundance is under combined control of estradiol and progesterone. Therefore, it is proposed that galanin may serve to evoke oviposition through mechanism of the induction of shell gland and vaginal contractions (Li et al., 1996; Tsutsui et al., 1997, 1998).

Epinephrine and norepinephrine do not play significant role in egg oviposition; however, release of epinephrine under stress causes the egg to retain in the shell gland, which is the result of the diastolic effect of catecholamines on the uterus (Rzasa, 1977; Hrabia, 2000).

35.6 The egg

The avian egg is a biological container possessing all materials and nutrients required for generating a new individual. It is composed of the yolk which accounts for 32−35% of the egg, the albumen accounts for 52−58%, and the eggshell with shell membranes accounts for 9−14%. In the yolk and albumen, the proteins, lipids, minerals, growth factors, and vitamins are stored. Eventually, proteins are used for tissue growth, while the lipids are served as a main source of energy for the developing embryo. The mineralized eggshell participates in gas and water exchange provides calcium, and protects the embryo from physical impacts and pathogens. In addition, eggs are an excellent source of protein of high-biological value that offer specific health benefits to humans. A novel functional activities of egg proteins has been identified. Among other, some egg proteins are good candidates for use as immunomodulatory agents in the food and pharmacological industries or can be used in cancer therapy (for details see Lee and Paik, 2019). Egg constituents has been well described in Gilbert (1971), Hodges (1974), Etches (1996), Solomon (2010), Nys et al. (2001, 2004), Tian et al. (2010), Hincke et al. (2010, 2012), and Ahmed et al. (2017).

35.6.1 The yolk

The ovulated oocyte filled with huge amount of yolk is enveloped with the vitelline membrane (i.e., plasma membrane, oolemma) and perivitelline layer [counterpart of mammalian zona pellucida (ZP)], which are product of the ovary. In the infundibulum, captured oocyte is further surrounded with the middle continuous layer and extravitelline layer (outer layer of the vitelline membrane), which contain proteins released from the epithelial cells of the infundibulum. These four layers together make up the yolk membrane. The vitelline membrane (8 nm thick) tightly apposed to the perivitelline layer, in some regions of the yolk is perforated. In the area of the germinal disc (blastodisc), the vitelline membrane possesses numerous microvilli that project into a perivitelline space splitting the perivitelline layer from the vitelline membrane (Etches, 1990). The perivitelline layer (egg coat; 2 to 4 μm thick) which surrounds the vitelline membrane is a unique multifunctional ECM, composed of a loosely intermeshed network of fibers, which include the ZP glycoproteins. Based on phylogenetic analyses, ZP glycoproteins are classified into six subfamilies such as ZP1, ZP2/ZPA, ZP3/ZPC, ZP4/ZPB, ZPD, and ZPAX (for more details see Okumura, 2017; Nishio et al., 2018). In birds, ZP proteins constituting the perivitelline layer are highly conserved. Among them, ZP1, ZP3, and ZPD are the predominant molecules accumulating in the matrix around the mature ovum, whereas ZP2, ZP4, and ZPAX are under detectable levels or in faint amount. These ZP proteins are secreted by granulosa cells, except for ZP1 which is liver-derived (Nishio et al., 2014, 2018). The physiological roles of ZP proteins are related to the mediation of egg−sperm interactions, induction of sperm acrosome reaction, oocyte or early embryo defense, and modification of the egg-coat architecture (Okumura, 2017; Nishio et al., 2018). In avian fertilization, the spermatozoa locally degrade and dissolve the matrix of the perivitelline layer and penetrate it through the hole made at the sperm-binding site. The sperm binds to the perivitelline layer overlying the germinal disc,

preferentially than in any other area of the egg. The middle continuous layer (50−100 nm thick) is an amorphous substance. The extravitelline layer, the thickest (6 μm) of the constituents of the yolk membrane, is composed of interwoven fibers that are deposited in concentric layers around the ovum.

The egg yolk contains approximately 48% water, 33% lipid, 17% protein, and traces of carbohydrates (∼1%; mainly oligosaccharides) and minerals (∼1%; largely phosphorus). Yolk lipids mostly include triacylglycerols, phospholipids, cholesterol, and cerebroside. The yolk provides nutrients to the growing embryo and its extraembryonic membranes during incubation.

The core of the egg is created by white yolk around which the yellow yolk, containing more protein and lipids, is deposited in concentric layers. The yolk is composed of fluid and spherical structures (∼up to 140 μm in diameter). The smaller spheres are called lipid or lipoprotein droplets. The larger spheres termed yolk spheres are enclosed by trilaminar membrane and containing subdroplets, particles, lamellar bodies (lipid-reach molecules in a membrane-like form), and aqueous phase. The subdroplets include lipids and VTG-originated proteins such as phosvitins (20 and 34 kDa of molecular weight) and lipovitellins (α- and β-lipovitellin; ∼400 kDa). The phosvitins are main proteins binding the phosphorus within the yolk (∼80%), and to a lesser extend the calcium, magnesium, and iron. The particles contain about 65% of the yolk solids and 95% of the yolk lipids. The aqueous phase contains approximately 10% of the yolk solids, majority of which are proteins, including only trace of lipids. The key proteins are serum albumin, serum α2-glycoprotein, and the immunoglobulin IgY (a counterpart of mammalian IgG). Some proteins of the aqueous phase serve as a carrier for vitamins. The yolk IgY, which concentrations range from 50 to 100 mg per egg yolk, is the avian-specific maternal immunoglobulin that protects embryos from infection before full maturation of their own adaptive immune system. It is synthesized in the B cells, secreted into the blood, delivered to the ovary, and eventually selectively incorporated into the growing oocyte in the follicle, through the Fc receptor-mediated endocytosis (Dias da Silva and Tambourgi, 2010; Murai et al., 2013). In turn, maternal IgY via yolk sac receptor FcRY (mannose receptor family member) is delivered to the prenatal chick circulation (Tesar et al., 2008).

35.6.2 The albumen

The egg albumen (egg white) secreted in the oviduct (as discussed in this chapter) is a reservoir of water, protein, and minerals for developing embryo, as well as it protects from the invasion of pathogens into the yolk. The egg albumen is composed of four layers: a chalaziferous layer closely applied around the yolk membrane, an inner thin layer, a viscous thick layer, and an outer thin layer. The layers account for about 2.7%, 17%, 57%, and 23%, respectively, of the total volume of the egg white. The chalaziferous layer contains dense albumen in which are embedded numerous mucin-like fibers. This layer forms a thin, compact structure keeping the egg yolk in the center of the egg. The inner and outer thin layers contain a higher proportion of the water-soluble proteins and these layers increase when eggs are stored. Compared with the yolk, the albumen consists largely of water (86−89%), with the remaining being solids: ∼10% proteins, ∼1% carbohydrates, traces of lipids, and minerals. Few of the vitamins are accumulated in the egg white, except the niacin and riboflavin. Minerals such as chlorine, magnesium, potassium, sodium, and sulfur are abundant in the albumen, whereas calcium, copper, iodine, iron, manganese, phosphorus, and zinc are abundant in the yolk.

Over 220 diverse proteins with the specific functions and physicochemical properties were found in the egg white (Ahmed et al., 2017). Among them, the major proteins evidenced in the egg albumen include the most abundant ovalbumin (54%), followed by ovotransferrin (12−13%; conalbumin), ovomucoid (11%), ovoglobulins G2 and G3 (8%), ovomucin (3.5%), lysozyme (3.4%), and present in lesser concentrations, ovoinhibitor (1.5%), ovoglycoprotein (1.0%), flavoprotein (0.8%), ovomacroglobulin (0.5%), avidin (0.05%), and cystatin (0.05%).

Ovalbumin is a main source of amino acids for developing embryo, and possesses antioxidant and enzyme inhibitor properties. Ovotransferrin serves as an iron chelator preventing iron utilization by microorganisms, thus exerts antibacterial effect against broad spectrum of bacteria. Ovomucoid inactivates trypsin enzyme (serine protease) and other proteases essential during bacteria growth. Similarly ovoinhibitor acts as a bacterial and fungal serine protease inhibitor. Likewise, cystatin has protease inhibitor properties and exerts both antimicrobial and antiviral activities. Ovomucin is another antimicrobial and antiviral protein. It is a highly glycosylated protein composed of α- and β-subunits differing by carbohydrate content and amino acid composition. The carbohydrate contents of α-ovomucin and β-ovomucin are approximately 15% and 60%, respectively. This insoluble fibrous protein with high-molecular weight maintains the viscosity and structure of egg albumen (mainly thick egg white) and block invasion of pathogens. Lysozyme has bacteriolytic activity, which occurs via hydrolyze of the bonds between N-acetylmuramic acid and N-acetyl-D-glucosamine residues in peptidoglycan and between N-acetyl-D-glucosamine residues in chitodextrinin of the bacterial cell wall. It is most effective against gram-positive bacteria. Avidin, also demonstrates antimicrobial activities against several bacteria due to its strong binding affinity to biotin as well as minerals, which are important for bacterial growth. It is a

glycoprotein composed of four subunits, each of them can bind a biotin molecule. Flavoprotein has ability to bind riboflavin.

35.6.3 The eggshell

The avian shell includes several layers that function together as a single unit. From the inner site, the shell layers are as follows: inner shell membrane (~15–26 μm thick), outer shell membrane (~50–70 μm), mammillary layer (~100 μm), crystal layer (palisade and vertical layers; ~200 μm), and cuticle (~5–10 μm). Chemical composition of the eggshell comprises of an inorganic material (primarily $CaCO_3$ mineral in the form of calcite; ~95% by weight) and an organic matrix (3.5%) that forms eggshell membranes, the mammillary cores, the shell matrix, and cuticle.

35.6.3.1 The shell membranes

The shell membranes are deposited around the albumen when the egg travels through the oviductal isthmus. The two membranes are tightly apposed to one other except at the blunt end of the egg where the two are separated over a small area to form the air cell (air chamber). During embryonic development, the membranes interface with the chorioallantoic membrane. Eggshell membranes are ECM, constituted by proteins (mainly fibrous, a highly cross-linked by disulfide and lysine-derived bounds), small amount of carbohydrates, and only trace of lipids. The membranes differ slightly in their chemical composition and morphology. The inner membrane is not calcified, while the fibers of the outer shell membrane are incorporated into the shell in areas termed mammillary cores that serve as center for the growth of crystals of $CaCO_3$. Recent proteomic analyses identified nearly 500 different proteins present in the shell membranes. Of these proteins, 163 are moderately and 124 are highly specified to the shell membranes. The family of proteins, recognized as shell membrane-specific, includes collagens which constitute about 10% of eggshell membrane proteins, cysteine-rich proteins (CREMPs), histones, avian β-defensins (AvBDs, formerly called gallinacins), lysyl oxidase-like 2 (an important collagen cross-linking enzyme), and ovocalyxin-36. The structural proteins such as CREMPs and collagens (types I, V, and in large part collagen X) are fundamentally associated with the formation of fibrous structure of the membranes and their subsequent physicomechanical properties that retain the egg albumen, provide structural base for biomineralization, and form the physical barrier against pathogen invasion of the egg interior. Another group of proteins, including ovocalyxin-36, AvBDs, and histones, serves as direct antimicrobial protection (Ahmad et al., 2017). In addition, other antimicrobial proteins including lysozyme and ovotransferrin have also been identified in the eggshell membranes.

35.6.3.2 The mammillary layer

The mammillary layer is a regular array of cones (mammillae, knobs) embedded in the outer shell membrane. The core of each cone is highly organic, composed largely of proteins, and in lesser abundance of mucopolysaccharides. Individual fibers of the outer shell membrane are fixed in the cores. The mammillae cores are the nucleation sites where calcification starts during the shell fabrication. The small calcite crystals in mammillary cones are deposited without particular orientation. As calcification proceeds, the calcite crystals increase their size, grow to a height of approximately 300 μm, and form the main eggshell thickness, the palisade layer. At some points, the crystals do not grow completely together, leaving pores. The roles of proteins identified as specific or highly expressed in the mammillary cones are attributed to regulation of initiation of eggshell calcification and calcium ion binding. The first group comprises ECM proteins such as ABI family member 3 (NESH) binding protein (ABI3BP), tiarin-like, hyaluronan and proteoglycan link protein 3, collagen X, collagen II, and fibronectin. The calcium-binding proteins include calumenin, EDIL3, nucleobindin-2, and SPARC (Rose-Martel et al., 2015).

The size and spacing of the mammillary cones affect the overall strength and biomechanical features of the completed eggshell. During embryo development, the mobilization of calcium, necessary for its growth, occurs from the calcium reserve body located at the base of each cone. The calcium reserve bodies contain reactive microcrystals of calcite with spherulitic texture which are more susceptible to dissolution of the mineral. Moreover, the weakened eggshell is easier to crack by developed chick during hatching (Hincke et al., 2012).

35.6.3.3 The crystal layer

The crystal layer is a continuation of the mammillary layer and constitutes the greater part of the fully formed eggshell. The lower region of the crystal layer is called palisade layer, and upper part is called vertical layer. These layers possess a specific structure composed of mineral and organic precursors that are secreted into the shell gland fluid bathed the egg during shell deposition (discussed in point 35.3.4.1). The calcified eggshell consists mostly of calcite (96%), organic matrix (2%), and remaining elements such as magnesium in the form of magnesium carbonate, phosphorus, and variety of trace elements. The palisade layer is build of groups of columns that extend outwards from the mammillary cones and are perpendicular to the eggshell surface. This layer is covered by the outer vertical

layer (3−8 μm thick) which has a crystalline structure of higher density and with greater vertical dimension to the egg surface than that of the palisade region (Nys et al., 2004; Hincke et al., 2010, 2012).

The crystal layers contain organic matrix, composed of soluble and insoluble proteins, glycoproteins, phosphoproteins, and proteoglycans rich in sulfated molecules. The elements of the organic matrix influence the texture and mechanical properties of the unique eggshell by controlling the size, shape, and orientation of the polycrystalline structure. In addition, many eggshell matrix proteins are responsible for antimicrobial defense. Matrix proteins are incorporated sequentially into the calcifying eggshell leading to their differential distribution across the mammillary and palisade layers.

The proteins in the eggshell matrix are arranged into three groups: major egg white proteins (e.g., ovalbumin, lysozyme, and ovotransferrin) localized in basal layer of the shell, ubiquitous proteins present also in other tissues (e.g., osteopontin and clusterin), and specific eggshell matrix proteins (e.g., ovocleidin-17, ovocleidin-116, ovocalyxin-21, ovocalyxin-25, ovocalyxin-32, and ovocalyxin-36). Among about 900 different proteins identified in the chicken eggshell matrix, over 700 are specific for the eggshell (Gautron, 2019). Several of these proteins are present in abundance in the eggshell matrix and plays specific role in shell mineralization and function. For instance, ovocleidin-17 is one of the most abundant chicken eggshell matrix proteins, concentrated largely in the mammillary layer. Ovocleidin-116, another prominent eggshell matrix protein is widely distributed via the palisade layer, and its role is related to eggshell thickness and shape. Ovocalyxin-32 influences the variability of crystal traits and, in turn, the thickness profile of the shell (Takahashi et al., 2010). Ovocalyxin-36 is highly expressed during the shell calcification and has antimicrobial activity, thus might play a role in the natural defense of the egg against pathogens (Gautron et al., 2011). Further details regarding the eggshell mineralization and characteristic of matrix proteins can be found in an excellent reviews of Nys et al. (2004) and Hincke et al. (2010, 2012).

35.6.3.4 The cuticle

The outermost layer of the eggshell is a noncalcified cuticle which coats the entire outer surface of the crystal layer including the mouths of the pores. It is a thin, invisible layer, varying in thickness between 5 and 10 μm in different eggs and in different regions of the eggshell, and may even be missing. The cuticle is composed of glycoprotein (90%), polysaccharides (4%), lipids (3%), and inorganic phosphorus (3%) including hydroxyapatite crystals. The function of the cuticle is to serve as a protection of the egg from water lost and against microbial invasion. Among the numerous proteins identified in the cuticle are those with known antibacterial properties (Rose-Martel et al., 2012; Mikšik et al., 2014). The cuticle and the outer region of the calcified eggshell comprise pigments responsible for shell color (described in point 35.3.4.2). The physical features and color of eggshells are rooted in the genetic factors of the species, breeds, and individuals. In addition, eggshell color is affected by feed with individual components contributing more or less (Wilson, 2017).

35.6.3.5 The respiration through the eggshell

The shell is penetrated by about 7000 to 17,000 pores, which are the areas of incomplete crystallization. They arise between the mammillae basally, traverse the shell, and are eventually open beneath the cuticle on the surface of the shell. The number of pores per unit area reduces from the blunt end of the egg toward the sharp end. The role of the pores is to permit water vapor and gas exchange between the developing embryo and the ambient air (i.e., air cell of the egg and external environment). Gas exchange occurs by diffusion via the chorioallantoic membrane and the shell membranes before lung respiration starts. The air cell of the egg, which volume increases with the egg incubation progress, enables a more effective gas diffusion (Rokitka and Rahn, 1987). The decrease in the air cell volume has a negative effect on gas exchange, embryonic development, and hatchability. The elliptical shape of the avian egg maintains the blunt end with the air chamber up after oviposition or during incubation, which favors the most effective gas exchange and high hatchability (Mao et al., 2007).

Chapter 36

Reproduction in male birds

Jorge A. Vizcarra[1], Natalia Cerón-Romero[1], Nurudeen Taofeek[1] and John Kirby[2]
[1]Food and Animal Sciences, Alabama A&M University, Huntsville, AL, United States; [2]College of the Environment and Life Sciences, The University of Rhode Island, Kingston, RI, United States

36.1 Introduction

Reproduction is a process that can be organized into distinct developmental and functional phases. In the case of the male, these include fertilization, formation of a patent reproductive tract, production of sperm, manifestation of male-specific behavioral patterns, and expulsion of sperm from the body. This perspective can provide insight that may be missed if reproduction is viewed primarily as an isolated act. For example, although the reproductive tract is fully functional only in the adult, it is formed, for the most part, prior to hatching. Furthermore, while spermatogenesis is associated with puberty, spermatogenesis is not constrained by chronological age, but rather by the extent to which testicular cells proliferate and differentiate, which in turn, is coupled to the developmental limitations of gonadotropin secretion. Finally, androgens essential to the function of the reproductive tract, the appearance of secondary sexual attributes, and male behavior may have detrimental effects upon the development of immune and connective tissue if the hormonal signal appears during the period of rapid prepubertal growth and differentiation. Thus, this chapter will discuss the process of reproductive system development and function in the male bird.

36.2 Reproductive tract anatomy

36.2.1 Testis

The gross morphology and relative position of the male reproductive organs are shown in Figure 36.1. For detailed reviews see (King, 1979; Lake, 1981; Nickel et al., 1977). Paired reproductive tracts lie along the dorsal body wall. Each tract consists of a testis, an epididymis, and a highly convoluted deferent duct running alongside the ureter. The testes are connected to the body wall by a mesorchium. This peritoneal fold not only serves as an attachment for the testis but also as a conduit for nerves and blood vessels as well. Each testis is an aggregate of anastomosing seminiferous tubules with associated interstitial tissue enveloped by a connective tissue capsule. The testicular capsule is an important component of the contractile mechanism of the testes and is composed of three layers, including the tunica serosa, tunica albuginea, and tunica vasculosa. Of these three layers, the tunica albuginea represents the main tissue layer and comprises cellular elements that alternate with thick bundles of collagen fibers. The testicular capsule is, in general, thinner in birds than in mammals; however, studies in ratite birds have revealed a capsule that is considerably thicker than that of other bird species (Aire and Ozegbe, 2007; Ozegbe et al., 2008).

The testis contains two types of parenchymal tissue: the interstitial tissue and the seminiferous epithelium. The interstitial tissue contains blood and lymphatic vessels, nerves, peritubular epithelial cells, and Leydig cells; whereas thin concentric layers of myoepithelial cells, fibroblasts, and connective tissue fibrils overlie the basal lamina of the seminiferous tubule (Rothwell and Tingari, 1973). The seminiferous epithelium within the seminiferous tubules of sexually mature males is compartmentalized into basal and adluminal regions via tight junctions between adjacent Sertoli cells (Osman, 1980; Bergmann and Schindelmeiser, 1987). The seminiferous epithelium contains developing germ cells in distinct associations referred to as *stages*. The stages are arranged sequentially in a helix that extends along the length of the seminiferous tubule (Lin and Jones, 1990).

In birds, the left testis is commonly larger than the right, which may either be a byproduct of evolutionary selection for asymmetry in the female reproductive tract or an adaptation to facilitate flight (Birkhead et al., 1998; Denk and Kempenaers, 2005). The overall size of the testis scales allometrically to body mass; however, once controlled for body mass, testes size is often larger in bird species that experience a higher degree of sperm competition

Sturkie's Avian Physiology. https://doi.org/10.1016/B978-0-12-819770-7.00022-0

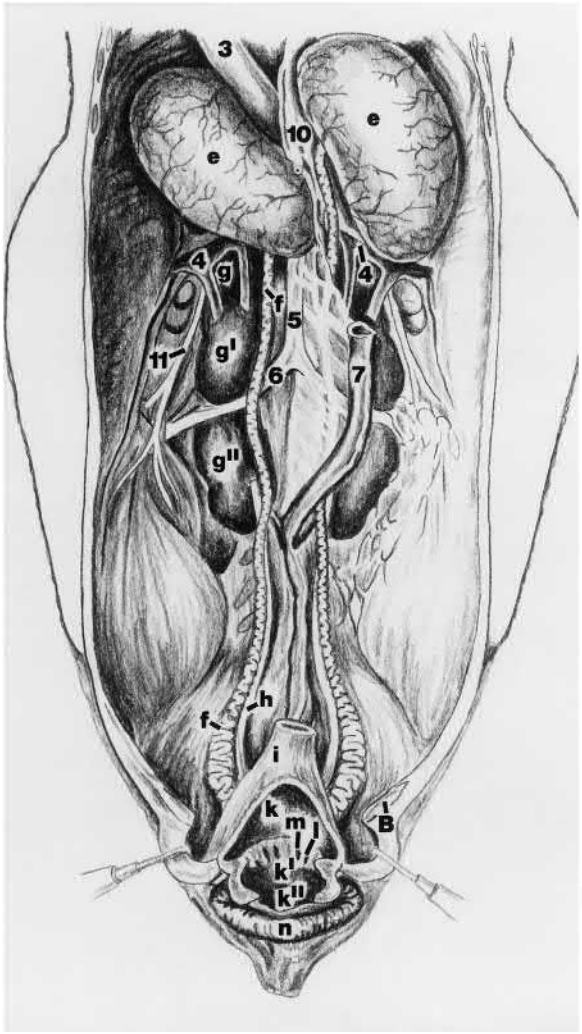

FIGURE 36.1 Topography of the dorsal body wall of the rooster. Paired testes (e) are located anterior to the cranial lobe of the kidneys (g). The deferent ducts (f) run alongside the ureters (h) towards the cloaca (k–k″), ultimately opening (l) into the urodeum (k′). Abbreviations: b, pubis; e, testis; f, ductus deferens; g, cranial; g′, middle, and g″, caudal lobes of the kidney; h, ureter; I, colon; k, coprodeum; k′, urodeum, k″, proctodeum; l, opening of left ductus deferens; m, opening of left ureter; n, anus. *Modified from Nickel et al. (1977).*

(Moller, 1991; Moller and Briskie, 1995; Pitcher et al., 2005). Sperm competition occurs when the sperm of two or more males is present in the female reproductive tract and must compete for egg fertilization. Although many bird species are socially monogamous, extra-pair copulations often occur. Species that participate in extra-pair copulations more frequently experience a more intense degree of sperm competition and have developed larger testis than species which do not frequently participate in extra-pair copulations (Moller, 1991; Moller and Briskie, 1995; Pitcher et al., 2005).

In male broiler breeders, no significant differences were observed in the weight of the right and left testis from 2 to 50 weeks of age (n = 2700; Vizcarra and Kirby, unpublished results). Testis of male broiler breeders reared under a "pedigree" breeding program had an exponential increase in weight after photostimulation (18 weeks of age; Figure 36.2). Within 10 weeks (i.e., week 18 to 28), testis weight increased from 0.4 to 28 g. However, after 28 weeks of age, testis weight was significantly decreased reaching a minimum weight of 15 g by week 42 (Figure 36.2). The reason for the testicular weight regression after 28 weeks of age is not completely clear at this time. Decreased follicle-stimulating hormone (FSH) concentrations might be responsible for testicular weight regression (Vizcarra et al., 2010). In male white Leghorns, an increase in both body and testis weight is observed as the bird ages. The growth rate reported in an 8-day-old embryo to 1-day-old chick is proportionally higher when compared to the growth rate from 1 day old to 28 weeks of age (Gonzalez-Moran and Soria-Castro, 2010). Similarly, testis weight increases but the rate of increase was much higher from 6 weeks of age to 28 weeks of age when compared to 8 days old embryo to 6 weeks of age. It can be inferred that testis growth rate increased rapidly relative to body weight (Gonzalez-Moran and Soria-Castro, 2010).

36.2.2 Excurrent ducts

The excurrent ducts or excurrent canals are ducts associated with the male reproductive tract that derive from the

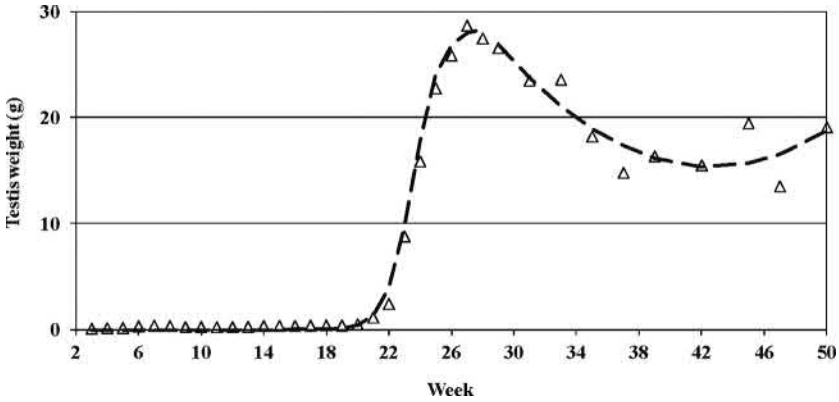

FIGURE 36.2 Least squares regression (lines) and means (symbols) for testis weight in male broiler breeders. Males on a "pedigree" breeder program were reared on a 23L:1D photoperiod and unrestricted food and water intake for 6 weeks. At 7 weeks, males were placed on a restricted diet and the photoperiod was reduced to 8L:16D. At week 18, birds were photostimulated (16L:8D) until the end of the experiment. Each symbol represents an average of 30 testes. *Modified from Vizcarra et al. (2010).*

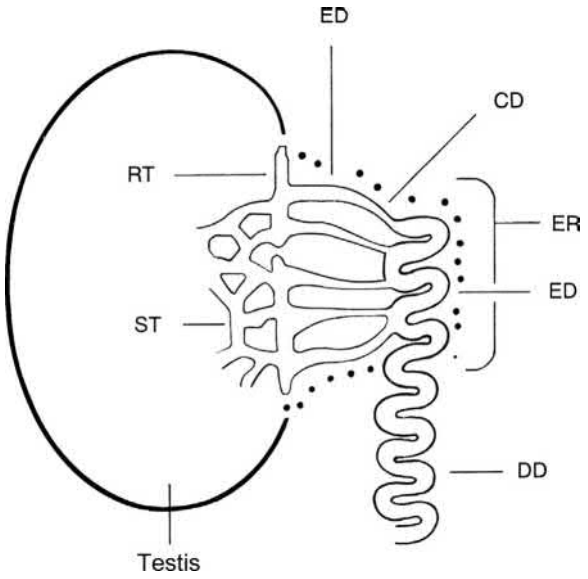

FIGURE 36.3 Schematic of the excurrent ducts of the testis. *ST*, seminiferous tubules; *RT*, rete testis; *ED*, efferent duct; *CD*, connecting duct; *ER*, epididymal region; *ED*, epididymal duct; *DD*, deferent duct. *Reproduced with permission from Academic Press, London and redrawn from Lake (1981).*

mesonephros and encompass the efferent ducts, epididymis, and deferens ducts. The epididymis is located on the dorsomedial aspect of the testis, which is referred to as the hilus (Figure 36.3). The epididymis is actually a series of ducts that ultimately empty into the deferent duct. The ducts within the epididymis include the rete testis, efferent ducts, connecting ducts, and the epididymal duct. The epididymal ducts and the deferent duct are referred to collectively as the excurrent ducts of the testis. Seminiferous tubules connect with the rete testis at discrete sites along the testis-epididymal interface (Tingari, 1971). Osman (1980), identified three distinct types of junctures between the seminiferous tubules and rete testis of the rooster: (1) a germ cell free epithelium of modified Sertoli cells that abruptly gives way to a rete-like epithelium, referred to as a terminal segment and tubulus rectus, respectively; (2) a terminal segment that connects directly to the rete testis; and (3) anastomosis of a seminiferous tubule with the rete testis. Tubuli recti have also been observed in quail testes (Aire, 1979a).

The rete testis has intratesticular, intracapsular, and extratesticular regions (Aire, 1982). As depicted in Figure 36.3, the rete testis exists as lacunae. In some avian species including domestic fowl, quail, guinea fowl, and ducks, the rete testis is lined with simple cuboidal and simple squamous epithelial cells (Aire, 1982), whereas in ratite birds, such as the ostrich, the epithelium contains cuboidal and columnar cell types (Aire and Soley, 2000, 2003). In gallinaceous birds, the rete testis exits the hilus after coursing through the testicular capsule before entering the epididymis which is in close proximity. In contrast, the rete testis of ratite birds makes up a much lower volumetric proportion of the epididymal tissue, and the rete testis travels a relatively larger distance from the testicular capsule before entering the epididymis (Ozegbe et al., 2010). Unlike the rete testis, the efferent ducts are wide at their proximal ends and narrow at their distal ends in many bird species (Aire and Soley, 2003; Simões et al., 2004); however, in ratite birds, both ducts are of similar height and diameter, which makes them less easily distinguished from one another (Aire and Soley, 2000; Ozegbe et al., 2006), whereas in emu and ostriches, the relative proportion of epididymal duct unit and the interductal connective tissue constituted a larger portion of the epididymis as compared to the rete testis and efferent ducts when combined (Ozegbe et al., 2010). On a volumetric basis (Table 36.1), the efferent ducts are the principal excurrent duct within the epididymis (Aire, 1979b; Aire and Josling, 2000). In most bird species, the efferent duct mucosa is highly folded, especially in the proximal portion (Tingari, 1971; Aire, 1979a; Bakst, 1980; Aire and Josling, 2000; Simões et al., 2004). In ratite birds, however, neither the proximal nor distal efferent ducts possess mucosal folds and they are regular in outline both internally and externally, which differs from other species (Ozegbe et al., 2006). In general, the efferent duct mucosa is characterized by a pseudostratified columnar epithelium that contains ciliated and nonciliated epithelial cells (Tingari, 1972; Budras and Sauer, 1975; Hess and Thurston, 1977; Aire, 1980; Simões

TABLE 36.1 Species Variation in Volumetric Proportions (%) of Epididymal Structures[a]

		Species	
Structures	Chicken	Japanese Quail	Guinea Fowl
Rete testis	13.3	9.9	10.7
Proximal efferent ductules	27.6	40.8	45.7
Distal efferent ductules	7.7	15.2	16.2
Connecting ducts	2.3	1.7	0.7
Epididymal duct	7.6	2.4	1.8
Connective tissue	38.7	27.3	22.6
Blood vessels	2.5	2.7	2.3
Aberrant ducts	0.3	–	–

[a]*Adapted from Aire (1979a).*

et al., 2004) as well as sparsely distributed intraepithelial lymphocytes (Aire and Malmqvist, 1979a). The epithelium of the connecting ducts is also composed of pseudostratified columnar cells (Tingari, 1971, 1972; Hess and Thurston, 1977; Aire, 1979a; Bakst, 1980; Aire and Josling, 2000). The distinguishing attributes of the connecting tubules are a narrow luminal diameter relative to that of adjacent excurrent ducts and the smooth contour of the mucosal surface (Tingari, 1971; Aire, 1979b; Bakst, 1980; Aire and Josling, 2000).

The tortuous epididymal and deferent ducts are characterized by low mucosal folds covered with nonciliated pseudostratified columnar epithelial cells (Tingari, 1971; Aire, 1979b; Bakst, 1980; Aire and Josling, 2000; Simões et al., 2004). In gallinaceous birds, the epididymal duct constitutes between 2.5% and 10% of the total epididymal volume (Aire and Josling, 2000), whereas in ratite birds, the volumetric proportion of the epididymal duct is as much as tenfold higher (Ozegbe et al., 2010). Based upon histological and morphological evidence, the deferent duct is a continuation of the epididymal duct. Luminal diameter gradually increases by threefold between the cranial epididymal duct and the distal deferent duct (Tingari, 1971). One notable difference between the epididymal duct and the deferent duct are the layers of dense connective tissue and smooth muscle surrounding the mucosa of the latter (Tingari, 1971; Aire and Josling, 2000). A dense capillary network envelope the excurrent ducts from the level of the proximal efferent ducts to the deferent duct (Nakai et al., 1988). The distal deferent duct straightens and then abruptly widens at its juncture with the cloaca. This structure, known as the receptacle of the deferent duct, has a bean-shaped appearance when it is engorged with semen. Each deferent duct terminates in the cloacal urodeum as a papilla immediately below the ostium of a ureter (Figure 36.4).

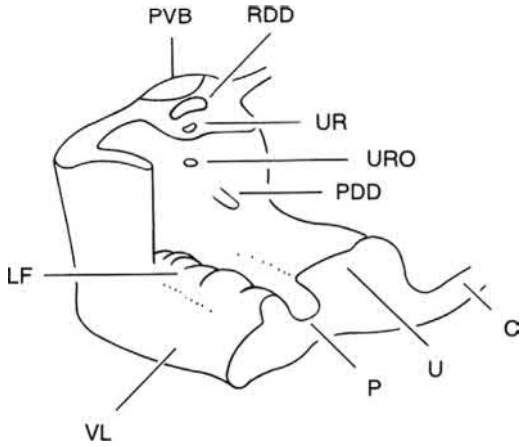

FIGURE 36.4 Schematic of the lower left quadrant of the cloaca. Before entering the cloacal wall, the deferent duct straightens then widens to form the receptacle of the deferent duct. The paracloacal body, also seen sectioned but shaded, is attached to the lateral aspect of the receptacle. The papilla of the deferent duct is within the urodeum of the cloaca. *PVB*, paracloacal vascular body; *RDD*, receptacle of the deferent duct; *C*, ventral wall of coprodeum; *U*, ventral wall of urodeum; *P*, ventral wall of proctodeum; *VL*, ventral lip of vent; *LF*, lymphatic folds. *Reproduced from King (1981), with permission from Academic Press.*

36.2.3 Accessory organs

Accessory reproductive organs include the paracloacal vascular bodies, dorsal proctodeal gland, and lymphatic folds (Fujihara, 1992). The accessory reproductive organs are either in proximity to or are an integral part of the cloaca. As shown in Figure 36.4, the paracloacal vascular body is found alongside the receptacle of the deferent duct, and lymphatic folds exist within the wall of the proctodeum. An intromittent phallus exists in only 3% of birds species (Herrera et al., 2013) including ratites and the waterfowl. In chickens, the phallus is nonintromittent and sperm is passed to the female via the "cloacal kiss" during matting (Briskie and Montgomerie, 2001). The cloacal kiss entails the union of the male and female cloacae for a few seconds. During copulation or in response to massage, a nonintromittent phallus forms a tumescent lymphatic tissue is everted through the vent immediately before ejaculation. As reviewed by Fujihara (1992), the paracloacal vascular bodies are essential for lymphatic tissue tumescence, as they are the sites where lymph is formed by ultrafiltration of blood. Thus, phallus erection in birds is lymphatic. The lymph needed for bird's lymphatic erection is produced in the paralymphatic bodies and the vascular body of the phallus, an ellipsoid spongy organ located alongside the middle of the cloaca (Brennan and Prum, 2012). In mammals, penile erection is blood-vascular and during ejaculation, semen is transported via the urethra. However, in birds semen is transported by the *sulcus spermaticus*, an external groove present in the phallus (Brennan et al., 2010).

Courtship behavior in male birds consists of searching and approaching a potential female (for an extensive review see (Ball and Balthazart, 2004)). For instance, quails display a series of sexual behaviors that include mounting and aggressive pursuit for mating (Hutchison, 1978). Most of the evidence suggests that the medial portion of the preoptic area (POA) of the brain is responsible for the control of male behavior (Adkins and Alder, 1972; Konkle and Balthazart, 2011). The POA is significantly larger in males than females, and male castration causes a reduction of the volume of this area (Panzica et al., 1987). In addition, castration reduces the normal sexual behavior in males and exogenous testosterone restores the normal behavior (Ball and Balthazart, 2004). In castrated males, estrogen can also restore normal behavior, but co-injection of testosterone and an aromatase inhibitor blocks this effect (Balthazart et al., 1997). It is now widely recognized that aromatization of testosterone in the POA is responsible for the normal

courtship behavior observed in male birds (Wade and Arnold, 1996; Cornil et al., 2011).

36.3 Ontogeny of the reproductive tract

36.3.1 Overview

The adult male reproductive tract is derived from two embryonic organs: a gonad and its associated mesonephros. However, the formation of the mesonephros precedes that of the gonad (Figure 36.5). In fact, the gonad arises from the ventromesial surface of the mesonephros (Figure 36.6). As reviewed by (Romanoff, 1960), three distinct pairs of excretory organs appear sequentially during embryonic development: the pronephros, mesonephros, and metanephros. The most anterior organ, the pronephros, disappears by day four of incubation in the chicken. Nonetheless, the pronephric duct, also known as the Wolffian duct, persists through time to (1) induce the formation of the mesonephric tubules, (2) induce the formation of the Müllerian duct, (3) temporarily link the mesonephros with the cloaca, and (4) ultimately serve as the deferent duct in males. The critical point in the ontogeny of the reproductive tract is gonadal differentiation; prior to this point in time, the embryo has bipotential gonads and the rudiments of oviducts and deferent ducts in the form of the Müllerian and Wolffian ducts, respectively.

Sex determination in mammalian species is associated with the expression of the sex-determining region Y (SRY) gene located in the Y chromosome of the heterogametic XY male. The major function of the SRY gene is to facilitate Sertoli cell differentiation via the SRY-box transcription factor 9 (Sox9) that, in turn, promotes testis development as previously reviewed (Knower et al., 2003). In contrast to mammalian species, male birds are

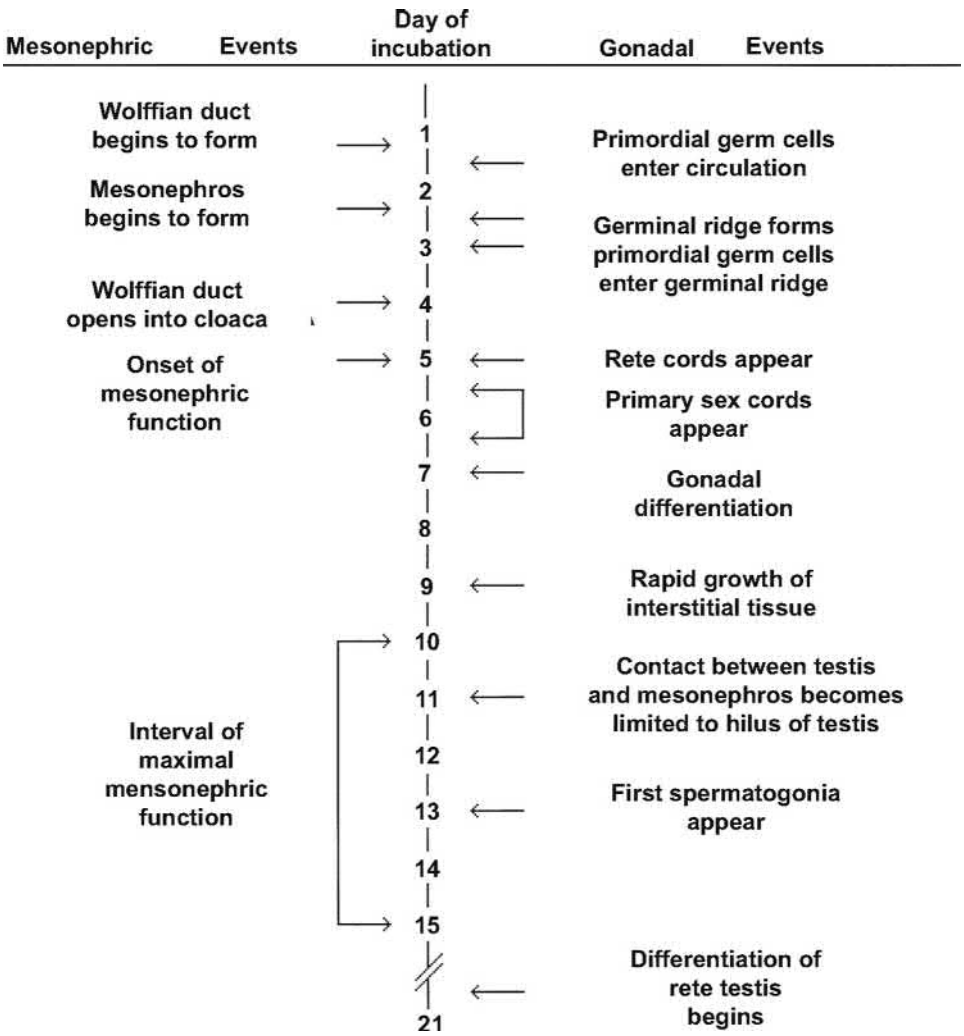

FIGURE 36.5 Chronology of developmental events in ovo associated with the formation of the male reproductive tract in Gallus domesticus. See text for details.

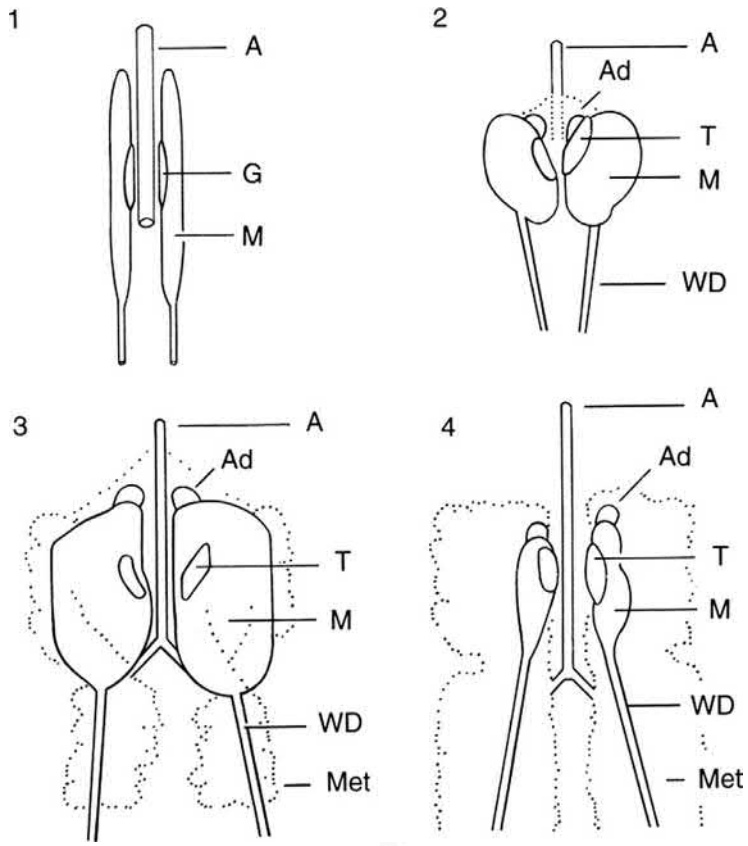

FIGURE 36.6 Stages in the development of the male urogential system. Numbers denote the first, second, third, or fourth quarter of incubation. The mesonephros forms before the differentiation of the gonad. After the metanephros becomes functional midway through incubation, mesonephric function declines and the mesonephros recedes apart from where it contacts the testis. *A*, aorta; *G*, undifferentiated gonad; *M*, mesonephros; *Ad*, adrenal gland; *T*, testis; *WD*, Wolffian duct; *Met*, metanephros. *Reproduced from Romanoff (1960), with permission from the MacMillan.*

homogametic and females are heterogametic (ZZ and ZW gonosomes, respectively). Thus, the molecular mechanism of sex determination in birds is different from mammalian species. Because females are heterogametic, one possibility is that the W chromosome is responsible for female development even when the W-linked determinant is still unidentified. Notwithstanding, the overexpression of the determinant W-linked histidine triad nucleotide binding protein in male embryos does not induce ovarian differentiation (Smith et al., 2003). In this scenario, a factor (similar to the SRY gene in male mammals) will be coupled to female differentiation. However, very few W-linked genes have been reported in the literature (Hori et al., 2000; O'Neill et al., 2000), suggesting that other mechanisms are responsible for male development. A second possibility is that a gene in the Z chromosome triggers male development when two copies of the gene are present. The Z chromosome "dosage" theory states that higher doses of a gene can initiate male differentiation if the additional copy is transcribed and translated in higher doses of the resulting protein. It has been shown that the Doublesex and Mab-3 Related Transcription factor 1, encoded by the DMRT1 gene (a zinc finger-like DNA-binding transcription factor), is a male sex determining factor in chickens (Smith et al., 2009a). In all birds studied to date, the DMRT1 gene is present in the Z chromosome and absent in the W chromosome (Chue and Smith, 2011). Reduction of DMRT1 protein expression, using RNA interference technology in early male embryos, resulted in feminization of the gonads. These data and other, supports the Z chromosome "dosage" theory in birds (Nanda et al., 1999; Chue and Smith, 2011). Similar to mammalian species, there is evidence that activation of the male determining factor in birds facilitates Sertoli cell differentiation via Sox9 or via anti-Müllerian hormone (AMH) which are upregulated in the chicken testis during gonadal development (Da Silva et al., 1996; Oreal et al., 1998; Bagheri-Fam et al., 2010). Taken together, mammals and birds use a different molecular mechanism for sex differentiation (SRY and DMRT1, respectively). After genes are expressed, a common pathway that involves a Sertoli cell differentiation factor (Sox9) promotes testicular differentiation and development (Figure 36.7).

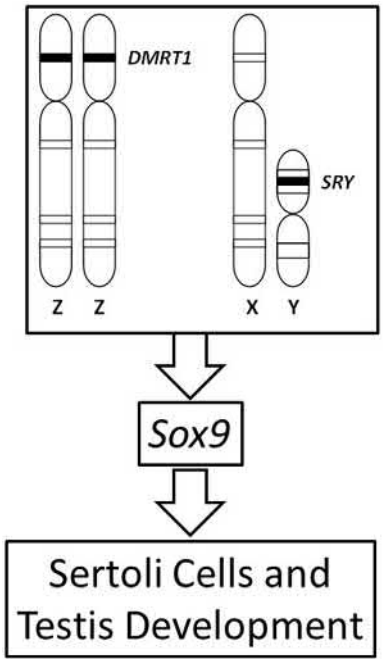

FIGURE 36.7 Differential mechanisms for sex differentiation in mammalian and avian species. In mammals, the XY male uses the SRY gene, while in birds the ZZ male uses the DMRT1 gene to facilitate Sertoli cell differentiation (via Sox9) that, in turn, promotes testis development.

36.3.2 Formation of the undifferentiated Gonad

Even though the gonad forms upon the ventromesial surface of the mesonephros, a fully differentiated mesonephros is not required for gonadal development (Merchant-Larios et al., 1984). The gonad is formed by the invasion of primordial germ cells into coelomic epithelium overlying a portion of the mesonephros (Figure 36.5), known as the germinal ridge (Romanoff, 1960; Clinton, 1998; Shimada, 2002). Primordial germ cells arise from endoderm along the anterior interface of the blastoderm's area opaca and area pellucida. After entering embryonic circulation, primordial germ cells are randomly distributed throughout the vasculature of the embryo (Meyer, 1964; Shimada, 2002; Yoshida, 2016). Subsequently, primordial germ cells colonize the germinal ridge (Fujimoto et al., 1976; Shimada, 2002). The undifferentiated gonad contains rete cords and primary sex cords in the anterior and middle regions, respectively (Romanoff, 1960).

36.3.3 Gonadal differentiation and Müllerian duct regression

Gonadal differentiation in chick embryos occurs at approximately 6.5−7 days of incubation (Figure 36.5). In comparison to the ovary, the cells of the medullary cords condense and coalesce into Sertoli cells, the cell to first emerge in the testis (Major and Smith, 2016). Embryonic testis is characterized by a germinal epithelium that recedes with time (mitotic arrest), a thicker capsule, the absence of secondary or cortical sex cords, as well as the presence of primary sex cords surrounded by stroma (Romanoff, 1960; Clinton and Haines, 1999; Shimada, 2002). Also, in the outer epithelial layer, there is no hyperproliferation (Major and Smith, 2016). The primary sex cords contain numerous primordial germ cells and are anlage of the seminiferous tubules. Biochemically, gonadal differentiation is evident in terms of increased cyclic nucleotide concentrations (Teng, 1982), increased protein synthesis (Samsel et al., 1986), and the pattern of sex steroid synthesis (Guichard et al., 1977; Imataka et al., 1988; Mizuno et al., 1993). It is noteworthy that these traits become evident prior to the development of the pituitary-gonadal axis, which appears to become functional at 13.5 days of incubation in the chick (Woods and Weeks, 1969). It must also be noted that the interval of sexual bipotentiality differs among species.

Once the testes have formed, the Müllerian ducts cease development and undergo regression in a caudocranial direction (Romanoff, 1960; Hutson et al., 1985). Müllerian duct regression is attributable to AMH, also known as Müllerian Inhibiting Substance (Bruggeman et al., 2002; Smith and Sinclair, 2004). This hormone is a 7.4 kDa gonad-specific glycoprotein (Teng et al., 1987), which, in the male, is derived from the progenitors of Sertoli cells found within the primary sex cords (Stoll and Maraud, 1973; Oreal et al., 2002). The gene encoding AMH is expressed in both males and females, but is consistently higher in males during sexual differentiation (Smith et al., 1999). Regression of the Müllerian ducts in males occurs because they contain insufficient circulating estrogen levels to counteract the effect of AMH which may be a direct result of aromatase suppression by AMH itself (MacLaughlin et al., 1983; Hutson et al., 1985; Bruggeman et al., 2002).

36.3.4 Formation of the excurrent ducts

The excurrent ducts are derived from the mesonephros. As shown in Figure 36.5 and 36.6, the mesonephros is active throughout the second and third quarters of incubation. The functional unit of the mesonephros includes a malpighian corpuscle, proximal, intermediate, and distal tubules, as well as a connecting tubule. The latter connects the series of mesonephric tubules with the Wolffian duct. The malpighian corpuscle is a capillary tuft or glomerulus within a double-walled epithelial enclosure known as Bowman's capsule. The visceral epithelial layer adheres to the glomerulus. At the pole of the corpuscle where the afferent and efferent arterioles are attached to the glomerulus within, the visceral epithelium folds back upon itself to form the parietal epithelium. As the parietal epithelium extends away from the vascular pole, it is separated from

the visceral epithelium by a lumen. After the mesonephros becomes functional, glomerular filtrate enters the lumen of the proximal tubule. After the metanephros becomes functional during mid-incubation (Romanoff, 1960), the mesonephros begins to degenerate except where there is contact with the embryonic testis. Consequently, the mesonephros undergoes a profound change in size during embryonic development (Figure 36.6).

During the last third of incubation, a subset of mesonephric tubules are converted into the excurrent ducts of the testis (Budras and Sauer, 1975) and the malpighian corpuscles in proximity to the rete cords fuse. The glomeruli undergo progressive degeneration while the simple squamous epithelial cells of the parietal epithelium differentiate into simple columnar cells. This tissue becomes the epithelium of the proximal efferent ducts. Proximal, intermediate, and distal mesonephric tubules are transformed into distal efferent ducts, connecting ductules become the connecting ducts, the Wolffian duct associated with the mesonephros becomes the epididymal duct, and the distal Wolffian duct becomes the deferent duct.

The transformation of the mesonephric ductules into the excurrent ducts of the testis is dependent on androgen production by the Leydig cells (Maraud and Stoll, 1955; Stoll and Maraud, 1974; Bruggeman et al., 2002), and is initiated shortly after the concentration of blood plasma testosterone has peaked *in ovo* (Woods et al., 1975). However, the entire process of ductule conversion in the chicken requires an interval of 8–10 weeks (Marvan, 1969; Budras and Sauer, 1975). During this time, mean plasma testosterone levels stay constant at about 12–13% of those observed in sexually mature males (Driot et al., 1979; Tanabe et al., 1979). In contrast to the mesonephric tubules, differentiation of the rete cords begins at about the time of hatching and is complete by 5 weeks of age (Budras and Sauer, 1975). The convolutions of the newly formed epididymal and deferent ducts increase until sexual maturity (Budras and Sauer, 1975). The final length of the deferent duct has been estimated to be four times greater than the linear distance between the epididymis and cloaca due to these convolutions (Marvan, 1969).

36.4 Development and growth of the testis

36.4.1 Proliferation of somatic and stem cells in the testis

The testis of the mature bird is organized into discrete, easily discernible cellular associations and functional compartments (Figure 36.8D). However, during embryonic and early posthatch development of this organization is less apparent. In white Leghorn embryos, from day 8 to day 13 of incubation, the cells of the epithelium that gives rise to

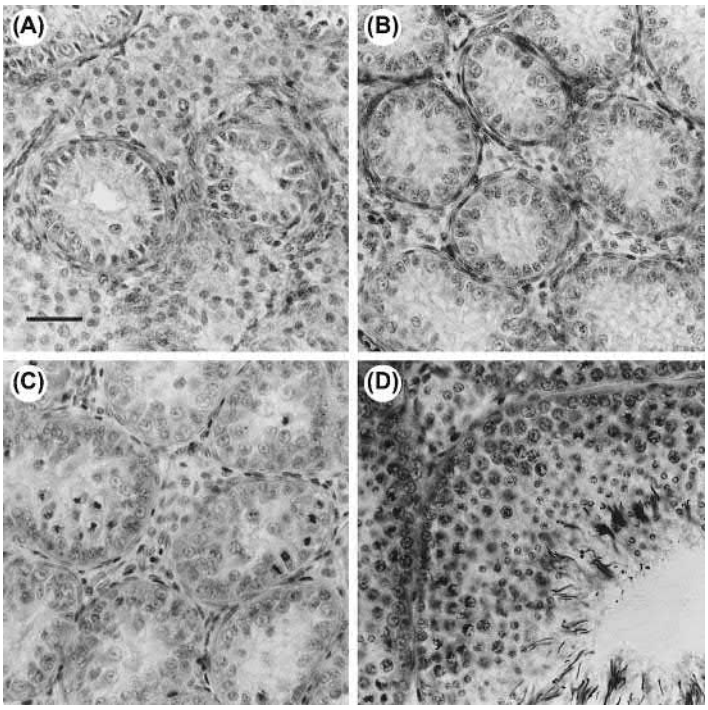

FIGURE 36.8 Cross-sections of testes of cockerels reared under 8h of light (A–C) and of an adult male on 14h of light (D). (A) Cross-section of a testis from a 14 day old male. Notice the simple single layer of spermatogonia and Sertoli cells in the tubules and the relative abundance of interstitial space. (B) Cross-section of a testis from a 56 day old cockerel. The single layer of cells within the seminiferous tubule has become taller and more complex. (C) Cross-section of a testis from a 140 day old cockerel. Notice the appearance of spermatocytes (cells with darkly stained chromatin) that have moved away from the basement membrane. (D) Cross-section of a testis from an adult male, which clearly demonstrates active spermatogenesis and the dramatic reduction in the relative area of the interstitium. The bar in (A) equals 20μm; all of the micrographs are of equivalent magnification. *Photographs by the author.*

Sex cords change from undulated (A) to a reticulum shape (B). interstitium (I), tunica albuginea (T). Magnification is represented by a 50-mm scale in A and B. *Microphotograph adapted from (Gonzalez-Moran and Soria-Castro, 2010).*

the tunica albuginea change from cuboidal to flatten (Figure 36.9A). The initial sex cords tend to form a reticulum that connects with the primordial tunica albuginea (Figure 36.9B). Hyperplasia of primordial germinal cells and Sertoli cells occurs proportionally as embryonic development progresses (Gonzalez-Moran and Soria-Castro, 2010). These primordial germinal cells differentiate into spermatogonia and remain arrested until 10 week of age (Oiso et al., 2013). In addition to Sertoli and primordial germinal cells, a side population (SP) of cells has been identified in the prenatal gonads. The SP cells play an important role enhancing germ cell and stem cells function in the gonad. For instance, SP cells have a particular membrane-pump system activated by Brcp1 gene. It has been suggested that BCRP seems to play an important function in genome integrity for stem cells, thereby enrichment for the niche in which stem cells colonize the male gonad (Bachelard et al., 2015).

The posthatch development of the fowl's testis can be divided into three distinct phases: (1) proliferation of spermatogonia and the somatic cells that support spermatogenesis (Sertoli, peritubular myoid, and interstitial cells); (2) differentiation and the acquisition of functional competence by somatic support cells; and (3) spermatogonial differentiation resulting in the initiation of meiosis. Although the boundaries of these phases are not clearly defined, this three-step process results in functional seminiferous tubules that can sustain spermatogenesis when the appropriate hormonal cues are present. There is some evidence that FSH may play an important role in embryonic gonad growth by stimulating cell division. Treatment with FSH increased the mitotic index in both the seminiferous tubules and peritubular cells of chicken embryo testis at around 14 days of development (Mi et al., 2004).

The testis of the young cockerel (approximately 0–6 weeks of age) is characterized by an abundance of interstitial tissue and seminiferous tubules with only a single layer of cells within the basal lamina surrounded by several layers of myoid cells (Figure 36.8A). The majority of cells located within the seminiferous tubules at this time are Sertoli cells and spermatogonia, with macrophages and mast cells observed as well (de Reviers, 1971b). The seminiferous tubules at this time are narrow (approximately 40 μm in diameter) with either a poorly formed lumen or no apparent lumen at all (seminiferous cords). This is a period of rapid cellular proliferation, as while the tubules are only slowly growing in diameter, they are growing rapidly in length (de Reviers, 1971a). Even though the somatic and stem cells are proliferating, the absolute weight and volume of the testis is increasing slowly from day eight of incubation to 6 weeks of age as the seminiferous tubules displace interstitial cells (Marvan, 1969; de Reviers, 1971a; Gonzalez-Moran and Soria-Castro, 2010). In white Leghorn, the increase in size of the seminiferous tubules is attributed to hyperplasia of the Sertoli cells. During early days of age (one to six doa), the population of Sertoli cells are dominant, whereas at 28 weeks of age the germ cells are more abundant. The growth rate of the testis from the sixth to the eighth week was greater than the rate of increase of body weight (Gonzalez-Moran and Soria-Castro, 2010).

36.4.2 Differentiation of somatic cells within the testis

Following a posthatching period of Sertoli cell proliferation, these cells become mitotically quiescent and differentiate (for a review see Russell and Griswold (1993)). In a study by (de Reviers and Williams, 1984), hemicastration was shown to result in compensatory hypertrophy of the remaining testis of males up to 8 weeks of age. As hemicastration typically results in significant hypertrophy only during the period of Sertoli cell proliferation in mammals, it is possible to postulate that Sertoli cells are proliferating in the fowl to about 8 weeks of age. A more recent study by Bozkurt et al. (2007) provides support for this hypothesis. In this study, the mitotic proliferation of Sertoli cells was observed in the testis of fowl from 1 to 10 weeks of age. Initially, the density of germ cell nuclei was less than that of Sertoli cell nuclei; however, by week six, the volume density of the two cell types had converged and remained constant until the commencement of meiosis. In addition, clear labeling of both Sertoli and germ cells was observed from weeks one through seven, but, by week eight, the only cells still labeled were germ cells. These data confirm that

the cessation of Sertoli cell proliferation occurs around eight weeks in domestic fowl.

Sertoli cells differentiate into highly polarized cells that extend from the basal lamina to the lumen of the seminiferous tubule. The mature Sertoli cell is a complex, columnar cell that contains numerous crypts into which developing sperm cells are embedded (Sertoli, 1865, 1878; Nagano, 1962). Sertoli cell functions are thought to be regulated by a myriad of endocrine and paracrine factors, although FSH and testosterone have been most thoroughly studied (Brown et al., 1975; Brown and Follett, 1977). A primary function of Sertoli cells is to provide a carefully regulated environment, including the sequestration of postmeiotic germ cells into the adluminal compartment is accomplished by the formation of tight junctions between adjacent Sertoli cells at a point basal to the maturing, meiotic, germ cell (Bergmann and Schindelmeiser, 1987; Pelletier, 1990). While tight junction formation appears to be androgen dependent in the fowl, tight junctions are maintained during periods of spermatogenic quiescence in the mallard (*Anas platyrhynchos*) (Pelletier, 1990). Another indicator of mature Sertoli cell function is the complex complement of proteins synthesized and secreted in response to androgen and/or FSH stimulation. While studied only superficially in male birds, spermatogenic stage-specific protein synthesis and secretion is well documented in other groups (see Russell and Griswold (1993)). The presence of a distinguished rough endoplasmic reticulum, lysosomes, and macrophage function in Sertoli cells has been associated to the fas-induced apoptosis mechanism that controls germinal cell population. Therefore, the number of Sertoli cells determine and regulate the development of stem primordial germinal cells into spermatogonia (Thurston and Korn, 2000).

The growth of the seminiferous tubules is associated with a reorganization and reduction of the testicular interstitium (Figure 36.8A–D). While the seminiferous tubule is the compartment where spermatogenesis will occur in the adult, Leydig cells of the interstitium are responsible for testicular androgen production. In the interstitium, there is the presence of mesenchymal cell-like Leydig cell precursors, which have vesicles of smooth endoplasmic reticulum and lipid droplets (Connell, 1972). The differentiation of these cells into their mature form is under the influence of LH (Narbaitz and Adler, 1966; Brown et al., 1975; Driot et al., 1979). Mature Leydig cells are formed following a continuum of cellular differentiation that occurs during the period of testicular growth leading to the prepubertal increases of circulating LH levels (Rothwell, 1973). While limited testosterone production is observed during embryogenesis and early development, the capacity to produce testosterone at sexually mature levels requires the presence of a fully differentiated Leydig cell population (for a review of testicular steroidogenesis see (Johnson, 1986). The mature Leydig cell of the rooster has extensive smooth endoplasmic reticulum, a prominent Golgi complex, mitochondria with tubular cristae, abundant lipid droplets, and lysosomal elements (Rothwell, 1973).

36.4.3 Initiation of meiosis

During the period of Sertoli and Leydig cell differentiation, the population of spermatogonia increases in size and complexity. As described later in the chapter, spermatogonia undergo a series of transformations prior to committing to meiosis. However, once a spermatogonium is transformed into a preleptotene spermatocyte, it separates from the basement membrane and shifts toward the adluminal compartment of the seminiferous tubule. The onset of active meiosis is marked by the presence of pachytene and zygotene spermatocytes which are easily discernible due to their highly condensed and darkly stained chromatin (Figure 36.8C). The initiation of meiosis appears to occur only after the completion of Sertoli cell proliferation, and an increase in circulating androgens is encountered (de Reviers, 1971a, b). The onset of meiosis can be significantly altered by manipulation of the photoperiod (Ingkasuwan and Ogasawara, 1966). When broiler breeders were reared on a 23L:1D photoperiod and ad libitum food and water intake for 6 weeks, males showed precocious testicular maturation with zygotene or pachytene, or both, spermatocytes visible in all seminiferous tubules at 7 weeks of age. In contrast, when broiler breeders were reared on a 15L:9D photoperiod and ad libitum food and water intake for only 2 weeks, the structures previously described were not present at seven weeks of age (Vizcarra et al., 2010).

36.4.4 Altering the pattern of testis growth and maturation

The temporal component of testicular maturation can be altered by manipulation of the endocrine milieu. Specifically, onset of meiosis and sustained spermatogenesis can be altered dramatically in the fowl by manipulating the photoperiod (Ingkasuwan and Ogasawara, 1966). Male fowl reared on a long photoperiod (14 h light or more per day) will typically have reached sexual maturity by 16–20 weeks of age (Ingkasuwan and Ogasawara, 1966; Sharp and Gow, 1983). However, as shown in Figure 36.8C, when males are reared on short days (in this case 8 h of light per day), the onset of spermatogenesis is delayed. Eventually, male fowl became refractory to short days, FSH and LH levels increase, and spermatogenesis commences. Conversely, precocious puberty and the onset of spermatogenesis can be accelerated in the fowl by chronic treatment with tamoxifen, an estrogen receptor antagonist (Rozenboim et al., 1986). Males treated with tamoxifen exhibited adult behaviors and produced viable

spermatozoa by 9 weeks of age, months ahead of their nontreated siblings (Rozenboim et al., 1986).

Testicular maturation can also be altered by exposure to estrogen and estrogen-like compounds. Rooster embryos exposed to ethinylestradiol, a synthetic form of estrogen, exhibited significant reduction in the average area of their seminiferous tubules. In addition, exposed birds had a decreased proportion of seminiferous tubules and an increase in the proportion of interstitial tissue (Blomqvist et al., 2006). In Japanese quail, male embryos exposed to ethinylestradiol became feminized and had ovary-like tissue within the testis along with persistent Müllerian ducts (Berg et al., 1999).

36.5 Hormonal control of testicular function

36.5.1 Central control of testicular function

Spermatogenesis is the process in which the division of spermatogonial stem cells ultimately yields sperm cells while a population of stems cells is maintained. This complex phenomenon occurs within the seminiferous epithelium and depends upon the availability of testosterone and FSH, the activity of Sertoli cells, as well as interactions between germ cells and Sertoli cells (Sharpe, 1994). Although spermatogenesis is controlled, in part, by cells within the testis, the process is ultimately controlled by neurons within the central nervous system (CNS; see review by (Sharp and Gow, 1983)). Neurosecretory activity, in turn, is affected by somatic and environmental stimuli. Wingfield et al. (1992) have proposed a model accounting for the central integration of environmental information that affects gonadotropin secretion on a seasonal basis. The model is based upon the interplay of endogenous "predictive" rhythms and supplementary environmental information. The duration of the period of light in a subjective day (24 h period) is the principal environmental factor that stimulates spermatogenesis in galliform birds. As reviewed by (Kuenzel, 1993), photoreceptors that affect spermatogenesis are neither found within the retina nor the pineal gland. Most of the evidence suggests that the most plausible site associated with the photoperiodic response is the medial basal hypothalamus (MBH) via direct innervations of GnRH neurons by encephalic photoreceptors (Saldanha et al., 2001) or via the pars tuberalis of the adenohypophysis (Yoshimura, 2006, 2010; Watanabe et al., 2007; Yasuo and Yoshimura, 2009). It has been reported that the pars tuberalis synthesize and secretes β-thyroid stimulating hormone (TSH) when Japanese quails are exposed to long-day stimulation (Yoshimura et al., 2003). In turn, TSH is retrogradely transported to the MBH via nonclassical mechanisms (Krieger and Liotta, 1979; Mezey et al., 1979). In the MBH, TSH regulates the expression of genes encoding type 2 (*Dio2*) and type 3 (*Dio3*) deiodinases. Thyroxine (T4) is converted (within the MBH) to the bioactive T3 (triiodothyronine) form that, subsequently, stimulates the photoperiodic response of the gonadal axis (Yoshimura et al., 2003). In photosensitive and scotorefractory quails (Figure 36.10), the mechanism by which Gonadotropin-Inhibitory Hormone (GnIH), GnRH-I and −II are regulated has been associated with the stimulation of deep brain photoreceptors and the photoreceptive neurons (psin-5 and VA-opsin) (Banerjee and Chaturvedi, 2017).

36.5.2 Control of adenohypophyseal function in males

Gonadotropin-releasing hormone (GnRH) is a decapeptide that plays a fundamental role in the release of gonadotropins from the pituitary gland, and is the primary hormone that regulates reproduction. Andrew Schally and his team isolated and synthesized for the first time the decapeptide GnRH, after the extraction of more than 250,000 pig hypothalami (Matsuo et al., 1971; Wade, 1978). In addition to GnRH, the occurrence of other two GnRH isoforms were first reported in chickens more than 10 years after of Dr. Schally's initial report. The nomenclature used to distinguish different GnRH isoforms between mammalian and nonmammalian species have been described using a variety of phylogenetic and genomic synteny analyses (Millar et al., 2004; Borosky et al., 2011; Kim et al., 2011; Tostivint, 2011). In the vertebrate classification, avian species as part of the gnathostomes have three GnRH clades (GnRH1, GnRH2, and GnRH3). Thus, cGnRH-II and −I are part of GnRH1 and GnRH2, respectively (Ubuka et al., 2013). For the purpose of this chapter, we adopted the nomenclature based on the species in which they were first discovered, depicted in Table 36.2, and described elsewhere (Millar et al., 2004).

Chicken GnRH-I (King and Millar, 1982; Miyamoto et al., 1982) differs in only one amino acid compared with the mammalian form (cGnRH-I; [Gln8]-GnRH); whereas chicken GnRH-II (Hattori et al., 1986) differs in three amino acids (cGnRH-II; [His5-Trp7-Tyr8]-GnRH). The coordination of gonadotropin secretion via cGnRH is also modulated by the interaction of the GnRH peptide with its receptors. The Gonadotropin-releasing-hormone receptors (GnRHRs) have the characteristic feature of a classical seven transmembrane, G-protein-coupled receptor (Neill, 2002; Millar, 2003, 2005). Four vertebrate GnRHR lineages have been proposed using genome synteny and phylogenetic analyses; nonmammalian type I, nonmammalian type II, nonmammalian type III/mammalian type II, and mammalian type I (Kim et al., 2011).

Two GnRHRs have been identified in chickens (Shimizu and Bédécarrats, 2006; McFarlane et al., 2011).

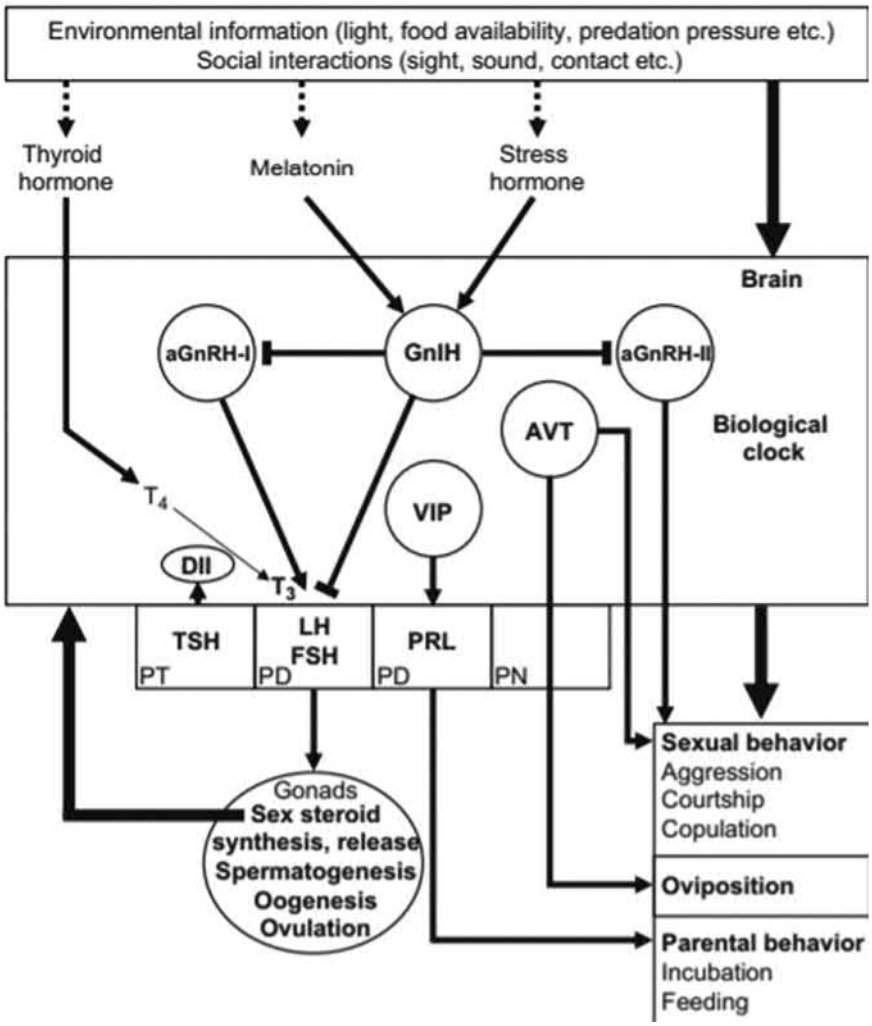

FIGURE 36.10 Neuroendocrine Control of Reproduction in Birds. *Adapted from (Ubuka and Bentley, 2011).*

TABLE 36.2 Amino Acid (AA) Sequence of GnRH Isoforms

	1 2 3 4 5 6 7 8 9 10
Mammal (mGnRH)	**pGlu-His-Trp-Ser-**Tyr-Gly-Leu-Arg**-Pro-Gly**
Chicken-I (cGnRH-I)	**pGlu-His-Trp-Ser-**Tyr-Gly-Leu-Gln**-Pro-Gly**
Chicken-II (cGnRH-II)	**pGiu-His-Trp-Ser-**His-Gly-Trp-Tyr**-Pro-Gly**

The bolded regions represent the conserved NH_3- and COOH- terminal residues. The numbers represent the relative position of each AA in the GnRH peptide (1 represents the N-terminal AA).

The nonmammalian type I receptor is predominantly expressed in the chicken pituitary gland (Shimizu and Bédécarrats, 2006; Joseph et al., 2009); whereas the nonmammalian type II receptor is not only expressed in the pituitary and the brain but also in the gonads and other tissues (Sun et al., 2001b). The nonmammalian type I receptor in chickens (NCBI accession number: NP_001012627) has been previously referred as cGnRH-R-III (McFarlane et al., 2011), GnRHR1/III (Kim et al., 2011), or GnRHR2 (Shimizu and Bédécarrats, 2006), whereas the nonmammalian type II receptor in chickens (NCBI accession number: NP_989984) has been previously

referred as cGnRH-R (Sun et al., 2001a; Kim et al., 2011) or cGnRHR 1 (Shimizu and Bédécarrats, 2006).

The affinity of the cGnRH-I peptide to the nonmammalian type II receptor is higher than the affinity of cGnRH-II peptide to the same receptor (Sun et al., 2001a). The nonmammalian type I receptor in the chicken pituitary is differentially expressed with respect to the reproductive status, and is associated with the control of gonadotropin secretion (McFarlane et al., 2011).

In the chicken, GnRHergic neurons arise within the olfactory epithelium on day 4.5 of embryonic development, reach the CNS by migrating along the olfactory nerve, and stop migrating by day 12 of embryonic development (Sullivan and Silverman, 1993). GnRHergic neurons are found within extrahypothalamic and hypothalamic sites (Kuenzel and Blahser, 1991). However, only those neurons whose axons terminate within the median eminence are believed to induce gonadotropin secretion in vivo (Mikami et al., 1988). Based upon immunocytochemical analysis, GnRH-positive axons are found within the median eminence by day 14 of embryonic development (Sullivan and Silverman, 1993). The significance of GnRHergic neurons was demonstrated well in advance of the purification of chicken GnRH with experiments that induced functional castration by either electrolytic lesions or deafferentation within the hypothalamus (Ravona et al., 1973; Davies and Follett, 1980). Axons of GnRHergic neurons terminate in proximity to capillaries within the median eminence of the hypothalamus. GnRH secreted from these axons reaches target cells within the adenohypophysis via the hypothalamo-hypophyseal portal vessels (Gilbert, 1979).

In avian species, only indirect measurements of the GnRH pulse generator is available by measuring plasma LH concentrations in frequent samples or in pituitary extracts (Wilson and Sharp, 1975; Sharp and Gow, 1983; Chou and Johnson, 1987). In addition, the episodic nature of LH and FSH was evaluated in unrestrained male broiler breeders using serial blood sampling (Vizcarra et al., 2004). Gonadotropin secretion in males is characterized by a pulsatile pattern with LH pulses being more frequent and having greater amplitude than FSH pulses (Figure 36.11). In chickens, LH- and FSH-containing gonadotrophs reside in separate cells within the pituitary gland (Proudman et al., 1999). We observed that there was a lack of synchrony between the episodic release of LH and FSH. Only 23% of the LH pulses were associated with FSH episodes, suggesting that in the adult male fowl, LH and FSH secretion are regulated independently (Vizcarra et al., 2004).

Both cGnRH-I and -II stimulates gonadotropin release in vivo and in vitro in the chicken. However, most of the evidence indicates that cGnRH-I is the prime regulator of gonadotropin release in birds (Katz et al., 1990; Sharp et al., 1990; Dawson and Sharp, 2007; Ubuka and Bentley, 2009).

Nevertheless, the relative contribution and the potency of each cGnRH isoforms on the hypothalamic–pituitary–gonadal (HPG) axis of male birds is controversial. For instance, cGnRH-II was not found in the median eminence of the male white-crowned sparrow (*Zonotrichia leucophrys gambelii*), suggesting that in these species, cGnRH-II does not regulate pituitary gonadotropin secretion (Meddle et al., 2006). On the other hand, concentrations of FSH in small cockerels were not affected by cGnRH-I challenges (Krishnan et al., 1993).

In immature cockerels (Chou et al., 1985) and male turkeys (Guemene and Williams, 1992), GnRH-II was more potent than GnRH-I in vitro and in vivo to release LH, suggesting that very small doses of GnRH-II at the pituitary level might be sufficient to induce gonadotropin release. However, no significant differences were observed between cGnRH-I and cGnRH-II, in LH releasing activity from young cockerels pituitary samples (Hattori et al., 1986). When the LH response to cGnRH-I and -II was evaluated in cockerels, both peptides were equally potent (Sharp et al., 1987). However, in a similar experiment, the response to cGnRH-II, in terms of LH release was consistently greater than the response to GnRH-I in male chickens (Wilson et al., 1989). These data suggest that there may be age differences in the LH response to both decapeptides. Whether this differential response is due to different steroid inhibitory feedback mechanism is still unknown. The negative feedback of testicular steroids on GnRH-I have been reported in starlings (*Sturnus vulgaris*). Castrated male starlings significantly increased immunoreactive GnRH-I in the rostral POA of the hypothalamus, suggesting that this may represent the neuroanatomical location that mediates steroid negative feedback (Stevenson and Ball, 2009).

Active immunization against cGnRH-I and cGnRH-II in adult broiler breeder males was associated with a differential response on the ability to produce an immune reaction (Vizcarra, 2013). Titers were increased in cGnRH-I but not in cGnRH-II treated birds compared with BSA immunized males (Figure 36.12). Concentrations of LH and FSH in frequent samples were not affected by treatment; however, testis weight was significantly decreased in cGnRH-I birds compared with the other treatments (Figure 36.13). Taken together, these data support the idea that cGnRH-I is the prime regulator of gonadotropin release in male birds.

Behavioral, visual/auditory cues, and the breeding season also regulates GnRH-I and –II in birds (Figure 36.10). In male ring doves (*Streptopelia risoria*) and male starlings (*Sturnus vulgaris*), courtship interaction increases cGnRH-I synthesis (Mantei et al., 2008; Stevenson and Ball, 2009), suggesting that sexual behavior can have a significant effect on the HPA axis. In most seasonal breeders birds, the stimulation of the gonadotropic axis is influenced by photoperiod (for review see [Dawson and Sharp, 2007]).

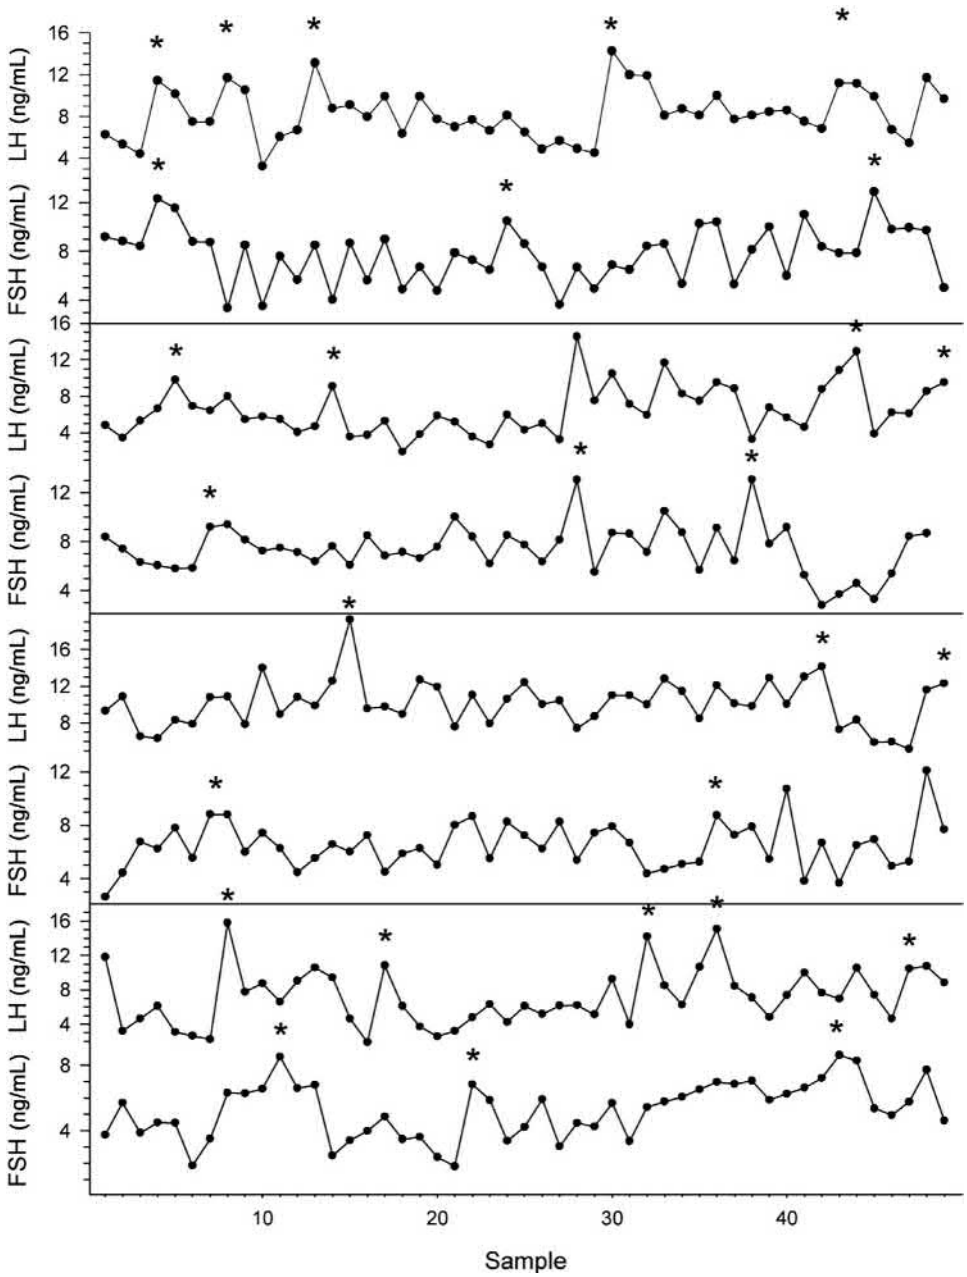

FIGURE 36.11 Pulsatile secretion of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) in plasma of four birds. Blood samples were obtained every 10 min for 8 h. Asterisks indicate the presence of a pulse of LH or FSH, as determined by Pulsar. *Adapted from Vizcarra et al. (2004).*

Hypothalamic photoreceptors transduce the energy from light into a biological signal that regulates the secretion of GnRH. Encephalic photoreceptors are in close proximity with GnRH-I neurons, indicating that brain photoreceptors communicate directly with GnRH-neurons and terminals (Saldanha et al., 2001). During the breeding season, GnRH-I increases in males birds including the house finches (*Carpodacus mexicanus*), the dark-eyed juncos (*Junco hyemalis*), and the European starlings (*Sturnus vulgaris*) (Foster et al., 1987; Cho et al., 1998; Deviche et al., 2000). The contribution of GnRH-II during the breeding season is associated to the regulation of sexual behavior (Ubuka et al., 2013). In nonbreeding mature male zebra finch (*Taeniopygia guttata*), the number of cGnRH-II neurons is significantly reduced during the nonbreeding compared with the breeding season, but the area and optical density of the stained cells did not differ (Perfito et al., 2011).

Until recently, there was no known neuropeptide that directly inhibited gonadotropin secretion; however, Tsutsui et al. (2000) isolated GnIH, a hypothalamic

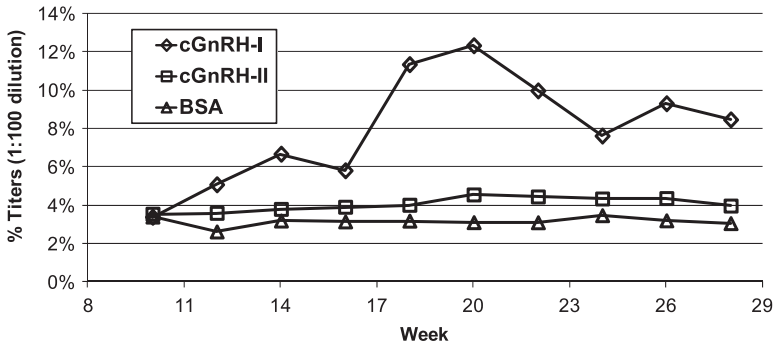

FIGURE 36.12 Antibody titers (^{125}I-cGnRH bound, %) of male broiler breeders immunized against cGnRH-I, cGnRH-II, and BSA. Titers were increased ($P<0.05$) in cGnRH-I but not in cGnRH-II treated birds compared with BSA-immunized males. *Adapted from Vizcarra (2013).*

dodecapeptide from the Japanese quail (For review see Son et al., 2019). This dodecapeptide consists of 12 amino acids in the sequence Ser(62)-Ile(252)-Lys(233)-Pro(226)-Ser(38)-Ala(194)-Tyr(173)-Leu(148)-Pro(104)-Leu(108)-Arg(45)-Phe(52) with RFamide at the C-terminus. GnIH significantly inhibits LH and FSH release in cultured quail cells (Tsutsui et al., 2000) and also inhibits circulating LH in vivo when administered continuously via osmotic pump (Ubuka et al., 2006). Interestingly, chronic GnIH treatment inhibits photoinduced testicular development, causes decreased plasma testosterone and testicular apoptosis, and results in decreased spermatogenic activity in the testis of adult quail (Ubuka et al., 2006). Similarly, testicular growth and plasma testosterone are suppressed in immature quail (Ubuka et al., 2006). Osugi et al. (2004), found that GnIH injected simultaneously with GnRH inhibited plasma LH surge in song sparrows and decreased LH concentrations in breeding free-living Gambel's white-crowned sparrows. GnIH reactive neurons were found to be localized within the paraventricular nucleus and mesencephalic regions of the hypothalamus in quail, white-crowned sparrows, and European starlings (Tsutsui et al., 2000; Bentley et al., 2003; Ubuka et al., 2003; Ukena et al., 2003). The action of GnIH is mediated by the G protein-couple receptors (GPR) GPR147 (pituitary and hypothalamus) and GPR74 (different tissues) (Aparicio et al., 2005; Osugi et al., 2012; Abdul-Rahman et al., 2016). In addition, the GnIH receptor was found to be expressed in the thecal cells, Leydig cells, germ cells, and epididymis in male quail, which suggests roles for the hormone in regulating: gonadal steroid synthesis and release, differentiation of germ cells, and sperm maturation (Bentley et al., 2003, 2008).

Melatonin and stress may be key factors involved in GnIH neural functions as the neurons of male quail have been found to contain a receptor for melatonin (Ubuka and Bentley, 2011; Osugi et al., 2012) (Figure 36.10). Administration of melatonin via implants (s.c.) stimulated the expression of GnIH in a dose-dependent way in birds that had undergone pinealectomy and orbital enucleation (Ubuka et al., 2005). In addition, hypothalamic explants from quail exposed to long-day photoperiods released greater amounts of GnIH during dark periods than during light periods in vitro. Conversely, LH concentrations decreased during dark periods. GnIH expression also increased under short-day periods when the duration of nocturnal melatonin secretion typically increases (Chowdhury et al., 2010). These results clearly indicate a role for melatonin in stimulating the release of GnIH in birds. Stimulation of GnIH, in turn, inhibits gonadal activity and sex steroid by decreasing gonadotropin synthesis and release. In Japanese quail, a prolonged photoperiod reduces the expression of GnIH and melatonin receptors (Mel_{1c}), while prolonged photoperiods increases the refractory effect and leads to desensitization of GnIH neurons (Chowdhury et al., 2010).

36.5.3 Effects of gonadotropins on testicular function

Gonadotropins exert their effects on the testis by binding to specific cell-surface receptors on two distinct types of testicular parenchymal cells: Leydig and Sertoli cells. These cells have been described in detail by Rothwell

(1973) and by (Cooksey and Rothwell, 1973), respectively. The principal role played by each type of cell has been determined by experiments in which one type of gonadotropin has been administered to hypophysectomized males, sexually immature males, or, in the case of Leydig cells, cells in culture (Brown et al., 1975; Ishii and Furuya, 1975; Ishii and Yamamoto, 1976). Such experiments have demonstrated that the principal effects of LH and FSH are exerted upon Leydig cells and Sertoli cells, respectively.

Leydig cells contain the steroidogenic enzymes necessary for the production of androgens [reviewed in Johnson (1986)] and respond rapidly to LH through rapid increases in the second messenger cAMP (Maung and Follett, 1977). The principal steroids secreted by Leydig cells include testosterone and androstenedione, a precursor of testosterone (Nakamura and Tanabe, 1972; Galli et al., 1973; Sharp et al., 1977). The concentration of testosterone in the general circulation is in the range of 5−15 nM, secreted as discrete pulses (Figure 36.14), which closely follow LH pulses (Driot et al., 1979; Bacon et al., 1991; Vizcarra et al., 2004), and are several times less than that in the testicular vein (Ottinger and Brinkley, 1979). The association between LH and testosterone pulses averaged 83% in unrestrained male broiler breeders fitted with jugular cannulas and free access to feed and water (Vizcarra et al., 2004). Testosterone in the adult male is essential for spermatogenesis, maintenance of the excurrent ducts and secondary sexual attributes, the expression of specific behaviors, and, as mentioned above, altering the pattern of GnRH secretion. These actions, as well as the inactivation of the hormone, depend upon transformation of testosterone by enzymes such as aromatase, 5α-reductase, and 5β-reductase (for reviews, see Ottinger (1983); Balthazart (1989)).

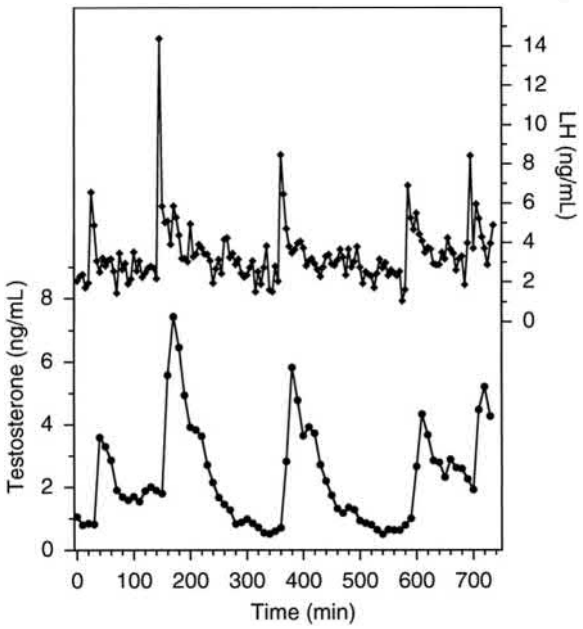

FIGURE 36.14 The pattern of pulsatile changes in circulating luteinizing hormone (LH; upper panel) and testosterone (lower panel) in an adult male domestic turkey (*Meleagris gallopavo*). The peaks of the discrete LH pulses occur prior to those of testosterone, demonstrating the close relationship between LH secretion and that of testosterone. *Figure and data kindly provided by Dr. Wayne Bacon, Ohio State University.*

Although FSH is known to affect Sertoli cells, the means by which FSH works is only poorly understood in birds. As reviewed by Walker and Cheng (2005), studies in other vertebrates have shown that the FSH receptor is a seven transmembrane G-protein, and FSH binding is known to activate at least five different signaling pathways in Sertoli cells. These pathways include the cAMP-PKA, MAP kinase, phosphatidylinositol 3-kinase, calcium, and phospholipase A2 pathways. It has been proposed that oligomerization of FSH receptors may provide a mechanism for bringing together the components of these multiple signaling pathways in order to refine and control intracellular signaling. It is well established that testosterone is absolutely essential for maintaining spermatogenesis and, unlike LH, the effect of FSH is potentiated by testosterone (Tsutsui and Ishii, 1978). As evidenced by the inability of exogenous testosterone to maintain spermatogenesis in hypophysectomized quail (Brown and Follett, 1977). LH and FSH appear to be essential for spermatogenesis in galliform birds. However, in male broiler breeders, more than 90% of the variation on testis weight was explained by changes in FSH while only 35% of the variation in testis weight was explained by changes in LH concentrations (Vizcarra et al., 2010). These results indicate that FSH is the most important regulator of Sertoli cell proliferation and differentiation. Although sperm production depends on the number of Sertoli cells (de Reviers and Williams, 1984; Sharpe, 1994), the process is ultimately controlled by the hypothalamus-pituitary-gonadal axis.

36.6 Spermatogenesis and extragonadal sperm maturation

36.6.1 Spermatogenesis

To date, spermatogenesis in galliform birds has been most fully characterized in the Japanese quail (*Coturnix coturnix japonica*). Four types of spermatogonial cells have been described in *Coturnix* (Lin and Jones, 1990, 1992). These have been designated as spermatogonia A_d, A_{p1}, A_{p2}, and B. The letter subscripts indicate intensity of staining and denote "dark" and "pale," respectively. The numerical subscripts denote ultrastructural differences (Lin and Jones, 1992). Spermatogonia A_d are stem cells. Based upon the model of stem cell renewal and spermatogonial proliferation proposed by (Lin and Jones, 1992), each division of an A_d spermatogonium yields A_d and A_{p1} daughter cells. Thus, spermatogenesis in *Coturnix* commences with the mitosis of an A_d spermatogonium. Cell types derived from each A_{p1}

spermatogonium include A_{p2} spermatogonia (n = 2), B spermatogonia (n = 4), primary spermatocytes (n = 8), secondary spermatocytes (n = 16), and spermatids (n = 32). Secondary spermatocytes and spermatids are formed by the first and second meiotic divisions, respectively.

Spermiogenesis is the transformation of spermatids into sperm cells without further cell division. Spermiogenesis in *Coturnix* entails 12 distinct morphological *steps* (Lin and Jones, 1990; Lin and Jones, 1993). In comparison, 8 to 10 steps have been reported for *Gallus* (de Reviers, 1971a; Gunawardana, 1977; Tiba et al., 1993), 10 steps for the guinea fowl (Aire, 1980), 12 steps for the turkey (Aire, 2003), 11 steps in the guinea cock (Abdul-Rahman et al., 2016) and six steps for the house sparrow (Goes and Dolder, 2002). Spermiogenesis entails formation of an acrosome and an axoneme, loss of cytoplasm, and replacement of nucleohistones with nucleoprotamine, which accompanies nuclear condensation (Nagano, 1962; Tingari, 1973; Okamura and Nishiyama, 1976; Gunawardana, 1977; Gunawardana and Scott, 1977; Oliva and Mezquita, 1986; Sprando and Russell, 1988). The reductions in cytoplasmic and nuclear volumes are striking; mature rooster sperm embody only 3% of the initial spermatid cell volume (Sprando and Russell, 1988). In summary, the seminiferous tubules contain Sertoli cells and a broad array of differentiating germinal cells including the various types of spermatogonia, spermatocytes, and spermatids.

However, germinal cells are not found in a physical continuum of differentiation within the seminiferous epithelium. Rather, they are found in distinct cellular associations. The cellular associations in *Coturnix* occupy an average of 17,902 μm^2 and contain an average of 13.5 Sertoli cells per association (Lin and Jones, 1990). There are 10 cellular associations in *Coturnix*, and each is referred to as a *stage* of the seminiferous epithelium (Figure 36.15). The seminiferous epithelium passes through each successive stage as a function of time at any fixed point. Once a complete series has been finished, a new series is initiated. Consequently, the series of stages is referred to as the cycle of the seminiferous epithelium. The duration of the cycle in *Coturnix* is 2.69 days (Lin et al., 1990). In comparison, the duration of the cycle of the seminiferous epithelium in *Gallus* has been estimated to be 3–4 days (de Reviers, 1968; Tiba et al., 1993). The time between the division of an Ad spermatogonium and spermiation, known as the duration of spermatogenesis is 12.8 days in *Coturnix* (Lin and Jones, 1990). Thus, 4.75 cycles of the seminiferous epithelium are required to produce 32 sperm cells from a single Ad spermatogonium at any fixed point within the seminiferous epithelium.

A complete series of stages in the context of a seminiferous tubule is referred to as a *spermatogenic wave*. As shown in Figure 36.16, these waves in *Coturnix* are

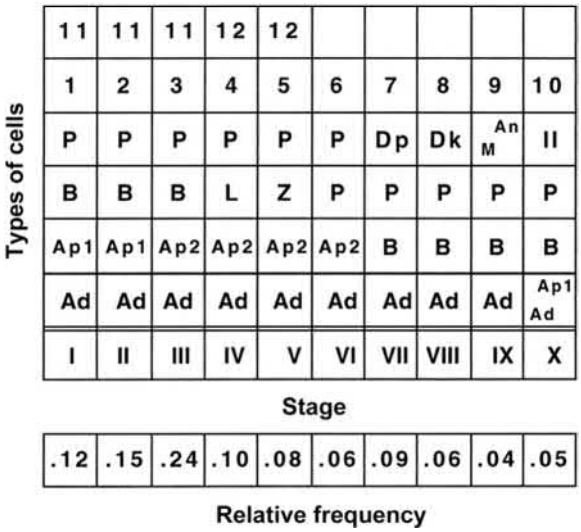

FIGURE 36.15 The cycle of the seminiferous epithelium of *Coturnix coturnix japonica*. The relative frequency of each cellular association, or stage, is shown below the stage's number. *Ad*, dark type A spermatogonia (stem cell); *Ap1 and 2*, pale type A spermatogonia; *B*, type B spermatogonia; *L*, leptotene primary spermatocytes; *Z*, zygotene primary spermatocytes; *P*, pachytene primary spermatocytes; *Dp*, diplotene primary spermatocytes; *DK*, diakinesis of primary spermatocytes; *M*, metaphase primary spermatocytes; An, anaphase primary spermatocytes; II, secondary spermatocytes; 1–12, step 1 through step 12 spermatids. *Adapted from Lin et al. (1990).*

arranged helically along the length of seminiferous tubules (Lin and Jones, 1990). It must be noted that while sequential stages may be contiguous in space (Figure 36.16), they are not observed at a common frequency (Figure 36.15) because duration of each of the stages ranges from 2.5 to 15.5 h (Lin et al., 1990). Consequently, the prevalence of any given stage is directly proportional to the stage's duration (Lin et al., 1990).

Daily sperm production may be defined as the number of sperm produced per gram of testis per day. Daily sperm production in *Coturnix* has been estimated to be 92.5×10^6 sperm per gram of testis per day (Clulow and Jones, 1982). This estimate is equivalent to the DSP of $80–120 \times 10^6$ sperm per gram of testis reported for *Gallus* (de Reviers and Williams, 1984), though the estimate was much higher for barred Plymouth Rock and Nigerian domestic fowl (*Gallus domesticus*) ($2.41 \pm 1.17 \times 10^9$ and $0.076 \pm 0.71 \times 10^9$, respectively) (Orlu and Egbunike, 2009). These values denote the number of fully formed sperm released per day from the seminiferous epithelium into the lumen of the seminiferous tubules. This phenomenon is defined as spermiation, which in *Coturnix* would be limited to the seminiferous epithelium in stage V (Figure 36.15). At the time of spermiation, superfluous cytoplasm found alongside the sperm cell's head is jettisoned as a residual body (Sprando and Russell, 1988; Lin and Jones, 1993). Sperm cells released from the seminiferous epithelium are

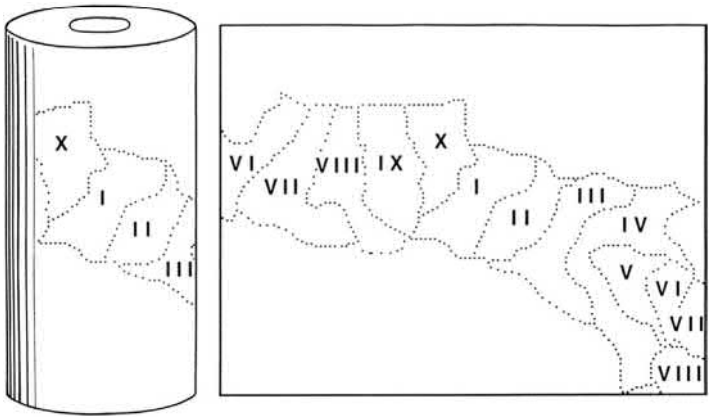

FIGURE 36.16 Spatial arrangement of the wave of spermatogenesis within a seminiferous tubule of *Coturnix coturnic japonica*. The cylinder to the right represents a section of a seminiferous tubule. The rectangle to its left denotes the two-dimensional representation of two contiguous cycles of the seminiferous epithelium. The cycle is arranged helically along the length of the tubule, Roman numerals denote stages. *Adapted from Lin and Jones (1990).*

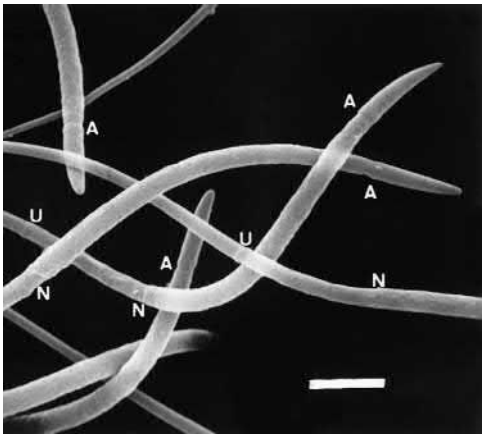

FIGURE 36.17 Scanning electron micrograph of chicken sperm cells. The constriction at the anterior end of the sperm cell (A) marks posterior boundary of the acrosome. The nucleus extends posteriorly from (A) to the neck region (N), which marks the anterior end of the midpiece. The midpiece, site of the anterior portion of the axoneme and the highly modified mitochondria, extends back to the raised annulus (U). The tail of the sperm extends from the annulus to the cell's termination. At the nucleus, chicken sperm are about 0.5 μm in diameter, with the overall length of the cell approximately 90μm. Bar = 2 μm. Adapted from Bahr and Bakst, 1987. *Reproduction in Farm Animals, fifth ed. Philadelphia, PA: © Lea & Febiger.*

immotile (Ashizawa and Sano, 1990). Galliform sperm are vermiform cells (Figure 36.17) with a maximum width of 0.5−0.7 μm and a length of 75−90 μm (Thurston and Hess, 1987). They contain a conical acrosome, a slightly bent cylindrical nucleus, and a helix of 25−30 mitochondria surrounding the proximal portion of a long flagellum, which accounts for approximately 84% of the cell's length (for review, see Thurston and Hess (1987)). The sperm of passerine birds tends to have a pointed, helical acrosome and ranges in length from 46.8−287.6 μm with the flagellum accounting for 79−95% of the total length (Helfenstein et al., 2009; Lüpold et al., 2009). One exception to this general trend is the Eurasian bullfinch, in which the sperm acrosome is rounded, not helical, and the midpiece size is extremely short (Birkhead et al., 2006). In these birds, extra-pair copulation frequency is rare in comparison to other passerines. It may be that a lack of sperm competition in this species could explain the marked difference in sperm morphology (Birkhead et al., 2006).

36.6.2 Extragonadal sperm transport and maturation

Following spermiation, sperm cells are suspended within fluid secreted by Sertoli cells. Sperm passage through the labyrinth of seminiferous tubules most likely depends upon the hydrostatic pressure of seminiferous tubule fluid and the contractility of the myoepithelial cells overlying the outer surface of the seminiferous tubule (Rothwell and Tingari, 1973). Sperm passage through the distal excurrent ducts, in particular, the deferent duct, presumably depends upon peristalsis (de Reviers, 1975). Like spermatogenesis, sperm transport through the excurrent ducts has been characterized most fully in the Japanese quail. Thus, an analysis of the phenomena and time-course of sperm transport through the excurrent ducts of *Gallus* has been estimated to take several days (Munro, 1938; de Reviers, 1975). Perhaps the most evident phenomenon that occurs during sperm transport through the excurrent ducts; as evidenced by a change in sperm concentration, is the absorption of seminiferous tubule fluid (Table 36.3). The concentration of sperm in the seminiferous tubule fluid of *Coturnix* is 3.8×10^4 sperm per μL whereas the concentration of sperm within the distal deferent duct is 2.3×10^6 per μL (Clulow and Jones, 1988). This 60-fold increase in sperm concentration is largely due to seminiferous tubule fluid absorption at the

TABLE 36.3 Estimates of Plasma Flux (Reabsorption) across the Epithelium Lining the Excurrent Ducts of Japanese Quail[a]

	Testicular Plasma	
Region	**Output (%)**	**μl/cm^2/h**
Rete testis to proximal efferent ducts	6.3	8.0
Proximal to distal efferent ducts	85.8	100.4
Distal efferent ducts to connecting ducts	6.5	21.6
Connecting ducts to epididymal duct	0.4	2.1
Epididymal duct to proximal deferent duct	0.2	0.1
Proximal to distal deferent duct	0.2	0.2

[a]*Adapted from Cluow and Jones (1988).*

level of efferent ducts. Nakai et al. (1989) demonstrated that the nonciliated epithelial cells in the proximal efferent ducts of *Gallus* incorporate fluid by pinocytosis.

The efferent ducts, which represent the principal excurrent duct within the epididymis (Figure 36.3), may be a critical site for sperm maturation. Due to extensive mucosal folding, apocrine secretion, the presence of ciliated cells, and epithelial cells with abundant microvilli, the efferent ducts appear to be a site where sperm are mixed with secretions as they are concentrated. Additional evidence of the importance of the efferent duct comes from studies of reproductive anomalies in turkeys and chickens. For instance, turkeys may ejaculate yellow rather than white semen (Thurston et al., 1982a). Epithelial cells within the efferent ducts of such turkeys have been shown to be hypertrophied, engorged with lipid droplets, and characterized by heightened phagocytosis of sperm (Hess et al., 1982). The latter phenomenon appears to be mediated by macrophages within the rete testis under normal conditions (Aire and Malmqvist, 1979b; Nakai et al., 1989), but can be mediated by epithelial cells in the excurrent ducts when the deferent duct is not patent (Tingari and Lake, 1972). Subfertile roosters with malformed proximal efferent ducts (Figure 36.18) provide a second example of the relationship between efferent duct function and reproductive performance (Kirby et al., 1990). The biochemical imbalances observed in semen from such roosters have been attributed to excurrent duct dysfunction (al-Aghbari et al., 1992).

In review, sperm are suspended in seminiferous tubule fluid prior to their passage through the excurrent ducts. The volume of this suspensory fluid and its composition (Esponda and Bedford, 1985) is altered prior to sperm entry into the epididymal duct. The resultant medium is seminal plasma. The chemical composition of seminal plasma is distinct from blood plasma as evidenced by differences in electrolyte, free amino acid, and protein composition (Lake, 1966; Lake and Hatton, 1968; Stratil, 1970; Thurston et al., 1982b; Freeman, 1984). The maintenance of these differences along the length of the excurrent ducts has been attributed to tight junctions between adjacent epithelial cells lining the ducts (Nakai and Nasu, 1991).

Apart from proteins specific to the reproductive tract (Stratil, 1970; Esponda and Bedford, 1985), the principal differences between seminal and blood plasma involve glucose, glutamate, K^+, Cl^-, and Ca^{2+} (Table 36.4). At present, it is not understood how the composition of excurrent duct fluid affects sperm motility. While Esponda and Bedford (1985) have demonstrated that sperm maturation proteins do exist in *Gallus* and while Ashizawa et al. (1988) have reported that the Na^+-to-K^+ ratio associated with the midpiece of rooster sperm increases as a function of sperm passage through the deferent duct, such changes do not induce motility; for sperm within the deferent duct are immotile (Ashizawa and Sano, 1990). Nonetheless, sperm acquire the potential for motility as they pass through the excurrent ducts (Munro, 1938; Clulow and Jones, 1982; Howarth, 1983; Ashizawa and Sano, 1990). This potential is distinct from fertilizing ability in that testicular sperm have the capacity to fertilize oocytes, providing they are placed in the oviduct above the vaginal sphincter (Howarth, 1983). As shown by Allen and Grigg (1957), sperm need not be motile to ascend the oviduct above the vaginal sphincter. Thus, the fertilizing ability of testicular sperm may not depend upon motility as much as the ability of sperm cells to undergo an acrosome reaction in response to contact with the oocyte's inner perivitelline layer (Okamura and Nishiyama, 1978).

The deferent duct, particularly the distal portion, contains the bulk of the extragonadal sperm reserve (ESR). In *Coturnix*, the number of sperm in the ESR is equivalent to the number produced daily by the testes, and 92% of these are found within the different duct (Clulow and Jones, 1982). In contrast, the ESR in *Gallus* is equivalent to $\leq$3.5 times the daily sperm production, but 95% of the ESR is found in the deferent duct (de Reviers, 1975). In either case, the duration of sperm storage within the deferent duct is relatively brief. As stated above, these sperm are immotile prior to ejaculation. While Ashizawa and Sano (1990) have proposed that a temperature change accompanying ejaculation may initiate sperm motility in *Gallus*, it is also likely that accessory reproductive fluids play a role in the initiation of sperm motility (for review, see Ashizawa et al. (2000); Fujihara (1992)). In this regard, Ca^+ and HCO^{-3} have been shown to be motility agonists in vitro (Ashizawa and Wishart, 1987; Ashizawa and Sano, 1990).

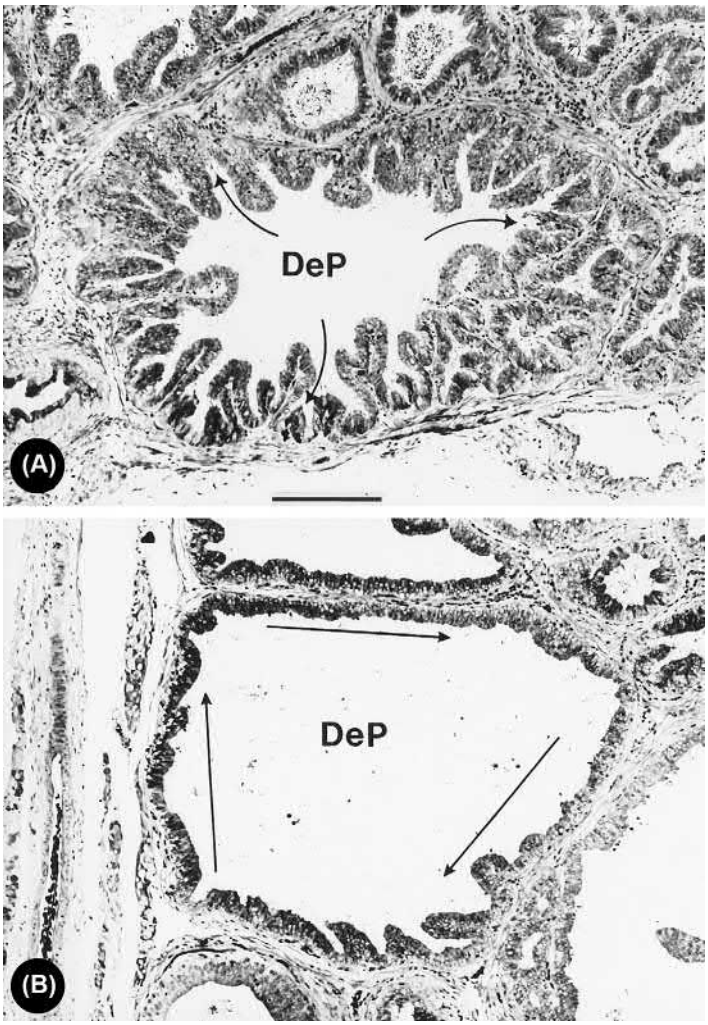

FIGURE 36.18 Cross sections through the proximal deferent ducts (DeP) of fertile (A) and subfertile (B) roosters. The presence of the sd allele in crossbred roosters (B) resulted in a twofold increase in DeP cross-sectional area and a 75% decrease in luminal surface area as compared to the wild-type (A) male. Males exhibiting this genetic defect of the DeP are characterized by poor semen quality, frequently exhibiting 30–90% dead and degenerate sperm in an ejaculate. Reproduced with permission from the Society for the Study of Reproduction. *From Kirby et al. (1990).*

TABLE 36.4 Comparison of Selected Substances in Rooster Blood Plasma and Deferent Duct Fluid[a]

Substance	Blood Plasma	Deferent Duct Fluid
Glucose (nM/L)	15	—
Glutamate (mM/L)	<1	100
Sodium (mEq/L)	160	142
Potassium (mEq/L)	5	34
Chloride (mEq/L)	115	40
Calcium (mEq/L)	5	1

36.7 Seasonal gonadal recrudescence and regression

36.7.1 Photoperiodic control of gonadal regression and recrudescence

Environmental photoperiodism is responsible for the generation of seasonal rhythms through the induction and termination of physiological processes (Dixit and Singh, 2011). The secretion of GnRH is controlled by photo induction and is directly related to the photoperiod (Dawson, 2015). Many bird species, especially long-distance migrants, face the challenge of a narrow reproductive window because of an intense selective pressure to restrict breeding to the time of year when food is most abundant [reviewed in (Dawson, 2008, 2013)]. Typically, male birds have regressed gonads for most of the year with gonadal

recrudescence occurring only immediately prior to reproduction. Birds are generally viewed as being long-day breeders (with some exceptions) such that the HPG axis responds to increasing day lengths with a marked increase in gonadotropin secretion and gonadal growth [reviewed in Ball and Ketterson (2008)]. The exact time and rate of gonadal maturation varies between bird species; however, it has been suggested that, as photoperiod increases during the spring, a critical threshold point is reached at which gonadal recrudescence is triggered. This threshold has been termed the critical photoperiod. A study in Japanese quail provides support for this hypothesis and found that the rate of gonadal maturation was low when the photoperiod was less than 11.5 h of light per day and maturation became rapid when light exposure was increased to 12 h per day (Follett and Maung, 1978).

While gonadal maturation in the spring is in response to an increase in photoperiod, longer photoperiods at the end of the breeding season induce a condition termed photorefractoriness, which causes the gonads to regress [reviewed in Robinson and Follett (1982); Dawson (2008)]. Two forms of photorefractoriness, absolute and relative, have been identified in various bird species. In the absolute form, continued exposure to long photoperiods leads to spontaneous gonadal regression after which a further increase in photoperiod does not induce renewed gonadal maturation until the next breeding season. This state has been successfully demonstrated in species such as the European Starling, Tree Sparrow, and White-crowned Sparrow and is only dissipated when birds experience short days in autumn. Such exposure to short photoperiods is thought to induce reacquisition of photosensitivity [reviewed in Ball and Ketterson (2008)]. In contrast, relative photorefractoriness is evident when a decrease in photoperiod is necessary to induce gonadal regression, but this regression occurs under a photoperiod that is still longer than the one which induced maturation earlier in the year. In addition, exposure to long photoperiods can inhibit regression and even induce recrudescence [reviewed by Dawson (2008)]. In general, it is thought that birds with early, predictable breeding seasons tend to become absolutely photorefractory whereas those with later or less predictable breeding seasons are more likely to exhibit relative photorefractoriness.

36.7.2 Other factors affecting gonadal maturation and regression

Due to the vast variety between and within species, birds exhibit plasticity in both gonadal maturation and regression. Though photoperiod plays an important role in regulating these processes, nonphotoperiodic cues such as breeding location, temperature, rainfall, climate change, and food availability are also important in determining the rate and timing of recrudescence and regression. For example, Caro et al. (2006) observed two separate populations of Blue Tits and noticed that, not only did one population breed earlier than the other but also earlier breeding birds exhibited a faster rate of testicular development than did their later breeding counterparts. White-crowned sparrows breeding at low latitudes experienced inhibition of gonadal maturation and delayed onset of photorefractoriness at low temperatures, but the same were not true for birds of the same species breeding at mid-latitudes (Wingfield et al., 2003). Retarded rates of testicular recrudescence were also observed in Juncos subjected to low temperatures between 4 and 8°C (Engels and Jenner, 1956). In Willow Tits, high temperatures were shown to accelerate testicular maturation, but the same effect was not evident in Great Tits (Silverin and Viebke, 1994). These data may suggest that temperature is more likely to affect species with longer and more flexible breeding seasons. Climate change is another factor affecting gonadal regression. Climate change is associated with higher than normal temperature and may decrease the number of breeding attempts in multibrooded species. Therefore, birds may be constrained to a degree where they will advance breeding to compensate for food abundance (Dawson and Visser, 2010).

Interestingly, rainfall has been shown to affect gonadal maturation in several tropical bird species. For example, two populations of rufous-collared sparrows separated by only 25 km were observed to have highly asynchronous reproductive physiology based on local rainfall patterns (Moore et al., 2006). In the rufous-winged sparrow, though seasonality is known to be photoperiodically controlled, the exact time of breeding occurs in response to rainfall (Deviche et al., 2006). Darwin's finches undergo gonadal maturation at drastically different times in different years in direct response to rainfall, yet the gonads have been shown to fully regress between breeding seasons (Hau et al., 2004). Another factor which may influence seasonal recrudescence is the availability of food resources. Food availability at stopover has been directly linked to gonadal maturation during spring migration. For example, Garden Warblers experiencing limited food conditions at stopover had significantly slower testicular recrudescence and decreased testosterone in comparison to birds allowed to eat *ad libitum* (Bauchinger et al., 2009). It is clear that many factors, both intrinsic and extrinsic, have the potential to influence patterns of seasonal gonadal recrudescence and regression. The mechanisms driving such patterns are complex and likely overlap with one another. As research in this area progresses, it will be important to investigate how these mechanisms interact in order to better understand the various factors that drive reproductive success in the male bird.

37.1 Introduction

The freshly laid avian egg contains most of the materials needed for embryonic growth and development, but lacks the oxygen and heat needed for successful development. Microscopic pores in the eggshell allow O_2 to diffuse into the egg from the environment and water vapor and CO_2 produced by the embryo to diffuse out. The adult bird has a key role in incubation, providing not only the heat necessary for embryonic development but also controlling the microclimate of the egg. In the poultry industry and for research purposes, the adult bird can be conveniently replaced by an incubator. The majority of research on avian incubation is undertaken using artificially incubated chicken (*Gallus gallus domesticus*) eggs. Thus, in this chapter, the chicken embryo is used to elucidate the development of physiological function during avian incubation, supplemented by additional species when data are available. Developmental physiology of the gas exchange, acid-base, cardiovascular, osmoregulatory, and thermoregulatory systems are examined. The optimal conditions for artificial incubation are outlined and embryonic responses to incubation extremes described.

37.2 The freshly laid egg

The mass of the freshly laid bird egg ranges from ~0.8 g in the bee hummingbird (*Mellisuga helenae*) to ~2 kg in the ostrich (*Struthio camelus*). The egg is composed of the eggshell and outer and inner shell membranes that

Sturkie's Avian Physiology. https://doi.org/10.1016/B978-0-12-819770-7.00030-X

encompass the albumen, which serves as a source of water and protein, and yolk, a source of necessary nutrients. The composition of the freshly laid egg is related to the maturity of the hatchling, which differs considerably between species. Hatchlings are divided into four major categories based on criteria such as mobility, amount of down, ability to feed, and locomotion. Precocial species are the most mature, and can walk, swim, or dive soon after hatching, while altricial species are the least mature and hatch naked, with eyes closed and are incapable of coordinated locomotion. Two intermediate categories, semiprecocial and semialtricial, describe species that are within these extremes. The amount of yolk in the freshly laid egg is much greater in precocial species than in altricial species (Sotherland and Rahn, 1987). The yolk is only 16% of egg mass in the altricial red-footed booby (*Sula sula*), while in the highly precocial kiwi (*Apteryx australis*), it is 69% of egg mass. As most of the energy contained in the egg is in the lipid fraction, most of which are in the yolk, the energy content of precocial eggs is higher than that of altricial eggs. Furthermore, most of the water in the egg is in the albumen, and as the yolk/albumen ratio is lower in altricial than in precocial eggs, altricial eggs have relatively higher water compared to precocial eggs (Sotherland and Rahn, 1987).

37.3 Incubation

37.3.1 Incubation period

Incubation encompasses the prenatal period, prior to "internal pipping" (IP) when the embryo penetrates its beak through the chorioallantoic and inner shell membranes into the air cell, and the perinatal or paranatal period from IP to when the embryo fractures the shell ["external pipping" (EP)] and hatches. The incubation period (I, days) increases with egg size and can be represented as follows:

$$I = 12 \cdot (\text{Egg mass})^{0.22} \tag{37.1}$$

where egg mass is in g (Rahn and Ar, 1974). In addition, as a first approximation, the product of incubation period and O_2 consumption ($\dot{M}_{O_2}$) at the stage where $\dot{M}_{O_2}$ remains unchanged (i.e., plateau) is proportional to egg mass (Rahn et al., 1974):

$$I \cdot \dot{M}_{O_2} = c \cdot (\text{Egg mass}) \tag{37.2}$$

where c is a constant. Thus, for a given egg mass, an egg which consumes less O_2 at the plateau stage needs a longer incubation period. Furthermore, because the $\dot{M}_{O_2}$ at the plateau stage is matched to the shell gas conductance, for a given egg mass, an egg with lower shell conductance requires a longer incubation period.

Apart from these general trends, eggs that are left unattended by the incubating parent for a period of time will exhibit cooling, and this results in slower embryonic growth and a longer incubation period. Some birds, notably tropical seabirds and petrels (Procellariiformes), have much longer incubation periods than that suggested by the general relationship (Whittow, 1980), even though they are incubated continuously.

37.3.2 Egg water content and shell conductance

As the embryo grows within the egg, water is lost and both the yolk and albumen diminish in mass. However, metabolic water is produced when fat in the yolk is oxidized. Part of the water is inevitably lost by diffusion through the pores in the shell to the microclimate of the egg. The rate of water loss ($\dot{M}_{H_2O}$, mg/day) is determined by two factors: the water vapor conductance of the shell and shell membranes (G_{H_2O}, mg/day/kPa) and the difference in water vapor pressure between the contents of the egg and the environment (ΔP_{H_2O}, kPa) (Rahn and Ar, 1974):

$$\dot{M}_{H_2O} = G_{H_2O} \cdot \Delta P_{H_2O} \tag{37.3}$$

G_{H_2O} is a function of the multiple factors, including: shell geometry (effective pore area, A_p, thickness of the shell combined with shell membranes, L); water vapor diffusion coefficient (d_{H_2O}); and the inverse product of the gas constant (R) and absolute temperature (T):

$$G_{H_2O} = [(A_p/L) \cdot d_{H_2O}]/RT \tag{37.4}$$

Both pore area and shell thickness increase in larger eggs (Ar et al., 1974; Birchard and Deeming, 2009). While a greater pore area increases G_{H_2O}, a thicker shell has the opposite effect because it lengthens the diffusion pathway for water vapor. The water lost from the egg is replaced by air, enlarging the air cell at the blunt pole of the egg during development. Shell thickness also decreases throughout development as the embryo absorbs calcium (Orłowski and Hałupka, 2015; Orłowski et al., 2016; Rosenberger et al., 2017). Upon IP and EP, the rate of water loss from the egg increases, as water vapor can diffuse through the cracks (pip-hole) in the shell. The water loss from the egg over the entire incubation period amounts to ~18% of the mass of the freshly laid egg.

37.3.3 Heat transfer

Many adult birds (typically but not always the female) play an important role in incubation of their eggs, by using their body and nesting material to alter the environment of the eggs. Most birds develop a seasonal bare patch of skin, the brood patch, on part of the thorax and abdomen. This directly contacts with the eggs permitting a greater rate of heat transfer than if the patch were covered with plumage. Accompanying the loss of feathers is an increase in the size and number of blood vessels in the bare skin. The adult can

adjust the rate of heat transfer to the egg by standing over or leaving the vicinity of the egg, but also by the closeness with which the bird applies its patch to the egg. The bird responds physiologically to variations in egg temperature (T_{egg}), increasing its metabolic heat production in response to cooling of the egg (Tøien et al., 1986; Rahn, 1991).

The amount of heat transferred to the eggs is directly proportional to the increase in heat production (Tøien et al., 1986). The efficiency of heat transfer to the eggs diminishes with decreasing ambient temperature and clutch size. Heat stored in the incubating bird while flying and foraging (i.e., while not incubating the eggs) can be transferred to the eggs on return to the nest (Biebach, 1986). If the egg is very cold, "cold vasodilation" occurs in the brood patch, increasing the patch blood flow and temperature and therefore heat transfer to the egg (Mitgard et al., 1985). The brood patch temperature varies from 34.9°C in the bonin petrel (*Pterodroma hypoleuca*) to 42.4°C in the dusky flycatcher (*Empidonax oberholseri*). The brood patch temperature is 1.1−5.5°C higher than the T_{egg} in numerous species (Rahn, 1991).

At the beginning of incubation, heat is transferred through the egg by conduction and the surface of egg on the opposite side to the brood patch may be 4°C or more below the brood patch temperature (Rahn, 1991). As incubation proceeds, this temperature difference diminishes as the embryo's developing circulation assists in the distribution of heat, and its increasing metabolism provides additional heat (Turner, 1987; Rahn, 1991). This effect of blood flow on heat flow is more important in large eggs than in small ones (Tazawa et al., 1988a). The main barrier to heat loss from the egg is a thin layer of air immediately adjacent to the shell, i.e., boundary layer (Sotherland et al., 1987). If the egg is in a nest, the nest itself imposes an additional resistance to heat loss.

As the embryo grows, incubation likely becomes more a matter of regulating the balance between heat gain from the mother and heat loss through radiation from the egg surfaces because the near-term embryo is producing considerable heat itself. The rate of heat loss from the egg is going to depend on many factors, though one of the more important ones may be the surface area-to-volume ratio of the egg. Thus, larger eggs (e.g., emu, ostrich) may have lower capacity for heat loss because of their smaller surface area-to-volume ratio. However, larger embryos may also show conventional metabolic scaling, with lower per gram body mass rates of temperature production than smaller embryos. Furthermore, embryos can utilize behavioral and physiological plasticity to respond to changes in their thermal environment (Du and Shine, 2015). A study that integrates egg size, embryo metabolic rate, and incubation behavior changes during embryonic development is highly warranted.

37.3.4 Energy use

As chicken embryos grow, their mass increases geometrically until growth rate slows during the last stages of development (Romanoff, 1967; Van Mierop and Bertuch, 1967; Tazawa et al., 1971a; Lemez, 1972; Clark et al., 1986; Haque et al., 1996). From the mean values of the above references, the geometrical increase in embryo wet body mass to day 16 of incubation is expressed by;

$$\text{Body mass(mg)} = 0.24 \cdot I^4 \tag{37.5}$$

Of the energy measured as oxygen uptake ($\dot{M}_{O_2}$), the majority is utilized by the embryo to synthesize new tissues for growth and to meet the physiological demands for maintenance during development. In addition, toward the end of incubation, the embryo uses energy for active control of body temperature and hatching. Prior to this, it is assumed that prenatal $\dot{M}_{O_2}$ is used for maintenance, which is proportional to body mass, and for growth, which is proportional to growth rate ($GR = \Delta Body\ mass/time$) as follows (Vleck et al., 1980; Mortola and Cooney, 2008);

$$\dot{M}_{O_2} = a \cdot (Body\ mass) + b \cdot GR \tag{37.6}$$

where coefficients a and b express the daily average cost of maintaining 1 g of tissue (mL O_2/g/day) and the cost of growing it (mL O_2/g), respectively. During days 9−18 of the ~21 day incubation period of chickens, and excluding early development when $\dot{M}_{O_2}$ of small embryos does not reflect total egg $\dot{M}_{O_2}$ because of uptake by extra-embryonic tissues, a and b are estimated as ~15 mL O_2/g/day and ~41 mL O_2/g, respectively (Mortola and Cooney, 2008). Therefore, the cost of growing 1 g of tissue averages ~3 times the cost of maintaining it. In addition, cooling due to low temperature incubation (35°C) only decreases GR with a decrease in the cost of growth, but hypoxic incubation decreases not only GR but also the cost of maintenance. That is, cold incubation decreases GR without altering the partitioning of energy expenditure while hypoxia decreases GR and alters the partitioning of the energy.

Daily energy use increases as the embryo grows and is reflected in an increase in $\dot{M}_{O_2}$. However, precocial and altricial birds show a different developmental pattern in embryonic $\dot{M}_{O_2}$ (e.g., Vleck and Vleck, 1987). In altricial species, $\dot{M}_{O_2}$ increases at an increasing rate throughout incubation, lacking a plateau. In precocial species, the rate of increase in $\dot{M}_{O_2}$ plateaus before the egg is pipped and then increases again after pipping. For a given egg size and incubation period, altricial species use less energy, so have a lower incubation energy cost to hatching than precocial species (Vleck et al., 1980). The high cost of incubation in precocial species is due to their rapid growth early in development, which results in higher maintenance costs,

i.e., there is more tissue to maintain for a longer time (Vleck et al., 1980).

Based on the assumption that both precocial and altricial species have an identical basic pattern of increase in $\dot{M}O_2$, including a plateau phase attributable to the shift of the gas exchange from the chorioallantoic membrane (CAM) to the lungs (Rahn and Ar, 1974), Prinzinger et al. (1995) defines the plateau phase as a clear interruption of the continuous exponential increase in $\dot{M}O_2$. This demonstrates no fundamental difference between both modes with respect to the presence of a plateau (Figure 37.1) (Prinzinger et al., 1995; Prinzinger and Dietz, 1995). They suggest that in small altricial species, the plateau lasts only a few hours and can be overlooked when $\dot{M}O_2$ measurement is not continuous or when many individual measurements are averaged. The extremely precocial mound-building birds (Megapodiidae) are one exception, having no plateau phase as they lack the CAM-pulmonary transition within the egg (Vleck et al., 1984).

Energy use can be reduced under hypoxic incubation conditions (Mortola et al., 2012). However, the timing of exposure is important, with $\dot{M}O_2$ reduced with hypoxia exposure during the middle period of incubation (day 6−12), but not with exposure during early (days 1−6) or late (days 12−18) incubation (Dzialowski et al., 2002).

37.4 Development of physiological systems

37.4.1 Gas exchange

The avian embryo completely enclosed within its hard egg shell has no opportunity for ventilatory movements until the very last phase of incubation. Thus, there is no convective gas exchange per se until the embryo's lungs begin to function upon IP just before hatching. Early in incubation, prior to a formation of the heart and even initially after the forming heart beats, O_2 can be adequately supplied from the environment to the embryo through diffusion. $\dot{M}O_2$ is normally maintained without blood convection, even in chicken embryos whose main vessel from the heart is ligated or hemoglobin (*Hb*) is rendered functionless due to carbon monoxide exposure (Burggren et al., 2000, 2004; Mortola et al., 2010). As gas transport by diffusion alone become inadequate, blood convection begins to meet O_2 demand during development. Three different gas exchangers sequentially function in the egg: the area vasculosa, the chorioallantois, and the lungs. Figure 37.2 shows the growth rate of the functional surface area of the area vasculosa and the chorioallantois (Ackerman and Rahn, 1981) and the associated $\dot{M}O_2$ of the chicken embryo. The area vasculosa is a well-vascularized region of the yolk sac which fans out from the embryo and rapidly grows around the yolk during days three to five of incubation in an increasingly ordered branching manner (Guidolin et al., 2020). The blood vessels of the yolk sac connect with the dorsal aorta of the embryo by day two and blood begins to circulate through the embryo and the area vasculosa. The fine reticulation of the vitelline circulatory system plays the role of the main gas exchanger until the chorioallantois makes contact with the inner shell membrane around day six (Ackerman and Rahn, 1981). Subsequently, respiratory function transitions from the area vasculosa to the chorioallantois.

Beginning on day five of incubation, the mesenchyme covering the fundus of the allantoic sac comes into contact with the mesenchyme lining the chorion. The two membranes begin to fuse and the growing allantoic sac flattens out beneath the chorion, which lies close to the eggshell. The outer limb of the flattened allantois, composed of the cohesive chorion and allantois, is the chorioallantois. The chorioallantois grows rapidly until day 12, when it extends to envelop the contents of the whole egg, lining the entire surface of the inner shell membrane (Figure 37.2). Chorioallantoic growth is moderate between day 13 and 18, and then regresses between day 18 and 20 prior to IP (Makanya et al., 2016). Additional information on the development and growth of the CAM are provided by Nowak-Sliwinska et al. (2014), Ribatti (2017), Tufan and Satiroglu-Tufan (2017), and Burggren and Rojas Antich (2020), often in

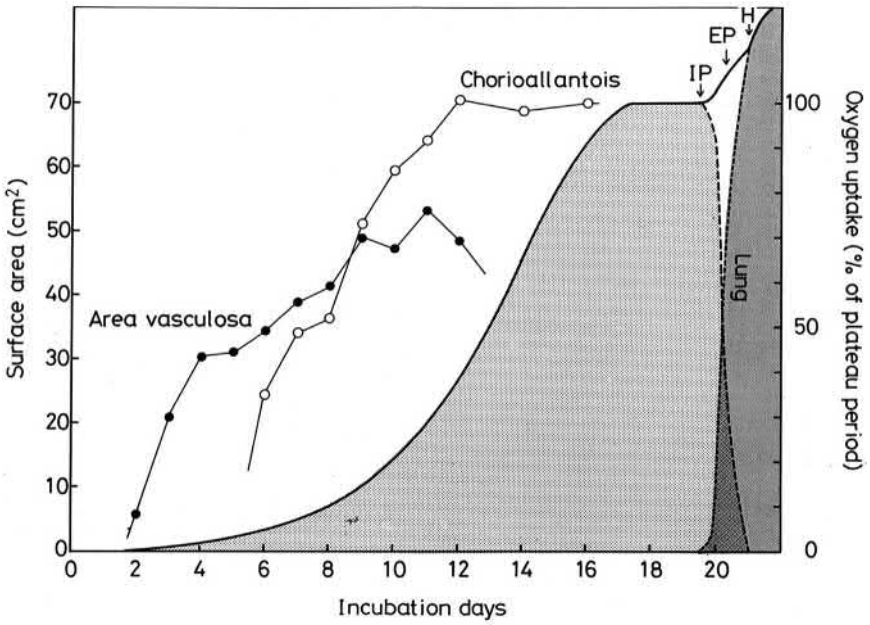

FIGURE 37.2 Daily changes in functional surface area of the area vasculosa and the chorioallantois (left ordinate), and developmental pattern of oxygen uptake ($\dot{M}_{O_2}$) during the prenatal period (until internal pipping, IP) and perinatal period (from IP to hatching, H) (right ordinate). External pipping (EP) occurs during the perinatal period. $\dot{M}_{O_2}$ is drawn diagrammatically with the plateau set at 100%. The lightly shaded area indicates $\dot{M}_{O_2}$ by diffusion through the area vasculosa/chorioallantois and the heavily shaded area $\dot{M}_{O_2}$ by the lungs. *From Ackerman and Rahn (1981) with permission from Elsevier.*

the context of using the CAM as an assay for toxicants or a model for angiogenesis.

The outer surface of the chorioallantois, i.e., CAM, is well vascularized (Wangensteen et al., 1970/71; Tazawa and Ono, 1974; Wangensteen and Weibel, 1982; Ribatti, 2017). Early in incubation, the capillaries lie on the mesenchymal surface of the CAM and vascular growth occurs through the process of "mergent angiogenesis" (Maibier et al., 2016). Capillaries begin to migrate through the ectoderm on day 10 and lie on its thin layer late in incubation. In addition, relocation of the nuclei of the CAM capillaries occurs (Mayer et al., 1995). The endothelial nuclei randomly distribute around the capillary lumen early in incubation and are located progressively on the portion of the capillaries away from the shell membrane after the chorioallantois envelops the whole contents of the egg. Together with capillary migration, the relocation of endothelial nuclei results in progressive thinning of the gas diffusion pathway between the interstices of the inner shell membrane (air space) and the capillary blood. The process of CAM angiogenesis and vascularization is influenced by ambient hypoxia. CAM growth increases under hypoxia to minimize the negative effects of reduced oxygen (Strick et al., 1991; Wagner-Amos and Seymour, 2003; Azzam and Mortola, 2007; Zhang and Burggren, 2012; Druyan and Levi 2012). Yet, various studies have demonstrated an increase, decrease, or no change in CAM vascularization under hypoxia (Burton and Palmer 1992; Wagner-Amos and Seymour, 2002, 2003; Druyan and Levi 2012). Such contradictory results may be due to differential effects caused by the timing, intensity, and duration of hypoxia (Zhang et al., 2017). CAM vasculature is also affected by toxicants such as crude oil (Burggren and Rojas Antich, 2020).

The CAM functions as a gas exchanger during prenatal development (prior to IP) until it degenerates when the embryo pips it and the inner shell membrane with the beak. The increase in $\dot{M}_{O_2}$ of the chicken embryo during the first ~16 days of incubation is enabled by the extension of the CAM (Figure 37.2). The gas exchange of embryos before IP takes place by diffusive transport across the porous shell, two shell membranes, and capillary blood of the CAM (Wangensteen and Rahn, 1970/71; Wangensteen et al., 1970/71; Wangensteen and Weibel, 1982). Then, the chick breaks the shell and breathes environmental air by lung ventilation (EP). As the near-term embryo begins ventilating the lungs, they replace the gas exchange function of the CAM.

When the CAM envelopes all contents of the egg, the gas exchange by diffusive transport is expressed by,

$$\dot{M}_{O_2} = G_{O_2} \cdot (PI_{O_2} - PA_{O_2}) \quad (37.7)$$

$$= D_{O_2} \cdot (PA_{O_2} - P\bar{c}_{O_2}) \quad (37.8)$$

where $\dot{M}_{O_2}$ is oxygen uptake (mL/min), G_{O_2} is oxygen conductance of the shell and shell membrane (mL O_2/min/kPa), D_{O_2} is the diffusing capacity of the CAM and capillary blood (mL O_2/min/kPa), PI_{O_2} is the effective

environmental oxygen partial pressure (kPa); PA_{O_2} is the air space oxygen partial pressure (kPa), and P_{CO_2} is mean capillary oxygen partial pressure (kPa).

G_{O_2} is related to G_{H_2O} by the diffusion coefficient ratio ($d_{O_2}/d_{H_2O} = 0.23/0.27$). G_{O_2} (in mL/min/kPa) is derived from G_{H_2O} (in mg/min/kPa) by multiplying by a factor of 1.06. Because G_{O_2} in air is constant during the prenatal incubation, PA_{O_2} decreases as the embryo grows and consumes more O_2 (Table 37.1). The increased difference of O_2 partial pressure between the environmental air and air space is the driving force that meets the increased O_2 demand of the developing embryo. Concurrently with the decrease in PA_{O_2}, P_{CO_2} also decreases. The O_2 flux from the air space to the *Hb* of capillary blood (inner diffusion barrier) is facilitated by an increase in D_{O_2} which is expressed by:

$$D_{O_2} = 60 \cdot V_c \cdot F\overline{C}_{OX} \cdot Hct \tag{37.9}$$

$$= \dot{Q}_a \cdot t_c \cdot F\overline{C}_{OX} \cdot Hct \tag{37.10}$$

where V_c is capillary volume of the CAM (μL), FC_{OX} is mean corpuscular oxygenation velocity during the contact time (s/kPa), *Hct* is hematocrit, $\dot{Q}_a$ is blood flow through the CAM (mL/min), and t_c is the contact time of erythrocytes with O_2 when they pass through the CAM capillaries (s) (Tazawa et al., 1976; Tazawa and Mochizuki, 1976) (Table 37.1).

D_{O_2} is increased by an increase in V_c, which depends on $\dot{Q}_a$ and t_c; $V_c = (\dot{Q}_a/60) \times t_c$ (Table 37.1). While $\dot{Q}_a$ increases about fivefold from days 10–18, the t_c halves, probably because of shortening of the blood circulation time, as cardiac output increases more rapidly than total blood volume. Consequently, V_c increases even after the CAM spreads over the whole surface of the inner shell membrane on day 12 and reaches a maximum volume on days 14 and 15. Nevertheless, D_{O_2} increases further after day 14. This is largely due to the increase in $\dot{Q}_a$ and *Hct*, as

TABLE 37.1 Gas exchange variables used to determine the diffusing capacity of the inner diffusion barrier (chorioallantoic membrane and capillary blood) in developing chicken embryos.

Age (days)	10	12	14	16	18
Body Mass	2.4	5.2	9.3	16.0	22.9

Body mass (g); from Tazawa and Mochizuki (1976), PA_{O_2} (air space P_{O_2}, kPa), PA_{CO_2} (air space P_{CO_2}, kPa), Pv_{O_2} (mixed venous blood P_{O_2}, kPa), Pv_{CO_2} (mixed venous blood P_{CO_2}, kPa); calculated from data in Tazawa (1973) and Wangensteen and Rahn (1970/71). Note: Unit of partial pressure is converted from 'mmHg' in original sources to "kPa" in current text. P_aO_2 (arterialized P_{O_2} in the allantoic vein, kPa); from Tazawa (1973), pH_a (arterialized blood pH corresponding to the allantoic vein); from Tazawa et al. (1971), S_aO_2 (oxygen saturation of arterialized blood, %); calculated by substituting P_aO_2 and pH_a into the modified Hill's equation of the O_2 dissociation curve (Tazawa et al., 1976), S_vO_2 (oxygen saturation of mixed venous blood, %); determined by microphotometer (Tazawa and Mochizuki, 1976), O_2 capacity (vol%); determined from Tazawa (1971) and Tazawa and Mochizuki (1977), $\dot{M}_{O_2}$ (oxygen uptake, mL/min); from Tazawa (1973), Q_a (allantoic blood flow, mL/min); calculated by $\dot{M}_{O_2}/[O_2$ capacity $(S_aO_2 - S_vO_2)]$, t_c (contact time, s); determined by microphotometer (Tazawa and Mochizuki, 1976), V_c (capillary volume, 10^{-3} mL), calculated by $Q_a/60 \times t_c$, $F\overline{c}_{OX}$ (oxygenation velocity factor, s/kPa); from Tazawa et al. (1976), *Hct* (hematocrit, %); from Tazawa et al. (1971a,b), D_{O_2} (diffusing capacity of inner diffusion barrier, mL/min/kPa); calculated by $60 \cdot V_c \, F\overline{c}_{OX} \, Hct$ or $Q_a \, t_c \cdot F\overline{c}_{OX} \cdot Hct$.

both variables increase after the CAM spreads over the inner shell membrane. Toward the end of prenatal development, the increase in D_{O_2} slows down and $\dot{M}_{O_2}$ reaches a plateau. This suggests an important contribution of the inner diffusion barrier to gas exchange, which contributes, along with the outer diffusion barrier (G_{O_2}), to the plateau status of $\dot{M}_{O_2}$. This results in the developmental pattern of $\dot{M}_{O_2}$ paralleling the daily changes in D_{O_2} (Table 37.1).

In chicken eggs, the variability of shell G_{O_2} is large, higher than that of egg mass. Mass-specific $\dot{M}_{O_2}$, measured on days 16–19 of incubation, is maximal at medium G_{O_2}, decreasing at both lower and higher G_{O_2} (Visschedijk et al., 1985). The maximum $\dot{M}_{O_2}$ at medium G_{O_2} values is considered to be optimal for embryo development, and the decrease in $\dot{M}_{O_2}$ at both higher and lower G_{O_2} is a sign of compromised development. When G_{O_2} is decreased by partially covering the shell with impermeable material or increased by partially removing the shell over the air cell at the beginning of incubation, $\dot{M}_{O_2}$ of day 16 embryos increases hyperbolically with increasing G_{O_2}, reaching a maximum at the control G_{O_2} of intact eggs and decreasing with further increase in G_{O_2} (Okuda and Tazawa, 1988). A similar increase in $\dot{M}_{O_2}$ is observed when the shell is removed over the air cell immediately prior to measurement in IP embryos (Ide et al., 2017b), indicative of diffusive limitation of $\dot{M}_{O_2}$ in late embryos. When part of the shell is covered and the other is exposed to hyperoxia, $\dot{M}_{O_2}$ and growth rate do not change, indicating uniform G_{O_2}, and therefore uniform chorioallantoic perfusion, is not required to maintain $\dot{M}_{O_2}$ (Wagner-Amos and Seymour, 2002).

Because the oxygen diffusion coefficient (d_{O_2}) affects shell conductance, G_{O_2} can be changed by replacing N_2 in air with an inert background gas whose density is different from that of N_2 (e.g., He or SF_6), thus changing d_{O_2} (Erasmus and Rahn, 1976; Ar et al., 1980; Tazawa, 1981a; Tazawa et al., 1981). Accordingly, the gas exchange of the egg can be manipulated by changing G_{O_2} with He or SF_6. The d_{O_2} is also inversely related to atmospheric pressure (P_B) and thus gas exchange of the egg is increased at high altitude because the shell G_{O_2} increases inversely with P_B. The reduction of G_{O_2} in eggs laid by birds incubating at high altitude occurs as a natural adaptation to altitude (Rahn et al., 1977; Hempleman et al., 1992).

As incubation proceeds, diffusive gas exchange governed by G_{O_2} and D_{O_2} is gradually replaced by convective gas exchange through the lungs during the perinatal period, beginning at IP (Figure 37.2). Breathing movements of perinatal embryos can be recorded as pressure changes using an optical system or pressure transducer (Romijn, 1948; Vince and Salter, 1967; Dawes, 1976). Conveniently, prenatal cardiac rhythms at the onset of IP and EP and the subsequent development of respiratory rhythms until hatching can be recorded by continuous measurements of cardiogenic, ventilatory, and hatching activities in chickens

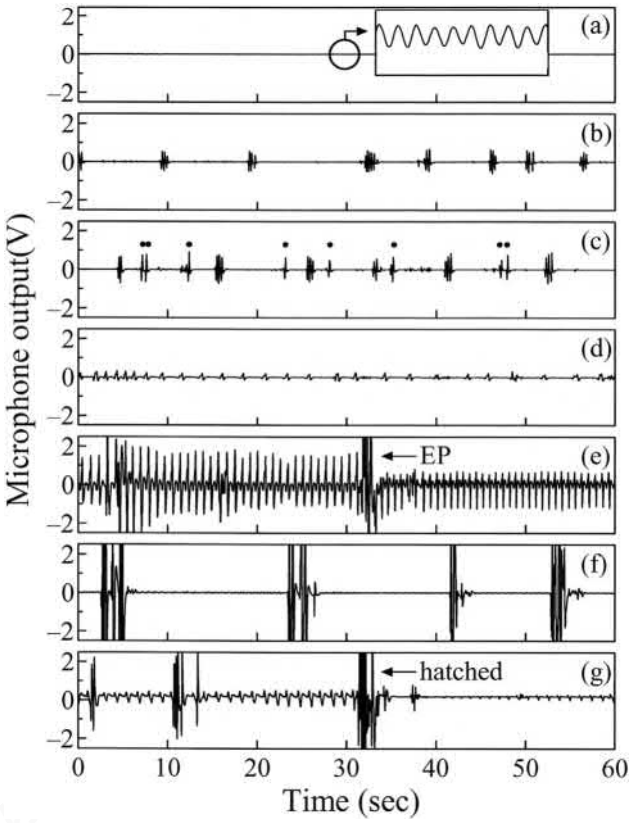

FIGURE 37.3 The cardiogenic and breathing activities of a chicken embryo from the prenatal through perinatal period to hatching, recorded by a condenser microphone attached hermetically on the shell. A 60 s recording is shown in each panel. (A) Cardiogenic signal (acousto-cardiogram, ACG) during the final stages of the prenatal period; ACG is evident in the enlarged inset. (B) Beak-clapping signals just prior to IP. (C) Onset of breathing signals occurring as single, irregular deflections (approximately once per 5 s) among beak clapping after IP (acousto-respirogram, ARG). (D) Rhythms become fast and somewhat irregular. (E) Breathing signals are more regular before and after EP. The onset of EP is evident by a sudden decrease in magnitude of ARG. (F) Approximately 1 h prior to hatching, large deflections due to hatching activities (e.g., climax) begin to occur and the breathing becomes intermittent. (G) The hatching activities continue before breathing regulates and finally the embryo hatches. Breathing signals are recorded after hatching because the microphone is located close to the beak of hatchling. *From Chiba et al. (2002), with permission from Elsevier.*

by means of a condenser-microphone measuring system (Figure 37.3) (Chiba et al., 2002; Bamelis et al., 2005). Using the breathing patterns of chickens from the onset of IP through EP to hatching, the length of the IP, EP, and whole perinatal periods are determined as 14.1 ± 2.0 (SEM) h, 13.6 ± 1.3 h and 27.6 ± 1.7 h long, respectively. The duration of the actual hatching event is 48 ± 6 min. The instantaneous respiratory rate (IRR in breaths/min) is approximately 10–15 breaths/min at the beginning of IP. IRR baseline increases up to 80–100 breaths/min with large fluctuations of IRR of 60–180 breaths/min after the onset of EP.

Pulmonary ventilation and gas exchange during the perinatal period has been quantified using a barometric plethysmograph or pneumotachograph (Pettit and Whittow, 1982a; Menna and Mortola, 2003; Sbong and Dzialowski, 2007; Szdzuy and Mortola, 2007; Ide et al., 2017a) and by measurement of gases in air cell and allantoic blood (Pettit and Whittow, 1982b; Tazawa et al., 1983b). The embryonic development of pulmonary ventilation and its regulation has been investigated and reviewed elsewhere (Mortola, 2009; Ide et al., 2017a; Whitaker-Fornek et al., 2019).

37.4.2 Acid-base regulation

Acid-base regulation in adult animals is achieved through a combination of rapidly acting molecular/biochemical changes, intermediately acting ventilatory effects, and slowly acting renal adjustments. The developmental onset and progression of these in vertebrates, including the avian embryo, has been reviewed recently (Burggren and Bautista, 2019). As the avian embryo consumes O_2, it produces CO_2, which is partially dissolved and stored in the blood and body fluids, but mostly eliminated through the eggshell. As with O_2, CO_2 elimination ($\dot{M}CO_2$) depends upon the eggshell CO_2 conductance (GCO_2) and CO_2 partial pressure difference between air cell ($PACO_2$) and atmosphere ($PICO_2$):

$$\dot{M}CO_2 = GCO_2 \cdot (PACO_2 - PICO_2) \qquad (37.11)$$

GCO_2 is a function of eggshell geometry (A_p and L), CO_2 diffusion coefficient (dCO_2), and the inverse product of R and T. $PICO_2$ is very close to zero when the egg is in air.

As embryos develop and their body mass increases, they produce more CO_2 which accumulates in the egg. $PACO_2$ increases, thus increasing arterialized blood PCO_2, P_aCO_2 (Meuer and Tietke, 1990). Consequently, arterialized blood pH is lowered (Figure 37.4) or stays relatively constant in the allantoic vein during the last half of prenatal development (Dawes and Simkiss, 1969; Girard, 1971; Erasmus et al., 1970/71; Boutilier et al., 1977; Everaert et al., 2011). The rate of decrease in pH during embryonic development slows, however, late in incubation. Although the plasma bicarbonate concentration ($[HCO_3^-]$) increases with development, the increase is more than would be expected from changes in pH and the buffer value (−16 mmol/L, Burggren et al., 2012). The pH change due to CO_2 accumulation is mitigated by an increase in non-respiratory HCO_3^- (Figure 37.4) (Tazawa, 1986, 1987). *Hb*, which serves as the noncarbonate buffer in blood, increases during the last half of incubation, and thus is partly responsible for the mitigated change in pH. Reflecting the developmental increase in *Hct* and *[Hb]*, the buffer value increases from ∼ −8 to −10 mmol/L on days 9−10 to ∼ −17 mmol/L on days 15−18 (Erasmus et al., 1970/1971; Tazawa and Piiper, 1984). In day 16 embryos, values ranging from −12.7 to −15 mmol/L are reported (Tazawa et al., 1981; Tazawa, 1980a, 1981b, 1982, 1986). Other studies have not found an increase in buffer value during development (Tazawa et al., 1983a; Andrewartha et al., 2011b; Burggren et al., 2012). The determination of the buffer value is a controversial issue, and clearly not all sources of variation have been identified. However, the value of −16 mmol/L reported by Burggren et al. (2012) is depicted in a pH-$[HCO_3^-]$ diagram (Davenport diagram, Figure 37.4) to show and estimate respiratory changes in acid-base balance.

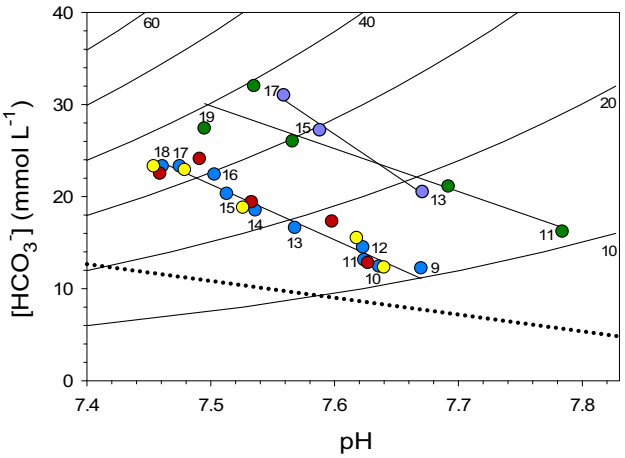

FIGURE 37.4 A Davenport diagram illustrating the daily changes in control acid-base balance of arterialized blood in chicken embryos developing in air. The dashed diagonal line is an arbitrary buffer line with the determined slope of −16 mmol/L/pH unit. Numbered curves are PCO_2 isopleths in mmHg. The numbers near the data points represent the ages of the embryos. Data are collected from the following studies; *blue circles*: Tazawa et al. (1971a), *red circles*: Tazawa et al. (1971b), *green circles*: Tazawa (1973), *purple circles*: Burggren et al. (2012), *yellow circles*: Tazawa et al. (2012). The *solid line* drawn through the data points corresponds to the following regression equation; (1) $[HCO_3^-] = -60.2$ pH + 472.6 for combined data from Tazawa et al. (1971a, 1971b) and Tazawa (1973), (2) $[HCO_3^-] = -90.9$ pH + 717.4 from Burggren et al. (2012), and (3) $[HCO_3^-] = -46.6$ pH + 379.1 from Tazawa et al. (2012).

Responses in acid-base balance to 1 day exposure to altered environmental gas mixtures differ depending on the gas mixture, age of embryos, and chicken strain (Burggren et al., 2012, 2015; Mueller et al., 2014b, 2017). One day of hypercapnic exposure (5% CO_2, 20% O_2) increases P_aCO_2 and decreases pH_a, producing respiratory acidosis that is partially (∼50%) compensated by metabolic alkalosis at all embryonic stages examined (days 13, 15, and 17). Similar patterns of partially compensated respiratory acidosis have been reported in embryos exposed to up to 10% CO_2 in air, with compensation proportional to CO_2 concentration (Dawes and Simkiss, 1969; Mueller et al., 2014b, 2017; Burggren et al., 2015). At 20% CO_2, metabolic compensation no longer increases with CO_2 concentration as observed at CO_2 levels below 10% CO_2 suggesting there is

a hypercapnic threshold for acid-base regulation >10% CO_2 (Burggren et al., 2015). Furthermore, one day of exposure to hypercapnic hypoxia (5% CO_2, 15% O_2) abolishes compensatory metabolic alkalosis in day 15 and day 17 embryos, but a metabolic compensation of ~37% still occurs in day 13 embryos. This suggests that a relatively high O_2 level is required for metabolic compensation to occur (Mueller et al., 2017). The lower $\dot{M}O_2$ and an overall higher allantoic P_aO_2 in air (Tazawa, 1971, 1980a; Tazawa et al., 1971a, b) in day 13 embryos compared with more advanced embryos preserves the metabolic compensation during hypoxia. One day of hypoxic exposure (15% O_2) creates a metabolic acidosis in day 15 and day 17 embryos, but not in day 13 embryos. Hypoxia produces hypometabolism without anaerobic energy compensation (Bjønnes et al., 1987; Mortola and Besterman, 2007; Ide et al., 2016; Haron et al., 2017). However, once a lower threshold $\dot{M}O_2$ is reached, embryos turn to anaerobic glycolysis and blood lactate concentration ($[La^-]$) increases (Grabowski, 1961, 1966; Bjønnes et al., 1987). Therefore, embryos exposed to severe hypoxia (e.g., 10% O_2) encounter metabolic acidosis caused by glycolysis (Tazawa et al., 2012). However, metabolic acidosis occurring in moderate hypoxia is attributed only slightly to glycolysis and other unverified mechanisms, such as O_2 level influencing HCO_3^- transfer across the CAM. One day exposure to hyperoxia (40% O_2) causes respiratory acidosis that varies with embryonic age. Hyperoxia causes hypermetabolism (and a consequent increase in $\dot{M}CO_2$) (Visschedijk et al., 1980; Høiby et al., 1983; Stock et al., 1985; Tazawa et al., 1992b). Increased CO_2 is accumulated in the blood and hydrated to create H^+ and HCO_3^-. Coupled with a fixed eggshell gas GCO_2, this results in respiratory acidosis. Age-specific differences in the magnitude of respiratory acidosis are due to hyperoxia causing a greater hypermetabolism in advanced embryos (Stock et al., 1985; Tazawa et al., 1992b).

Because eggshell GCO_2 is governed by dCO_2, respiratory acidosis also occurs in embryos exposed to a SF_6/O_2 gas mixture, which reduces GCO_2. Inversely, respiratory alkalosis occurs in embryos exposed to a He/O_2 atmosphere, which increases GCO_2 (Tazawa et al., 1981). Partially covering the eggshell with a gas impermeable material or by immersion in water produces respiratory acidosis while opening the eggshell over the air cell produces respiratory alkalosis (Tazawa, 1981a; Andrewartha et al., 2014). These respiratory disturbances to the acid-base balance occur rapidly and blood P_aCO_2 reaches a plateau ~10 min after changing GCO_2 (Tazawa, 1981a). Concurrently, blood pH changes to the value predicted by buffer capacity during the following 30–60 min (i.e., noncompensated respiratory acidosis/alkalosis) with a subsequent (2–6 h), but incomplete, change toward the control level, while P_aCO_2 is maintained at a constant value. Once partial metabolic compensation is achieved at ~4–6 h, the state of acid-base disturbance remains constant over the next 24 h in normoxia or hyperoxia (e.g., 5% CO_2/20% O_2 or 5% CO_2/40% O_2), but metabolic compensation is not preserved after 24 h in hypoxia (5% CO_2/15% O_2) (Mueller et al., 2013b, 2017). Therefore, preservation of metabolic compensation requires an O_2 concentration above 20%.

While partial metabolic compensation in response to hypercapnia or moderate hypoxia with hypercapnia (e.g., 15% O_2/5% CO_2) proceeds over the course of several hours in day 15 embryos, responses to severe hypoxia (10% O_2), with or without CO_2 (e.g., 5%), progress more quickly (Figure 37.5) (Tazawa et al., 2012). This is due to anaerobic glycolysis and the attendant rapid increase in $[La^-]$ that creates severe metabolic acidosis. If hypoxic embryos can preserve $[HCO_3^-]$ above ~10 mmol/L (in the case of day 15 embryos), which is generally reached beyond 2 h, embryos can survive and recover to the control state of acid-base balance in ~2 h after being returned in air (Figure 37.5) (Tazawa et al., 2012). Accordingly, hypoxia-induced acid-base disturbances are only transient and may not affect long-term survival.

Natural variations in eggshell conductance cause large differences in P_aCO_2 among eggs, but blood pH variations are minimal (Tazawa et al., 1983a). In eggs with low GCO_2, the *Hct* (and thus *Hb*) increases. In part, increased [*Hb*] may be responsible for the minimum change in pH.

The acid-base balance of chicken embryos also reacts promptly to metabolic disturbances, as shown by the time course changes in metabolic acid-base alterations created by infusion of electrolyte solution ($NaHCO_3$ and NH_4Cl) (Tazawa, 1982). For instance, the infusion of 15 μL 1 M

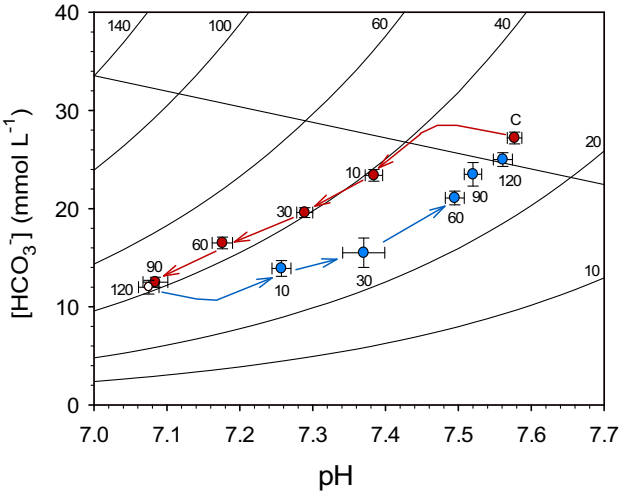

FIGURE 37.5 Time-course of acid-base disturbance in day 15 chicken embryos exposed to hypercapnic hypoxia (5% CO_2, 10% O_2) for 120 min (*red circles*) with recovery in air for 120 min (*blue circles*). Other details as in Figure 37.4. *Modified from Tazawa et al. (2012) with permission from Elsevier.*

$NaHCO_3$ increases plasma [HCO_3^-] and blood P_{CO_2}. Because the embryo has no convective ventilation, the metabolic disturbance is not subjected to respiratory compensation. The increase in P_{CO_2} 1 h after infusion indicates that the infused HCO_3^- is partly eliminated as dissolved CO_2. The acid-base status returns to control values 6 h after infusion. Besides elimination of CO_2 from the CAM, the increased fluid volume and hypertonicity of the infused $NaHCO_3$ solution may be partially responsible for the decrease in [HCO_3^-]. Additionally, penetration of HCO_3^- into the intracellular space and excretion of HCO_3^- into allantoic fluid through the CAM may contribute to the regulation (Tazawa, 1982, 1986).

In summary, acid-base regulation develops in concert with the increased CO_2 production as avian embryos grow. The ability of chicken embryos to tolerate and respond to acid-base disturbance, induced by environmental gas challenges, increases or decreases in G_{CO_2} or infusion of electrolytes, increases with development. By approximately two thirds of incubation, the chick embryo is able to mount at least partial compensatory responses to acidosis. Comparative approaches are required to examine species differences in acid-base regulation, and how tolerance to perturbations may be related to the incubation environment.

37.4.3 Cardiovascular system

37.4.3.1 Basic cardiovascular parameters

The primordial bird embryo's heart is a paired tubular structure that soon becomes a single tube. The heart begins to elongate more rapidly than the pericardial cavity containing it, and this space limitation forces the tubular heart to bend, contributing to the start of cardiac looping (Männer, 2000, 2006; Al Naieb et al., 2013). Molecular and cellular mechanisms underlying cardiac development in chicken embryos have been reviewed by Wittig and Münsterberg (2016). The impact of blood streams upon the inner surface of the contorted tube forms the external configuration and internal structure of the heart (Taber, 2001; Alford and Taber, 2003; Tobita et al., 2005) as well as contributing to blood vessel formation (le Noble et al., 2008; Burggren, 2013; Branum et al., 2013). However, the specific role of pressure and flow fluctuations to the contribution of normal and abnormal development of the heart and blood vessels remains somewhat enigmatic (Branum et al., 2013; Midgett et al., 2014, 2017).

The structural alterations that separate atrium from ventricle, ventricle from aorta, and the left from the right chambers take place during days three−eight of incubation, resulting in a four-chambered heart by days eight−nine (Pattern, 1951; Burggren and Keller, 1997; Al Naieb et al., 2013). The mass of the heart increases as a power function of incubation day (I) (Romanoff, 1967; Clark et al., 1986):

$$\text{Heart mass } (\mu g) = 12.62 \cdot I^{3.26} \qquad (37.12)$$

The growth of the heart relative to the whole body is greatest early in development and declines during incubation. The ratio of the heart mass to the whole-body mass falls from 1.8% on day 4 to 0.7% on day 18 of incubation.

The heart begins to beat at about 30 h of incubation and blood begins to circulate after about 40 h, when the connections between the dorsal aorta and the vessels of the yolk sac complete the circulation (Pattern, 1951). Despite the early generation of heartbeat and blood flow, heart rate is not initially required for convective blood flow to the tissues, but likely plays a role in angiogenesis (Burggren et al., 2000, 2004; Burggren, 2004, 2013; Branum et al., 2013).

Blood volume increases with incubation day (Figure 37.6B) (Yosphe-Purer et al., 1953; Barnes and Jensen, 1959; Lemez, 1972; Kind, 1975) and can be approximated by the following function (Tazawa and Hou, 1997):

$$\text{Blood volume } (\mu L) = 1.85 \cdot I^{2.64} \qquad (37.13)$$

The increase in blood volume during development is not as rapid as growth rate (Figure 37.6A), and therefore embryo mass-specific blood volume decreases during development from about 1 mL/g on day 4 to 0.15 mL/g on day 18.

As both the heart mass and blood volume increase, the stroke volume of the heart increases (Hughes, 1949; Faber et al., 1974; Hu and Clark, 1989; Phelan et al., 1995). During early development, prior to the left and right separation of the heart, stroke volume depends on blood volume and increases in parallel with embryonic growth (Faber et al., 1974). The relationship between stroke volume and incubation day (I, days 2−6) (Hu and Clark, 1989) can be described as:

$$\text{Stroke volume } (\mu L) = 0.002 \cdot I^{3.46} \qquad (37.14)$$

Even after the second week of incubation, stroke volume appears to increase as a power function of incubation day (Figure 37.6C) (Hughes, 1949).

For early embryos, the dorsal aortic blood flow increases as a power function of incubation day during days 2−6 (Hu and Clark, 1989). The mass (embryo)-specific value is 0.5−1 mL/min/g. The mass-specific cardiac output of days three−five embryos, determined from the stroke volume, is similar at 1 mL/min/g (Faber et al., 1974). Cardiac output calculated from the stroke volume of young embryos and that of day 16 chicken embryos estimated by model analysis and blood O_2 measurement (White, 1974; Rahn et al., 1985; Tazawa and Johansen, 1987) indicate that the mass-specific cardiac output of young/late embryos is in the narrow range of 0.5−1.5 mLmin/g. Thus, cardiac output appears to increase as a power function of incubation day (Figure 37.6D). Eventually, cardiac output may increase almost in parallel with embryonic growth. If it is assumed that the mass-specific cardiac output during the

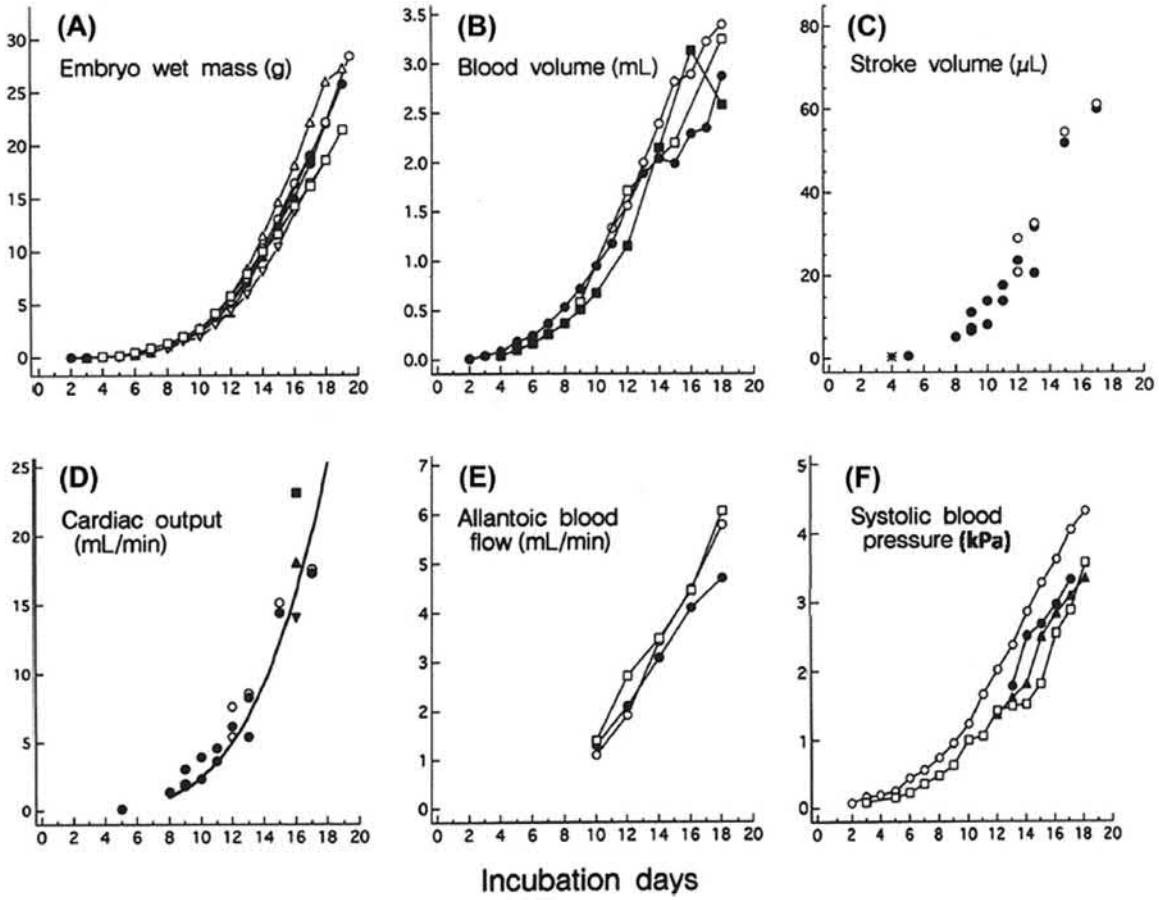

FIGURE 37.6 Developmental patterns of embryo wet mass (A), total blood volume (B), cardiac stroke volume (C), cardiac output (D), allantoic blood flow (E), and arterial systolic blood pressure (F) during the prenatal stage of chickens. Symbols connected by *solid lines* in (A, B, E, and F) indicate the developmental patterns from the papers cited in the text.

last 2 weeks of prenatal development is 1 mL/min/g, the cardiac output of young embryos is related to incubation day (I) as follows,

$$\text{Cardiac output } (\mu\text{L/min}) = 0.24 \cdot I^4 \qquad (37.15)$$

which is the same expression as that relating body mass of developing embryos to incubation day (Eq. 37.5, Figure 37.6A and D).

Blood flow through the CAM, determined from $\dot{M}_{O_2}$, blood gas analysis or via flow probe (Tazawa and Mochizuki, 1976, 1977; Bissonnette and Metcalfe, 1978; Van Golde et al., 1997), increases with embryonic growth (Figure 37.6E), but the mass-specific value decreases from ~0.5 mL/min/g on day 10 to ~0.25 mL/min/g on day 18. Although cardiac output increases in parallel with embryonic growth, its partition to the CAM decreases as the embryo grows. On days 10–13 about half of the cardiac output goes to the CAM and this decreases to ~40% on days 17–19 (Mulder et al., 1997; Dzialowski et al., 2011 for review) or to ~17–20% on days 16–18 (Tazawa and Johansen, 1987). Consequently, the percentage of cardiac output to the organs and tissues increases as development proceeds.

Arterial pressure (P_a) has been measured through several approaches. The easy access to vitelline through the shell of allows blood pressure measurement via a vitelline vessel in early embryonic chick development and an allantoic artery thereafter. Technologies that maintain normal gas exchange through the shell as blood pressure is measured have included micropipettes (Van Mierop and Bertuch, 1967; Girard, 1973), polyethylene catheters with our without needle tips (Tazawa, 1981c; Tazawa and Nakagawa, 1985) and, more recently, pressure volume catheters (Jonker et al., 2015). Arterial systolic pressure (P_{sys}), or, increases with incubation day (I) in the following manner (Figure 37.6F);

$$P_{sys}(\text{kPa}) = 0.015 \cdot I^{1.86} \qquad (37.16)$$

P_a of the vitelline artery is pulsatile by day two of chicken incubation (Van Mierop and Bertuch, 1967; Hu and Clark, 1989; Taber, 2001). While the presence of a dicrotic notch is reported in early embryos (Hu and Clark, 1989;

Yoshigi et al., 1996), a clear dicrotic notch is absent from allantoic P_a waves determined by others (Van Mierop and Bertuch, 1967; Tazawa and Nakagawa, 1985). However, the configuration of the P_a tracings and the ventricular pressure waves suggest that an arterial valve mechanism is present in early embryos which lack true cardiac valves (Van Mierop and Vertuch, 1967; Faber, 1968).

Investigations of chick embryo ventricular function, ventricular and vascular biomechanics, and hemodynamic and morphogenesis relationships, particularly in early (day two–four of incubation) development, are reviewed by Keller et al. (2020).

37.4.3.2 Mean heart rate

According to the equations expressing the relationship between incubation day and body mass (Eq. 37.5) or cardiac output (Eq. 37.15), both body mass and cardiac output in day 16 chicken embryos are ~16 g and ~16 mL/min. Assuming a mean heart rate (MHR) of 280 beat per min (bpm), the stroke volume and mass-specific stroke volume can be estimated to be ~60 μL and ~4 μL/g. The cardiac contraction generating this amount of stroke volume physically moves the body of the embryo by an almost imperceptible amount. These movements are transferred to the whole egg, producing cardiogenic ballistic movement of the egg—referred to as a "ballistocardiogram (BCG)" of the egg (Tazawa et al., 1989b). The egg movement determined by a laser displacement meter is ~1 μm (Sakamoto et al., 1995). The BCG measured by various means offers a convenient way to noninvasively determine MHR of avian embryos (Tazawa et al., 1999; Tazawa, 2005). Additionally, the heartbeat of the embryo inside the eggshell produces not only the ballistic movements of the egg but also acoustic pressure changes outside the eggshell. A conventional condenser microphone hermetically fixed on the eggshell detects the cardiogenic acoustic pressure changes, designated as an acoustocardiogram (Rahn et al., 1990), which can conveniently determine MHR of avian embryos. Use of near infrared sensing technologies provide additional methods for noninvasively measuring cardiac rhythms both in the laboratory and in the field (Lemus et al., 2009; Braune et al., 2012; Sheldon et al., 2018; Khaliduzzaman et al., 2019a,b). However, methods using infrared light have been criticized when used in small avian or reptilian eggs because the IR potentially heats up the egg shell and thus artificially increases heart rate (Sartori et al., 2015). Moreover, they may stimulate embryo movement and thus potentially interfere with detection of an accurate heart signal (Pollard et al., 2016). Most recently, a method based on photoplethysmography using a smart phone has been advanced (Phuphanin et al., 2019).

In contrast to developmental patterns of the circulatory variables that increase steadily with embryonic growth, the embryonic MHR of chickens increases rapidly after the heart commences beating and then becomes asymptotic until early in the second week of incubation (Cain et al., 1967; Van Mierop and Bertuch, 1967; Girard, 1973; Hu and Clark, 1989; Tazawa et al., 1991a; Burggren and Warburton, 1994; Howe et al., 1995). During the last half of incubation in the chicken embryo, the daily change in MHR is small with a temporal increase at 60–70% of incubation followed by a decrease toward IP and increase during hatching (Laughlin et al., 1976; Tazawa et al., 1991a). The change in MHR near the end of development in other precocial birds is shown in Table 37.2. Precocial species, from the smallest (king quail, *Coturnix chinensis*) to the largest (ostrich), show either a plateau or decrease in MHR prior to IP (Tazawa et al., 1991a, 1998a, 1998b, 2000; Pearson et al., 1998; Kato et al., 2002).

In comparison, HR increases rapidly toward hatching in small altricial embryos (Table 37.3) (Tazawa et al., 1994; Pearson et al., 1999). However, the increase in MHR during pre-pipping development slows in larger altricial eggs, e.g., MHR of crow (*Corvus corone*) and cattle egret (*Bubulcus ibis*) tends to remain unchanged during the last half of prenatal period (Pearson and Tazawa, 1999; Tazawa et al., 2001b). The trend for MHR to remain unchanged during the end of prenatal development also occurs in semiprecocial seabirds, e.g., the brown noddy (*Anous stolidus*) and laysan albatross (*Phoebastria immutabilis*) (Table 37.2) (Tazawa et al., 1991b; Tazawa and Whittow, 1994; Pearson et al., 2000). Hence, the pattern of change in MHR during development, particularly at the end of incubation, can be somewhat predicted by the degree of development at hatching. Precocial species tend to show a plateau or decrease in MHR near hatching, while MHR tends to increase in altricial species.

These determinations of embryonic MHR along with egg mass of various species (Tables 37.2 and 37.3) reveal a significant relationship between MHR at 80% of I and egg mass (Tazawa et al., 2001b). The allometric relationship derived for 20 species of altricial and semialtricial birds with egg mass ranging from 0.96 g of the zebra finch to ~41 g of the lanner falcon (*Falco biarmicus*) is:

$$\text{MHR at 80\% of } I = 371 \cdot (\text{Egg mass})^{-0.121} \quad (r = -0.846,\ P < 0.001) \tag{37.17}$$

The relationship for 13 species of precocial and semiprecocial birds with egg mass ranging from 6 g of the king quail to ~1400 g of the ostrich is:

$$\text{MHR at 80\% of } I = 433 \cdot (\text{Egg mass})^{-0.121} \quad (r = -0.963,\ P < 0.001) \tag{37.18}$$

The slopes for MHR are parallel, but MHR of semialtricial embryos is low compared to semiprecocial embryos from the same egg mass. In semialtricial embryos,

TABLE 37.2 Egg mass (g), incubation period (*I*, days), heart rate (HR, beats/min) at 80% of incubation and maximum heart rate (max HR) during prenatal development in precocial birds and heart rate prior to internal pipping (Pre-IP) and at the first star fracture of the eggshell in semiprecocial birds.

	Species	Egg mass (g)	Incubation period (*I*, days)	HR at 80% of *I* (beats/min)	Max HR (beats/min)

Modified from Tazawa et al. (2001b).

HR becomes maximal during the pipping period, and the maximum HR is significantly related to egg mass. Consequently, the allometric relationship of maximum HR and egg mass in semialtricial and that of 80% of *I* in semiprecocial is statistically identical, expressed by a single allometric equation:

$$\mathrm{MHR} = 437 \cdot (\text{Egg mass})^{-0.123} \quad (r = -0.948,\ P < 0.001,\ N = 33) \tag{37.19}$$

In addition, determination of MHR in embryos from the same clutch (siblings) in pigeons, bank swallows, and zebra finches demonstrates that developmental patterns of MHR in siblings are more alike than those of embryos from other clutches of the same species (Burggren et al., 1994; Sheldon et al., 2018). These findings may be termed the "sibling effect" in which siblings are predisposed to show particular physiological patterns. Whether these effects are genetically based (i.e., resulting from the common genetic heritage of the F_1 offspring), due to the shared environment, or involve epigenetic influences, is uncertain. Certainly, physiological process can be transferred across generations (see Ho and Burggren, 2010; 2012; Burggren 2014; Bautista et al., 2020) through epigenetic mechanisms. However, environmental effects on the mother may also cause siblings to undergo similar patterns of physiological development through a "maternal effect" or even direct effects on the gamete cells of the mother (Burggren et al., 1994; Dzialowski and Sotherland, 2004; Ho et al., 2011; Burggren, 2014).

37.4.3.3 Instantaneous heart rate

In addition to daily changes in MHR during development, HR varies from beat to beat [(i.e., instantaneous heart rate (IHR)]. At rest, the baseline of IHR in chicken embryos is more or less constant before ~day 11, indicating that neither IHR accelerations of adrenergic origin nor IHR decelerations of cholinergic origin occurs during early development. The flat baseline of IHR begins to fluctuate with the appearance of rapid, transient decelerations on ~days 12–13, with a subsequent augmented frequency of appearance (Figure 37.7) (Höchel et al., 1998; Tazawa et al., 1999; Chiba et al., 2004). Thereafter, IHR becomes arrhythmic with the appearance of transient accelerations on ~days 15–16 and more arrhythmic with augmented decelerations and accelerations toward hatching (Höchel et al., 1998; Tazawa et al., 1999, 2002a; Moriya et al., 2000; Khandoker et al., 2003; Aubert et al., 2004). These IHR decelerations are eliminated, and baseline HR is elevated, by intravenous administration of atropine. In late embryos whose IHR fluctuations comprise of complicated decelerations and accelerations with augmented magnitude and frequency, atropine diminishes decelerations only but preserves accelerations, while the HR baseline is markedly

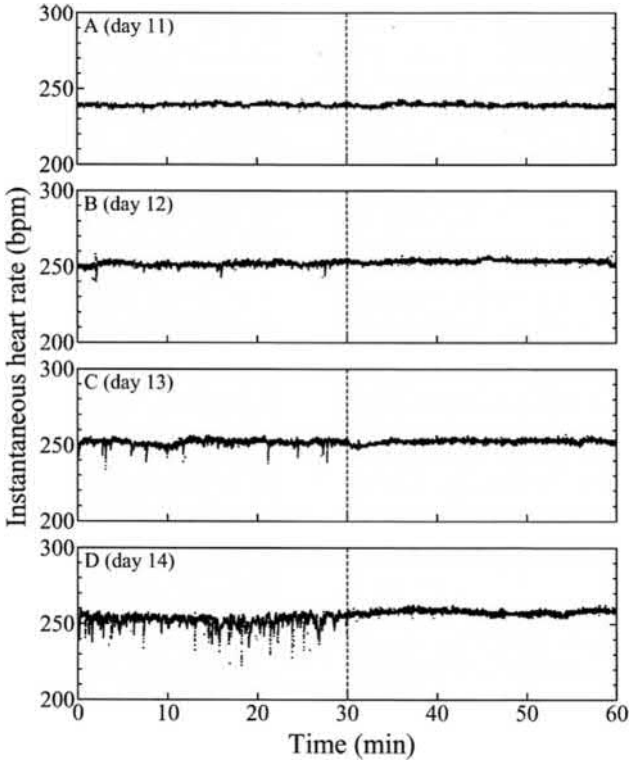

FIGURE 37.7 Instantaneous heart rate fluctuations before and after intravenous infusion of 20 μg atropine at 30 min in day 11 to day 14 chicken embryos. *From Chiba et al. (2004), with permission from Elsevier.*

elevated (Chiba et al., 2004), indicating that IHR decelerations are mediated by the vagus nerve. Accordingly, vagal tone begins to appear on ~days 12–13 of incubation in chickens, maturing with development, correcting previous reports on no vagal control of HR determined from blood pressure signals (Tazawa et al., 1992a). Furthermore, cholinergic chronotropic control of HR occurs on days 12–13 of incubation in both broiler and White Leghorn embryos (Yoneta et al., 2006c). These events coincide with the presence of a complete cholinergic effector pathway from 60% of chicken incubation (Pappano and Löffelholz, 1974).

Some controversy exists as to whether cholinergic tone is present at this developmental time point, i.e., blood pressure studies indicate no vagal tone on the heart during embryonic development of the chicken embryo (Crossley and Altimiras; 2000). Further, blood pressure studies using adrenoreceptor stimulation via pharmacological manipulation indicate that a positive β-adrenergic chronotropic tone can be induced from 60% of incubation (Crossley and Altimiras, 2000). The effect is enacted by circulating catecholamines, as ganglionic blockade with hexamethonium has no impact on HR. In contrast, pharmacological manipulation of blood pressure indicates that the emu heart is under both β-adrenergic and cholinergic control by 70%

of incubation (Crossley et al., 2003). Both cholinergic and adrenergic tone possess developmental plasticity, as evident in changes in HR and blood pressure under hypoxic incubation conditions (Mulder et al., 2002; Crossley et al., 2003; Lindgren and Altimiras, 2009).

Overall, the pattern of onset of regulatory mechanisms for blood pressure and heart rate is relatively complex, made more so by differences between species. Figure 37.8 represents an amalgam of known cardiovascular regulation in the chicken embryo.

Long-term measurement of IHR reveals the occurrence and development of various cardiac rhythms and irregularities. The developmental pattern of MHR (constructed from IHR measurement) of an embryo before and after hatching demonstrates the occurrence of infradian rhythm before and during IP, a gradual increase in HR baseline during IP, a sudden drop with a subsequent sudden increase in HR baseline during EP and the first occurrence of circadian rhythm of HR after hatching (Moriya et al., 2000). Recordings of IHR reveal respiratory arrhythmia is rare during IP (Tomi et al., 2019), but appears with EP. There are three unique patterns of IHR during the final stage of EP, i.e., relatively long-lasting cyclic small accelerations, irregular intermittent large accelerations, and short-term repeated large accelerations (Tazawa et al., 1999; Moriya et al., 2000). Short-term repeated large accelerations also occur in EP emu embryos, indicating imminent hatching (Kato et al., 2002).

After hatching, three types of IHR fluctuations (Type I, II, and III) are demonstrated in chickens (Moriya et al., 1999, 2000; Tazawa et al., 2002a). Type I is characterized as a widespread baseline HR (20−50 bpm) due to respiratory arrhythmia with a mean oscillatory frequency of ~0.7 Hz. Type II is evident by low-frequency oscillations of baseline HR at ~0.07 Hz, occurring at low T_a or when hatchlings are exposed to lowered T_a, and is thus related to thermoregulation. Type III is characterized as noncyclic irregularities, dominated by frequent transient accelerations. The image processing system developed to capture the movements of wing or whole body of the hatchling reveals that Type I and Type II HR oscillations are related to the periodic movements of the wing and Type III HR irregularities occur simultaneously with spontaneous whole body movements (Yoneta et al., 2006a). Consequently, it is likely that the chick moves the body at the same frequencies as Type I and Type II oscillations and simultaneously with Type III HR irregularities and these HR fluctuations and body movements are likely to be attributed to the same origins.

37.4.3.4 Cardiovascular regulation

The sympathetic nervous system is heavily involved in regulation of avian embryonic blood pressure (Altimiras et al., 2009; Crossley and Altimiras, 2012; Swart et al., 2014; Sirsat et al., 2018). Injection with the α-adrenoreceptor antagonist phentolamine causes hypotension from 60% of chicken incubation, indicating α-adrenergic tone on the vasculature (Girard, 1973; Saint Petery and Van Mierop, 1974; Tazawa et al., 1992a; Crossley and Altimiras 2000; Mueller et al., 2014a). Phentolamine also causes bradycardia, a likely indirect effect of vasodilation, and reduced venous return. β-adrenergic tone on the vasculature is also present from 60% of incubation, as evident by a P_a increase in response to the β-adrenereceptor antagonist propranolol (Girard, 1973; Saint Petery and Van

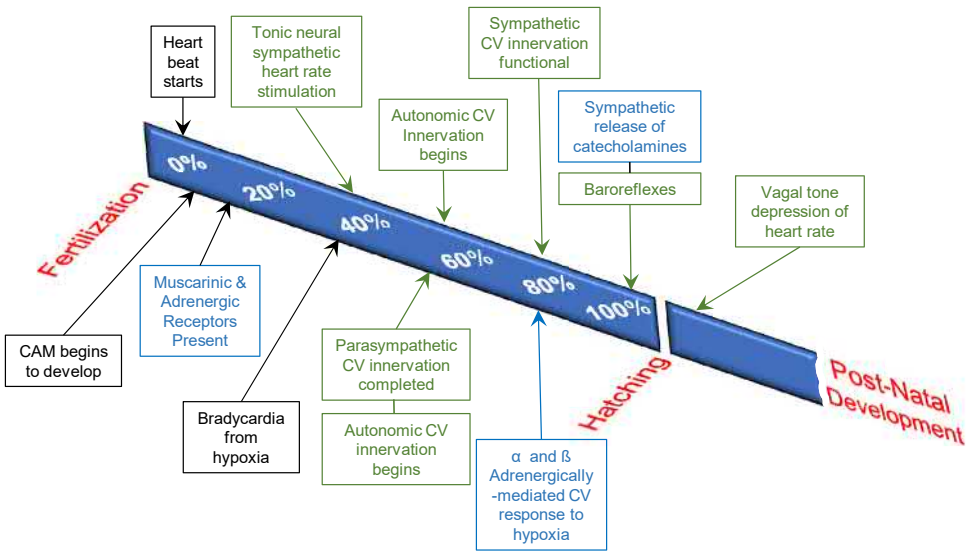

FIGURE 37.8 A proposed timeline for the onset of cardiovascular regulation in the chicken embryo. Developmental events in green relate primarily to neural components; events in blue relate primarily to hormonal components. *Modified from Burggren and Crossley (2002) with permission from Elsevier.*

Mierop, 1974; Tazawa et al., 1992a; Crossley and Altimiras 2000). The magnitude of both α- and β-adrenergic tone is maximal at 90% of incubation, just prior to IP (Crossley and Altimiras, 2000). The increase in adrenergic tone is matched to the maximal plasma catecholamine release on day 19. Catecholamine release is also elevated under hypoxic incubation of chicken embryos (Ruijtenbeek et al., 2000; Lindgren et al., 2011). Emu embryos also show signs of increasing α- and β-adrenergic tone on the vasculature matched to increasing levels of catecholamines as incubation proceeds (Crossley et al., 2003), although the onset of these responses differs from chicken embryos.

In addition to regulation via catecholamines, other hormones may also influence baseline cardiovascular function of avian embryos. The most extensively studied in chicken embryos is angiotensin II (ANG II), a strong vasoconstrictor and the active peptide of the renin-angiotensin system (RAS). Components of the RAS, including renin, angiotensin converting enzyme, ANG II, and its receptors, are present early in chicken ontogeny (Nishimura et al., 2003; Savary et al., 2005; Crossley et al., 2010). ANG II levels are elevated in embryos compared to adults, the peptide produces hypertension from at least 60% of incubation (Crossley et al., 2010), and contributes to baseline P_a at 90% of incubation (Mueller et al., 2014a). Despite an increase in P_a, ANG II does not alter MHR as it instead attenuates the embryonic cardiac baroreflex. The baroreflex is an important compensatory mechanism that buffers short-term changes in P_a and is composed of a peripheral limb adjusting vascular resistance and a cardiac limb that changes HR. A functioning baroreflex is present in chicken embryos from 80% of incubation (Altimiras and Crossley, 2000; Elfwing et al., 2011; Mueller et al., 2013a). ANG II decreases the sensitivity of the cardiac baroreflex at 90% of incubation so that reflex changes in HR in response to P_a changes are blunted (Mueller et al., 2013a). ANG II also raises the operating P_a of embryos, and it is via these short-term changes that the hormone partly enacts some of its influence on long term P_a.

Other potentially important moderators of cardiovascular function include nitric oxide (NO) and Endothelin-1 (ET-1), a potent vasodilator and vasoconstrictor, respectively, produced primarily in the endothelium, and natriuretic peptides (NPs), strong vasodilators excreted by heart muscle cells. NO tone is present from at least 70% of incubation and, unlike cholinergic and adrenergic tone, lacks plasticity as it remains unchanged under hypoxic conditions (Iversen et al., 2014). Components necessary for functional ET-1, including mRNA and converting enzymes, are found in chicken embryos from 15% of incubation (Hall et al., 2004; Groenendijk et al., 2008), and ET-1 alters chicken embryo hemodynamics (Groenendijk et al., 2008; Moonen and Villamor, 2011). Likewise, NP is present in the chicken heart and most likely contributes to hemodynamics from at least day 14 (Maksimov and Korostyshevskaya, 2013). Further research from the molecular to whole organism level is required to understand the contribution of these hormones to P_a and HR control, and therefore embryonic cardiovascular regulation.

37.4.4 Osmoregulation

During development, various avian embryos face one of two opposing osmoregulatory challenges: water loss through the pores of the eggshell in desiccating arid environments or excess water gain from the metabolic production of water as part of metabolizing the yolk stores (Ar and Rahn, 1980). Irrespective of the species-specific environmental challenge, the developing kidney and extra-embryonic structures, including the yolk, CAM and allantoic and amniotic fluids, work in concert to regulate ion and water balance. The embryonic kidney of chickens has three stages, actually comprising separate structures, the pronephros, mesonephros, and metanephros (Bolin and Burggren, 2013). The pronephros appears first and functions until day five–six of incubation (Abdel-Malek, 1950; Himura and Nakamura, 2003, Bolin and Burggren, 2013). Mesonephros function takes over from day five, is maximal on days 10–15 (Romanoff, 1960), and then degrades between days 18–19 (Atwell and Hanan, 1926). The mesonephros functions simultaneously with the metanephros, which begins developing from day four (Abdel-Malek, 1950; Klusonová and Zemanová, 2007) and continues to develop posthatching. The metanephros is the most complex of the three embryonic kidney structures, and comprises the functioning structure in adults. Figure 37.9 illustrates the developmental increase in glomerular volume of the kidney of the chicken embryo during the last third of development. The total number of nephrons grows during the middle of incubation, thereafter remaining stable until hatching. Interestingly, however, only about one-half of these nephrons are actually perfused with blood under control conditions (Bolin and Burggren, 2013). Potentially, then additional nephrons can be recruited, representing so-called "nephron-blushing," even at embryonic stages. The regulation of nephron recruitment in the avian embryo is currently unknown.

The allantoic sac first appears at ~days three–four of incubation, and acts as a repository for kidney secretions, as evident by the increase in uric acid content throughout development (Romanoff, 1967). The allantoic epithelium actively transports sodium across its membrane from days 12–19 (Stewart and Terepka, 1969; Graves et al., 1986; Gabrielli and Accili, 2010). These and other osmoregulatory mechanisms thus maintain the fluid hypo-osmotic to the blood and permitting reabsorption of water by the embryo (Hoyt, 1979; Bolin et al., 2017).

Osmoregulation is strongly tied to cardiovascular function through the synergistic maintenance of blood

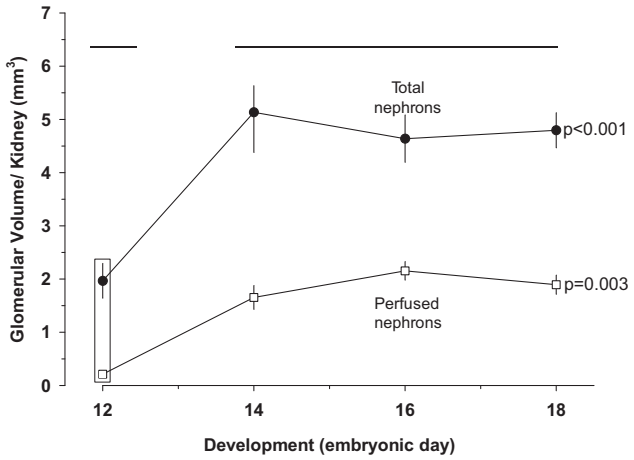

FIGURE 37.9 Total glomerular volume (*solid symbols*) and actual perfused glomerular volume (*open squares*) during days 12 through 18 of incubation in the chicken embryo. The potential exists for doubling renal function by recruiting nonperfused nephrons, though whether such control over renal function in the embryo exists is unknown. Data presented as mean values ± 1 SE and *P* values determined by one-way ANOVA for each volume across development. Mean values not significantly different from each other fall under the same *horizontal line*. Mean values within a common outlined box are not significantly different from each other. *From Bolin and Burggren (2013) with permission from Elsevier.*

pressure and osmotic homeostasis. Regulators of blood pressure, such as ANG II and NP (see above), may also contribute to ion and water balance in embryos. Chronic removal of ANG II from chicken eggs not only decreases P_a but also lowers osmolality, decreases Na^+, and increases K^+ concentration of the blood at 90% of incubation. These actions remove the osmolality gradient between the blood and allantoic fluid (Mueller et al., 2014a). Therefore, ANG II appears to influence osmotic balance and may do so by direct vasoconstrictive action or by stimulating the release of aldosterone and arginine vasotocin, which promote proximal tubular sodium reabsorption. Aldosterone is present in chicken embryo adrenal glands from day 15 (Pedernera and Lantos, 1973), and arginine vasotocin is present in the brain from day six and the plasma from day 14−16 (Klempt et al., 1992; Mühlbauer et al., 1993). Both aldosterone and arginine vasotocin alter allantoic fluid volume, allantoic salt content, and renal enzyme activity in chicken embryos (Doneen and Smith, 1982a). Prolactin and growth hormone also have osmoregulatory effects in chicken embryos (Doneen and Smith, 1982a,b; Murphy et al., 1986). The function of these hormones in osmoregulation requires further study, including how they may contribute to interactions between the developing cardiovascular and osmoregulatory systems and the maintenance of homeostasis.

37.4.5 Thermoregulation

Embryos produce metabolic heat, which increases as development progresses. Metabolic heat production of the chicken embryo increases from about 35 mW on day 12 to 130−140 mW on days 17−18 of incubation and reaches 160−170 mW at EP (Tazawa et al., 1988b). Over the same developmental range, the egg's thermal conductance is ~70 mW/°C (Tazawa et al., 2001a). This means that metabolic heat production at 38°C elevates egg temperature (T_{egg}) above ambient temperature (T_a) by ~0.5°C on day 12 and ~2.5°C in EP eggs. When eggs are cooled to 28°C, a new quasi-equilibrium state is reached in 5 h (defined as a change in T_{egg} of less than 0.2°C/h) (Tazawa and Rahn, 1987). The new difference between T_{egg} and T_a is lower so that even in EP embryos T_{egg} is only 1.2°C above T_a. In addition, during the quasi-equilibrium state at lowered T_a, embryos consume the amount of O_2 predicted by a temperature coefficient (Q_{10}) of 2 (Ide et al., 2017b). On the other hand, hatchlings, which are subjected to the same test, have body temperatures ~6°C above T_a, even right after hatching, and consume much more O_2 than that predicted by Q_{10} of 2 (Tazawa and Rahn, 1987). These observations suggest that chickens are essentially poikilothermic during embryonic stages, even at EP, and rapidly develop the capacity to maintain body temperature upon cold exposure soon after hatching.

When eggs incubated at 38°C are exposed to a T_a only 2°C lower, the heat loss from the egg is greater than the heat produced by young embryos and comparable with the heat production in late embryos. If the eggs are exposed to air 10°C cooler than the egg, the embryos would have to generate heat about 800 mW to keep T_{egg} steady (Turner, 1986). Yet, even EP embryos can generate at most 170 mW. Consequently, heat loss during cooling exceeds the embryo's maximum rate of heat production. A feeble compensatory capacity, if any, may be overwhelmed by the much larger losses of heat. The egg cools and its metabolic rate decreases as a result of the van't Hoff-Arrhenium effect. The detection of homeothermic capacity thus requires a procedure in which the heat loss from the egg does not overwhelm the heat production of the embryo. The gradual cooling test fulfills this requirement, and it shows that prenatal chicken embryos near term respond to lowered T_a by maintaining $\dot{M}O_2$ until T_a falls below 35°C (Tazawa et al., 1988b). This response in late embryos is evidently different from that in young embryos. In the prolonged cooling test, late chicken embryos are exposed to a slightly lowered T_a for a prolonged period, the $\dot{M}O_2$ is maintained at a level above that predicted by a Q_{10} of 2. This response also differs from that shown by young embryos (Tazawa et al., 1989a). Consequently, precocial chickens exhibit a feeble, incipient metabolic response to cooling, indicating endothermic homeothermy before hatching. This coincides with enhanced activity of the thyroid gland and increasing concentrations of peripheral thyroid hormones during the last stages of incubation (Decuypere et al., 1979; McNabb, 1987). In fact, while late prenatal embryos in eggs injected with saline show a feeble homeothermic metabolic response to gradual cooling, this response is absent in eggs treated with thiourea, which antagonizes the metabolic

effect of thyroid hormones (Tazawa et al., 1989c). Additionally, while the compensatory metabolic response disappears in embryos exposed to hypoxia, it is augmented in perinatal embryos in hyperoxia or following improved oxygenation by opening the shell over the air cell (Tazawa et al., 1989c; Dzialowski et al., 2007; Szdzuy et al., 2008; Ide et al., 2017b). These results indicate that the homeothermic metabolic response in precocial chickens in late development is "O_2 conductance limited" (Tazawa et al., 1988b).

The development of homeothermy in precocial and altricial birds has been modeled (Figure 37.10) and reviewed in detail (Tazawa et al., 1988b; Whittow and Tazawa, 1991; Tzschentke and Rumpf, 2011; Sirsat et al., 2016; Price and Dzialowski, 2018). The transition for a precocial bird takes place in four stages; (1) an Arrhenius-limited stage in which $\dot{M}O_2$ is directly related to the temperature with a Q_{10} value of approximately 2; (2) an O_2-conductance-limited stage in which $\dot{M}O_2$ is limited by the rate of diffusion of O_2 through the shell and CAM; (3) a power-limited stage in which the embryo has a limited capacity to generate heat in response to cooling, which is a function of the maturity of the tissues and development of thyroid activity; and (4) "full-blown" homeothermy. An altricial species does not pass through the O_2-conductance-limited stage and is subject to the Arrhenius limitation until after it hatches.

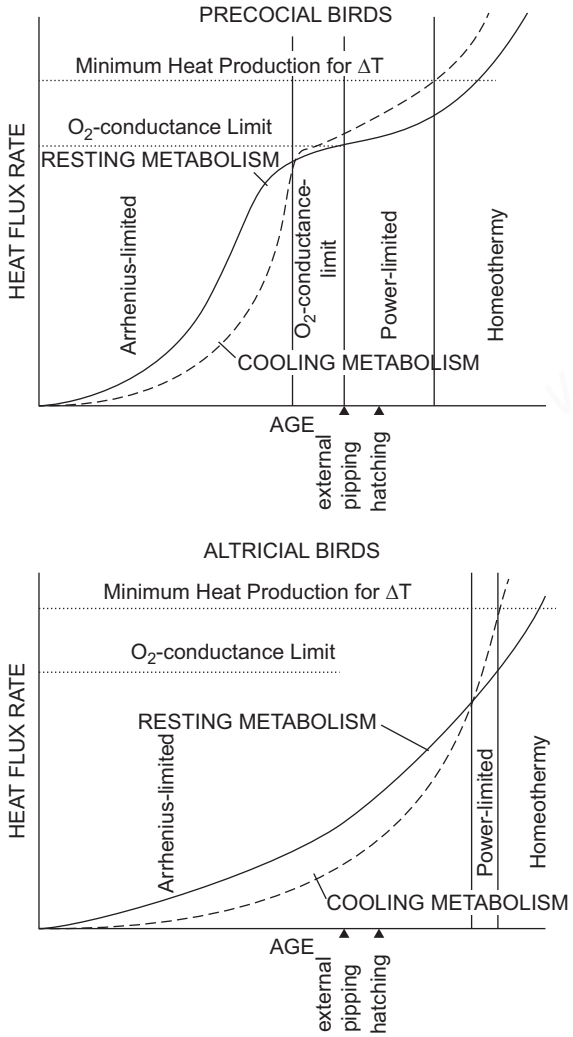

FIGURE 37.10 Models of the development of homeothermy in precocial and altricial birds. "Minimum Heat Production for ΔT" equals the amount of heat needed to keep the egg temperature warmer than ambient temperature by ΔT and homeothermy occurs when the embryo heat production reaches this level. *From Tazawa et al. (1988b), with permission from Elsevier.*

The comparative metabolic responses to prolonged cooling have been examined in the precocial duck (*Anas platyrhynchos domestica*), semi-precocial brown noddy and altricial pigeon (*Columba livia domestica*) (Matsunaga et al., 1989; Kuroda et al., 1990; Tazawa et al., 2001a; Sirsat and Dzialowski, 2016). Incipient homeothermic ability appears in the duck during prenatal development, but it is not evident in the pigeon even after emergence from the shell. The precocial chicken and semiprecocial noddy are intermediate in their metabolic response between the duck and the pigeon. Ventilatory changes, including a shift from high-breathing frequency and low-tidal volume in EP embryos to low-breathing frequency, higher tidal volume, and a ventilatory thermal sensitivity in hatchlings, that supports the endothermic metabolic phenotype (Sirsat and Dzialowski, 2016).

The development and maturation of homeothermy is expected to occur and progress even during the prenatal period in the highly precocial emu. In addition to the precocial nature of the emu, its large egg with a smaller surface area-to-volume ratio and greater contribution of blood circulation compared to smaller eggs most likely enhances thermoregulatory capacity. For emus, a more apparent metabolic response test is used in which embryos and hatchlings are exposed for a prolonged period (e.g., 1.5 h) to T_a altered sequentially by 10°C, e.g., 35-25-35°C for embryos or 25-35-25°C for hatchlings (sequential cooling-warming test, with ΔT_a of ±10°C) (Dzialowski et al., 2007). Hatchlings and EP embryos respond to ΔT_a with an endothermic change in $\dot{M}O_2$, showing an inverse metabolic response with marked increase and decrease in $\dot{M}O_2$ in response to sequential cooling and warming bouts. Late prenatal (day 45) and IP (day 49) embryos do not change $\dot{M}O_2$ in response to ΔT_a in air, but demonstrate partial (day 45) or apparent (IP) endothermic change in $\dot{M}O_2$ when the test is run in 40% O_2. This suggests that the late prenatal emu embryo already possesses homeothermic ability, but it is limited by the eggshell gas GO_2.

Changes in IHR, with apparent increases or decreases in HR baseline with oscillating pattern, in response to ΔT_a, is also effective in investigating endothermic capacity in precocial embryos and hatchlings (Tazawa et al., 2001a,

2004; Tamura et al., 2003; Khandoker et al., 2004). In the sequential cooling-warming test with ΔT_a of $\pm 10°C$, the sequence of exposure (cooling-warming and vice versa) does not affect the endothermic HR response (Yoneta et al., 2006b). In chick hatchlings, the endothermic HR response is demonstrated to be advanced by ~1 day in broiler compared with White Leghorn during 2 days of posthatch life (Yoneta et al., 2007).

In the chicken embryo, the baseline of IHR shows a thermo-conformity pattern in response to a decrease in T_a during EP (day 20), but it changes little on day 21. IHR rises accompanying HR oscillation on day 22, when the embryo stays inside the egg (Tazawa et al., 2001a; Andrewartha et al., 2011b). Although the embryo fails to hatch after EP, it matures equivalently to a hatchling on day 21 and day 22. In newly hatched chicks, HR oscillations with a period of 10–25 s occur frequently in air, reported as Type II HR fluctuation (Moriya et al., 1999, 2000). In addition, IHR oscillates with lowering T_a, resulting in Type II low frequency HR oscillation which disappears when hatchlings are transferred to high T_a (Tazawa et al., 2002b; Khandoker et al., 2004). Consequently, chicken hatchlings possess low frequency HR oscillation (Type II HR fluctuation) in relation to their thermoregulation (Tazawa, 2005 for review).

In pre-IP stage duck embryos (Figure 37.11A; day 24), the HR response during pre-IP stage indicates thermo-conformity (Andrewartha et al., 2011b). However, the recovery of HR (and T_{egg}) at T_a of 38°C is faster than chicken embryos (Tazawa et al., 2001a). By EP (C, D; day 27), duck embryos demonstrate an endothermic HR response (increase during cold exposure), larger than chicken EP embryos. Immediately after hatching, the wet duckling cannot maintain the increased HR, succumbs to the cold and HR decreases (E). However, HR of ducklings blotted dry within 2 h is maintained at similar values at T_a of 35°C (F), demonstrating incomplete endothermic capacity. By 2 and 13 h posthatching (G, H), the plumage of the ducklings has naturally dried and their HR shows an apparent endothermic response with a small decrease in body temperature, T_b ($\Delta T_b = -1.9$ and $-2.0°C$, respectively), close to full-blown homeothermy. Ducklings must attain thermoregulatory competence early (relative to the domestic chicken) during perinatal development to live in an aquatic environment soon after hatching.

In the more highly precocial emu, pre-IP and IP embryos exhibit thermoconformity and incomplete endothermic response of HR, respectively, but the apparent endothermic HR response occurs in EP embryos just like the endothermic metabolic response (Fukuoka et al., 2006; Dzialowski et al., 2007; Andrewartha et al., 2011b).

Finally, thermoregulation in chicken hatchlings has been investigated in the context of their immune responses (Amaral-Silva et al., 2020). Chicks injected with the endotoxin lipopolysaccharide showed an immune response that included transient changes in body temperature and $\dot{M}_{O_2}$, and effect that was interfered with by the common environmental pollutant TCDD (2,3,7,8-tetrachlorodibenzodioxin).

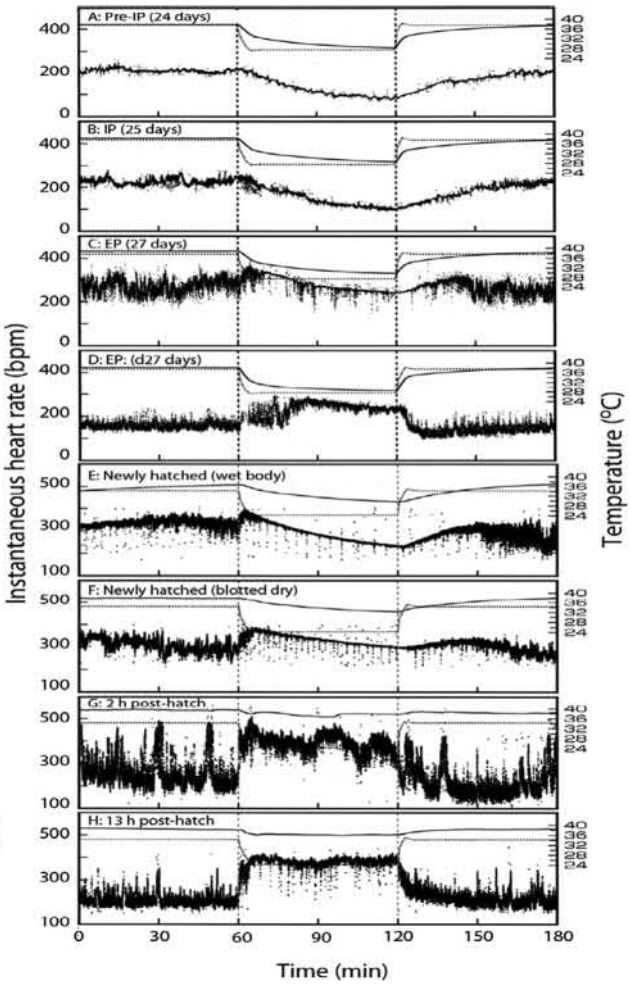

FIGURE 37.11 Responses of instantaneous heart rate (IHR) in duck embryos and hatchlings exposed sequentially to high ambient temperature ($T_a = 38°C$ for embryos and 35°C for hatchlings; *dotted line*), low-ambient temperature ($T_a = 28°C$ for embryos and 25°C for ducklings) and high temperature again for 60 min, respectively. The *solid line* represents egg temperature or body temperature. *From Andrewartha et al. (2011a), with permission from Elsevier.*

Assessments of $\dot{M}_{O_2}$ and HR responses to various tests that alter incubation temperature have been successfully utilized to assess thermoregulatory ability of avian embryos. The timing of endothermic responses differs along the precocial to altricial continuum, with precocial species generally showing thermoregulatory ability earlier than altricial species. Examination of mitochondrial, cellular, and tissue-level mechanisms is now required to further our understanding of how thermoregulatory ability develops in embryos and hatchlings.

37.5 Artificial incubation

37.5.1 Preincubation egg storage

Many precocial birds laying multiple eggs in a clutch start their incubation with the penultimate or ultimate eggs. Consequently, first laid eggs are stored in the nest until incubation starts, sometimes for many days. Egg storage is not just a phenomenon of nature, of course. Egg storage commonly occurs in commercial conditions of artificial incubation, leading to numerous studies on the effect of storage conditions on the biology of the embryos and hatchlings. If the storage temperature for freshly laid chicken eggs is kept below physiological zero (25−27°C), dormancy of the embryo is maintained and fertile eggs can be stored for several days without a major loss of hatchability (Butler, 1991; Wilson, 1991; Goliomytis et al., 2015; Branum et al., 2016). The optimal temperature for 3−7 days storage of chicken eggs is 16−17°C and it drops to 10−12°C for eggs stored for more than 7 days (Butler, 1991; Wilson, 1991). However, prolonged preincubation egg storage results in malformations and retarded growth of the embryos, decreased hatchability, increased incubation period, and it even influences hatchling growth (Arora and Kosin, 1966; Mather and Laughlin, 1979; Branum et al., 2016). Interestingly, short periods of incubation during egg storage ("SPIDES") can increase the hatchability of chicken eggs stored for more than 8 days (Dymond et al., 2013; Damaziak, 2018). The hatchability of the northern bobwhite quail (*Colinus virginianus*) remains above 70% after 14 d of preincubation storage at 20−22°C, but decreases to below 30% after 21 d of storage (Reyna, 2010). These deleterious effects are related to not only the length of storage but also the environmental and physical conditions, such as temperature, relative humidity (RH), atmospheric gas composition, orientation, and positional changes during storage (Brake et al., 1997).

Prolonged preincubation egg storage also affects the physiological function of developing chicken embryos (Haque et al., 1996; Fasenko, 2007; Goliomytis et al., 2015; Branum et al., 2016; Yalcin et al., 2017). Albumen quality, an indicator of overall egg quality, decreases with storage (Scott and Silversides, 2000; Reyna, 2010). Furthermore, while the developmental patterns of $\dot{M}_{O_2}$ are consistent among unstored (control) eggs, those stored for 20 and 30 days at 10−11°C are varied and depressed among eggs; the depression of the $\dot{M}_{O_2}$ increases in severity as the storage duration increases. The developmental trajectory of HR in stored eggs is also flattened compared with those of control eggs. As a result, the O_2 pulse (O_2 uptake every heartbeat) is markedly lowered by preincubation storage, decreasing blood O_2 transport, and retarding embryo growth in stored eggs, resulting in death during the last days of incubation (Haque et al., 1996).

37.5.2 Egg turning

In many avian species, incubating adults actively move their eggs in the nest (egg-turning). The critical period for lack of egg-turning in artificial incubation of the chicken egg ranges from day 3 to day 7 of artificial incubation (New, 1957; Deeming, 1989a). Chicken eggs should be turned minimally three times a day. Turning more than 24 times a day has long been assumed to not further enhance hatchability, although turning 96 times/day increased hatchability (Elibol and Brake, 2006). Lack of egg-turning is detrimental not only to hatchability but also can slow incubation, the development of the CAM, and embryo growth (New, 1957; Tazawa, 1980b; Deeming et al., 1987; Tullet and Deeming, 1987; Deeming, 1989a, b).

Failure to turn eggs during incubation also produces adverse effects on gas exchange through the CAM (Tazawa, 1980b). The movement of albumen into the amnion is retarded, and the unabsorbed albumen, which becomes more viscid and heavy as it loses water early in incubation, sinks toward the lower end of the egg where it remains. The chorioallantois fails to fold around the unabsorbed albumen and the interposition of the albumen between the CAM and inner shell membrane reduces gas exchange. These effects cause a pronounced fall in the arterialized blood P_{O_2} of late embryos, which is accompanied by an increase in *Hct*. The inhibition of gas exchange is reflected in the decreased $\dot{M}_{O_2}$ of unturned eggs compared to turned eggs (Pearson et al., 1996).

On an interesting comparative note, the eggs of many reptile species are killed or have greatly reduced hatchability, if they are turned during any point in incubation (Ferguson, 1985; Ruben et al., 2003), although there are species differences (Aubret et al., 2015).

37.5.3 Ambient temperature and incubation

For chickens, freshly laid eggs can be stored at a low temperature to maintain dormancy of embryos. However, once incubation starts, T_a must be kept within a certain range so that the chicken embryo temperature is maintained and cell proliferation can proceed. This differs from some other bird species. Emu eggs that are midway through their ~56 day incubation period, for example, can be cooled down to room temperature for several hours before incubation is resumed with no adverse effects (W. Burggren, pers. obs.). In artificial incubation of chicken eggs at constant T_a, hatchability decreases when T_a is lowered to 35°C or elevated to 40°C from the optimal temperature of 37.5°C. At 35°C, incubation period and embryonic development of chickens are ~3 days longer than at 38°C (Tazawa, 1973; Black and Burggren, 2004a). Survival of chicken embryos during total incubation period is reduced at 35°C (Black and Burggren, 2004a) and temperatures

below this threshold are lethal. Hypothermal incubation decreases $\dot{M}O_2$ in proportion to retarded development of embryos and preserves the relative timing of IP and EP (Tazawa, 1973; Black and Burggren, 2004a). However, at the final stages of hypothermal incubation, hematological development and blood O_2-carrying capacity are retarded (Black and Burggren, 2004b), and eventually hypothermal incubation causes a significant delay of the relative timing of the onset of thermoregulatory ability (Tzschentke et al., 2001; Nichelmann, 2004; Black and Burggren, 2004b; Mortola, 2006).

The tolerance limits of developing embryos to acutely lowered and elevated T_a have been investigated in chickens in reference to their HR (Tazawa and Rahn, 1986; Ono et al., 1994). When day 10 embryos are exposed to a T_a of 28 or 18°C, HR decreases in an exponential fashion to reach plateau values during 2–3 h of exposure. The plateau values are ~100 bpm at 28°C and ~30 bpm at 18°C, which are maintained until irreversible cardiac arrest occurs at ~100 and ~60 h after exposure to 28 and 18°C, respectively. Accordingly, day 10 embryos survive exposure to 28°C for no less than 4 days and to 18°C for about 2.5 days. Reduction of T_a to 8°C forces the heartbeat of day 10 embryos to cease after ~3 h. However, the cardiac arrest at this low T_a (8°C) does not mean the death of embryos. Ten-day embryos survive the low T_a, without a heartbeat, for 18 h more and the heart begins to beat again after rewarming at 38°C. The survival time at 8°C is reduced as the embryos grow. While the heart of day six embryos begins to beat even after 1 day exposure to 8°C, the heart of day 20 embryos fails to beat after an 8 h exposure (Tazawa and Rahn, 1986).

While chicken embryos can withstand a lowered T_a for a prolonged period without a heartbeat, at an increased T_a, the cardiac arrest following arrhythmia is irreversible and the embryos cannot withstand exposure to an increased T_a for a prolonged period (Ono et al., 1994). The HR of embryos increases in an exponential fashion at increased T_a. When T_{egg} reaches 46–47°C, regardless of the developmental stage of embryos, the HR becomes arrhythmic and irreversible cardiac arrest follows. The lethal T_a and tolerance time of chicken embryos depend upon the time T_{egg} takes to reach a lethal critical value of 46–47°C. At a T_a of 48°C, the tolerance time of day 12 embryos is ~100 min and that of day 20 embryos shortens by about half. The tolerance time to 48°C exposure is shortened as the embryos grow. This may be in part due to the higher metabolic heat which is produced by late embryos compared to earlier embryos. The HR reaches ~450 bpm at the critical T_{egg} (46–47°C) (Ono et al., 1994).

The embryos of ground nesting birds in semiarid and arid areas, in particular, experience environmental temperatures many degrees higher than typical avian incubation temperatures. For example, the northern bobwhite quail can experience nest temperatures as high as 45°C in the wild. Not surprisingly, this species shows remarkable tolerance to brief preincubation hyperthermia. Bobwhite quail embryos can survive 6 h exposure to 46°C, 3 h exposure to 49°C and, remarkably, 1 h exposure to 50°C (Reyna and Burggren, 2012, 2017). While these temperatures certainly increase mortality and decrease hatching rates, the high-temperature tolerance of the bobwhite quail highlights the importance of a comparative approach to examining temperature tolerance. Extreme temperatures in the natural environment may result in increased tolerance in avian species and warrants further investigation.

37.5.4 Humidity

Successful artificial incubation of chicken eggs occurs over an RH range of 40–70% (Robertson, 1961). Within the successful incubation range, 53% RH is optimal for embryo survival and hatchability (Bruzual et al., 2000). Either high (>85%) or low (<30%) humidity increases mortality in chicken embryos (Figure 37.12; Ar and Rahn, 1980; Bolin et al., 2017). Under low humidity, inadequate water content can result from increased water loss across the porous eggshell due to a high vapor pressure gradient between the inside of the egg and surrounding air. Under high humidity, water loss is reduced and this can exert osmotic stress on the embryo. Allantoic fluid volume, which is a balance between renal filtrate production and water reabsorption into the embryo, is reduced under high water loss conditions, and conversely increased when water loss is low (Davis et al., 1988). Under high water loss, water is reabsorbed from the allantois, uric acid levels in the allantois increase, and sodium is actively transported to maintain the allantoic fluid hypotonic to the blood and aid water reabsorption (Hoyt, 1979; Davis et al., 1988; Bolin et al., 2017). Plasma calcium, sodium, and potassium levels are elevated in late stage embryos, a sign of osmotic stress (Davis et al., 1988). After exposure to <30% RH, the kidneys of day 18 chicken embryos have additional glomeruli, more functioning glomeruli and high cloacal fluid osmolality, illustrating an increased filtering capacity (Bolin et al., 2017).

Extremes in humidity or water loss reduce hatching success (Davis et al., 1988; Bolin et al., 2017). Water balance appears to have the greatest effects on hatchability early in incubation, with hatchability related to water loss during the first half of incubation, rather than total water loss (Snyder and Birchard, 1982). Humidity extremes also affect late stage embryo wet mass, i.e., embryos from low humidity or high-water loss environments have smaller wet masses while those from high-humidity environments have higher wet masses (Bruzual et al., 2000; Bolin et al., 2017). In low-water loss environments, excess water is not always incorporated into wet mass, but is instead left behind in the albumen (Davis et al., 1988). Growth and oxygen

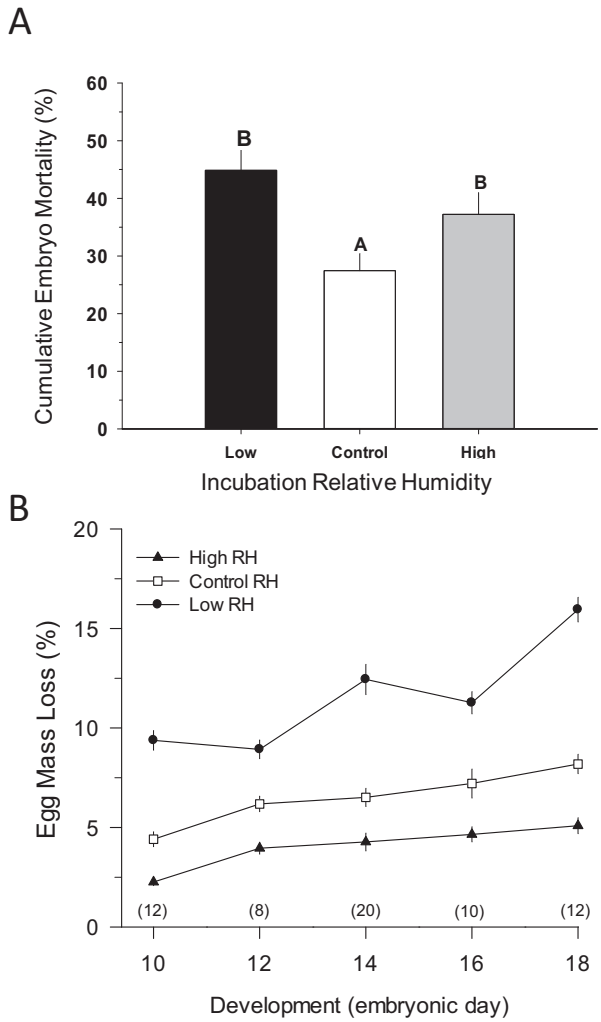

FIGURE 37.12 Effects of incubation relative humidity (RH) through the incubation period on (A) cumulative mortality and (B) body mass of chicken embryos. Low, control and high RH is 25–30%, 55–60% and 85–90%, respectively. Means ± SE shown. Letters indicated statistical comparisons of groups. N values in parentheses. *From Bolin et al. (2017) with permission from Elsevier.*

consumption can be retarded after exposure to extreme humidity (Bolin et al., 2017), but embryos that do hatch under extreme humidity reach normal weight within 7–10 days posthatch (Davis et al., 1988).

37.6 Conclusions and future directions

Incubation is the first important process experienced by the embryonic life stages of any avian species. The characteristics of the egg itself and the surrounding environment determine the success and timing of embryonic development. As we have discussed in this chapter, the study of avian embryonic physiology has provided extensive information on the complex processes that occur during avian development. A key aspect of avian development is the physical processes of incubation, including the transfer of water and heat between the egg and environment. Successful incubation outside of extremes in temperature, humidity, and other stressors enables the development of the form and function of the major physiological systems, including the gas exchange, acid-base, cardiovascular, osmoregulatory, and thermoregulatory systems.

Despite literally thousands of studies that have investigated some aspect of the physiology of the avian embryo, numerous possibilities still exist to expand our knowledge of avian development by utilizing new physiological techniques and undertaking studies using an across-discipline approach. Molecular and cellular studies will be important in revealing the mechanistic underpinnings of system and organism level observations. Furthermore, many fruitful areas of research at all levels, from genes to the whole organism, remain. These include the timing and control of important physiological events during development, how and when systems are perturbed during development and if recovery is possible, and how systems work together during development. Finally, comparative approaches are also needed to place physiological processes in an ecological and evolutionary context. The vast majority of avian developmental data have been collected in the chicken which, as a precocial bird, is not representative of all avian species. We need to find out how representative the data are from chicken embryos, especially given the venerable nature of the chicken embryo as a model for development in both basic and translational experiments (Burggren et al., 2018).

Additional research in these areas will allow us to further understand avian embryos for the complex, multisystem organisms that they are, while also contributing to the broader field of vertebrate development.

38.1 Introduction

Birds undergo profound changes in physiology, morphology, and behavior across their lifecycles, and the endocrine system plays a fundamental role integrating external and internal signals and orchestrating adequate responses ultimately selected to maximize individual fitness. Many of these changes occur in response to predictable fluctuations in the environment, like night-day and seasons, which allow year-round anticipatory organization of major life history stages (LHSs) in cyclic patterns. However, superimposed on predictable components are unpredictable perturbations (like severe weather, loss of social rank, habitat destruction, or human disturbance) which require rapid emergency adjustments in physiology and behavior generally termed the "*stress response.*" As in other vertebrates, the avian stress response involves two major pathways (Romero and Gormally 2019): (i) the catecholamine release from the adrenal medulla, responsible for a rapid, almost instantaneous "fight-or-flight" response mediated by the autonomic nervous system, and (ii) a slower release of *glucocorticoids* (GCs) (mostly *corticosterone*, the main GC in birds) following activation of the hypothalamic−pituitary−adrenal (HPA) axis which supports longer-term responses (Figure 38.1; Chapter 33). In this chapter, we will review the latter branch, summarizing research on the adrenocortical response to stress largely performed using wild birds as study models, with the aim of linking physiological responses to ecology and life-history traits (ecophysiology).

In response to disturbance, elevated blood GC levels promote adaptive physiological and behavioral changes that redirect the individual into a survival mode while suppressing nonessential activities. GCs support mobilization of body energy, increase cardiovascular tone, regulate the immune system, and inhibit a variety of costly anabolic processes including digestion, energy storage, growth, and reproduction (Sapolsky et al., 2000; Sapolsky, 2002). However, high and prolonged elevations of GCs, like those occurring during chronic adverse conditions, exert deleterious effects on critical body systems, causing disease and eventually death (Sapolsky et al., 2000). Furthermore, low levels of blood corticosterone are fundamental for basic physiological processes regardless of exposure to stress (Landys et al., 2006). The fact that the same hormone exerts opposing ("good and bad") actions depending on its level and duration, combined with the ambiguity of the term "*stress*" (Box 38.1), has prompted the development of recent conceptual frameworks, such as the *Allostasis Model* and the *Reactive Scope Model*, aimed at promoting integrative research linking the energy requirements of birds across their lifecycles with their adrenocortical responses within a context of avian ecology and life-history. These models will be explained in Section 38.2 with an updated review of the nomenclature describing corticosterone levels and actions in birds. Why, when, and how environmental conditions promote an activation of the HPA axis will be addressed in Section 38.3, with a classification of the types of perturbations and the resulting effects of corticosterone elevations on the normal progression of individuals' lifecycles. Short-term elevations of corticosterone levels activate a facultative "emergency life history stage" (ELHS),

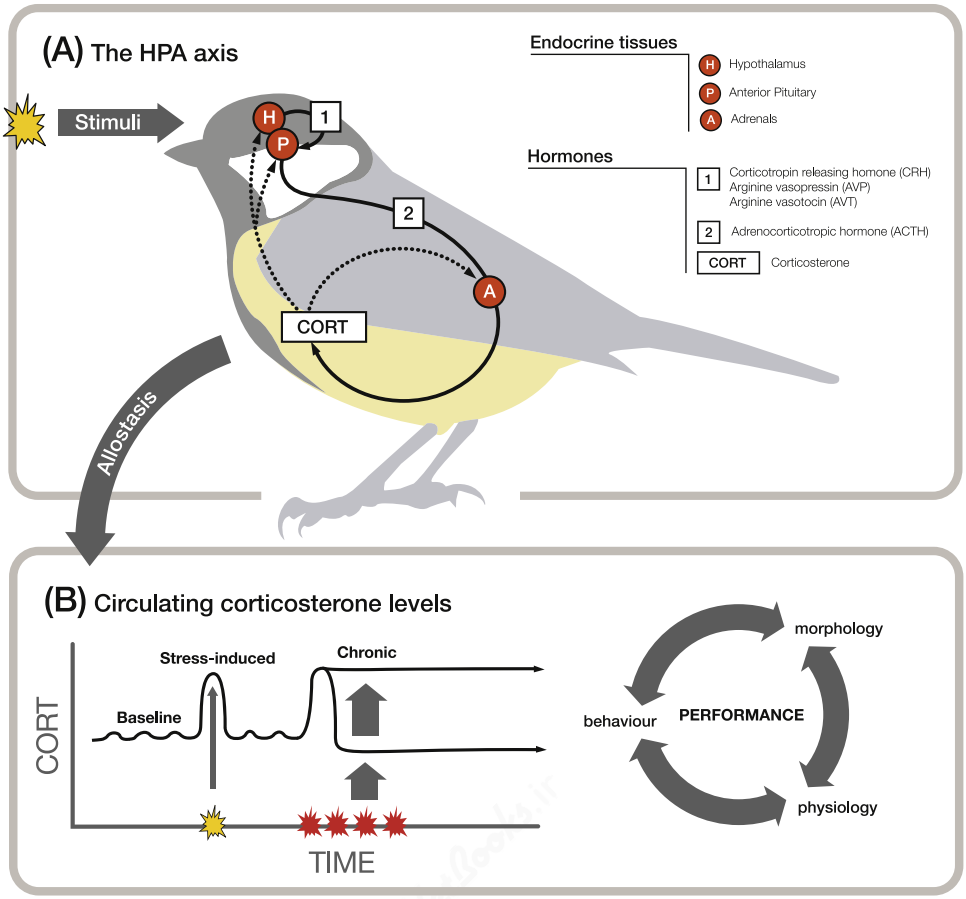

FIGURE 38.1 **The adrenocortical response to stress in birds.** (Panel 1): The hypothalamic–pituitary–adrenal (*HPA*) axis and endocrine pathway connecting the tissues (*black and white circles*) and hormones (*black and white squares*) involved in the adrenocortical response to stress. Following exposure to potentially noxious stimuli (e.g., a predator chase) the hypothalamus releases a number of hormones. These, in turn, stimulate the pituitary to secrete adrenocorticotropic hormone (*ACTH*) into circulation, which triggers the release of corticosterone (*CORT*) from the adrenal glands. Corticosterone secretion is subjected to negative feedback, as indicated with *dashed arrows*. (Panel 2): Time-related changes in circulating corticosterone levels during a stress response. Under normal (unstressed, predictable) conditions, corticosterone titers fluctuate within a narrow range of typically low levels known as "baseline" that allows a predictable adjustment of activity rhythms and metabolic functions in anticipation of change. Short-term exposure to perturbations (*black and white* star in x-axis) produces a rapid elevation of corticosterone into "stress-induced" levels, within a few minutes, which facilitate reactive changes in physiology and behavior (e.g., increased gluconeogenesis, suppression of reproductive behaviors, regulation of immune function) aimed at maximizing immediate survival. Once the perturbation has passed, corticosterone levels return to baseline range. However, prolonged or repeated exposure to perturbations (*black and white stars* in x-axis) can generate dysregulation of the HPA axis, leading to either hyper- or hyposecretion of corticosterone. In the long term, "chronic" dysregulation can jeopardize organismal performance. Ultimately, each level of corticosterone may facilitate specific changes in physiology, morphology, and behavior aimed at maintaining homeostasis through change (i.e., allostasis), and potentially affecting individual performance. *Credit: Figure modified and expanded from Blas and Baos (2008), Baos and Blas (2009), Blas et al. (2019).*

but longer-term exposure disrupts lifecycles, potentially leading to individuals' deaths and, by extension, population declines. The avian adrenocortical response shows all the features of a trait subjected to natural selection (high-individual variation, repeatability, and a genetic basis), but individuals also display a strong phenotypic plasticity. Section 38.4 reviews research on the adaptive variability of adrenocortical responses. Avian developmental modes range across a spectrum of altricial and precocial species, and the maturation of the adrenocortical response during early life varies with this gradient. This pattern has likely evolved to balance the costs and benefits of corticosterone actions with the ability of young birds to cope with perturbations without parental support. Corticosterone can be also transferred from mothers to offspring ("maternal effects"), potentially translating ecological and environmental conditions into permanent offspring responses and resulting in phenotypes that could be better adapted to cope with perturbations through "maternal programming." Adult birds of many avian species have been shown to modulate their adrenocortical response during reproduction and according to the value of their brood. Such findings suggest that modulation of corticosterone secretion allows them to trade-off energy and resources between current

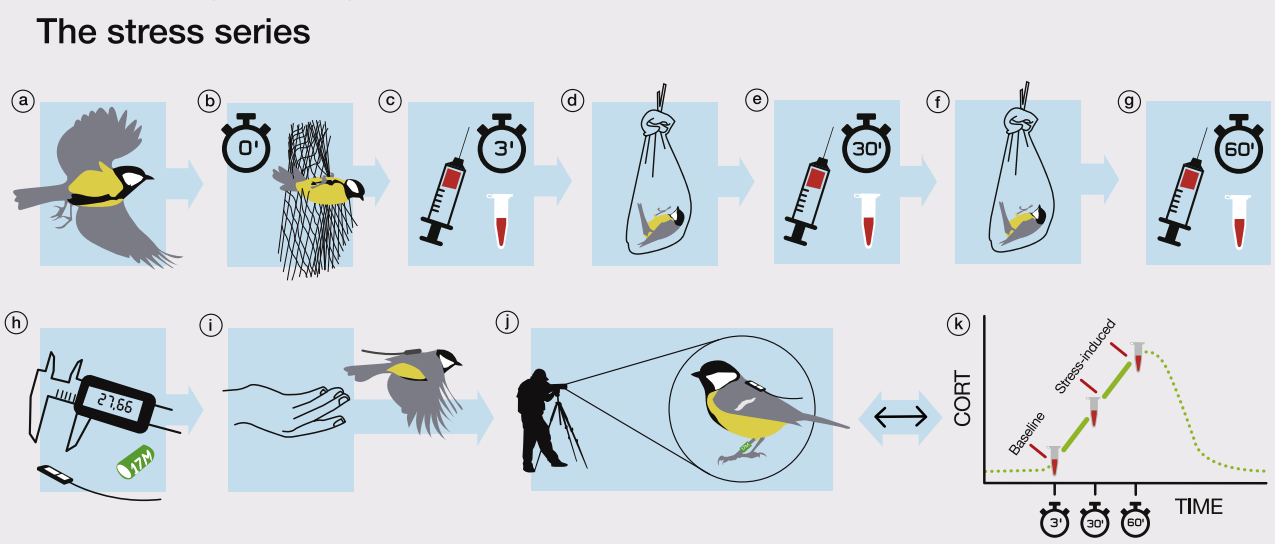
BOX 38.1 The stress series, baseline, and stress-induced corticosterone.

The Stress Series: The quantification of adrenocortical responses in wild birds is traditionally accomplished through a "stress series," which involves a *standardized capture, handling, and restraint protocol* accompanied by the serial collection of blood samples at specific time intervals. Plasma corticosterone levels are subsequently determined in the laboratory. Precapture conditions (a) are supposed to reflect the true *baseline corticosterone levels* of wild, unstressed specimens. Capture (b) sets the starting time of exposure to a noxious stimuli (i.e., the experimental perturbation), and should be performed in a consistent, standardized manner (e.g., through mist netting). The relatively slow response of the HPA axis allows taking a first blood sample within 3 min postcapture (c) for subsequent quantification of baseline corticosterone levels (sampling time is generally critical). Birds are then restrained (d) in standardized conditions (e.g., inside a cloth bag), and a second blood sample collected at a specific time (e.g., 30 min postcapture) allows determination of *stress-induced corticosterone levels* (e). Additional restraint periods and blood sampling episodes at preset times (e.g., 60 min postcapture) allows further quantification of individual stress-induced corticosterone levels (f–g). Biometric measurements and bird tagging (h) are typically performed prior to release (i). Subsequent monitoring of the tagged birds (j) and determination of plasma corticosterone in the collected samples (k) allows establishing ecophysiological links.

Baseline corticosterone levels are defined here as encompassing two related concepts:

(1) the "true" circulating level associated with routine daily activities and life processes, predictable allostatic load, and seasonal variation in LHSs in wild, "unstressed" individuals (*sensu* Landys et al., 2006); and

(2) levels from blood samples taken within a short time (typically 3 min) of capture that are assumed to reflect the precapture circulating level of the hormone. These sampled levels can only be expected to "not reflect the acute stress of capture" and, as such, they are more accurately referred to as "initial" levels (Schoenemann and Bonier, 2018), particularly when taken as part of a stress-series (see above).



Baseline and stress-induced corticosterone: There has been debate for years about proper terminology in studies of the adrenocortical response. This debate stems in large part from the nebulous term "stress" and its frequent (mis)usage in the literature (Section 38.2; Romero 2004; Romero 2012), as well as the increasingly common misinterpretation that stress can be measured directly using levels of GCs (MacDougall-Shackleton et al., 2019). In choosing the terminology for this chapter, we were faced with balancing our desire to use the most accurate terms and contribute to efforts to improve their usage, with the reality that some of these "short-hand" terms are now used pervasively (if incorrectly) by ornithologists and behavioral endocrinologists. Thus, to maximize uptake of this chapter, and to ensure our terms match the usage in the overwhelming majority of studies, we opted to use terms that would be most broadly recognizable. We fully support efforts to improve the usage of terminology in the literature (MacDougall-Shackleton et al., 2019), including avoiding referring to GCs as "stress hormones." To that end, in our definitions below we draw readers' attention to assumptions inherent in these terms that must be considered when using them in studies of the adrenocortical response.

The majority of studies that report baseline corticosterone levels from field and laboratory settings make the assumption inherent in the second definition and, further, use the levels as a proxy of the true (seasonal) baseline. Researchers should be aware of this assumption when drawing ecophysiological inference, as a variety of factors could result in the sampled baseline value departing from the true baseline. For example, a bird could have been chased by a predator immediately prior to capture, or could be diseased, and such factors that have the potential to affect (i.e., skew) baseline corticosterone levels are often not known to the researcher.

Continued

BOX 38.1 The stress series, baseline, and stress-induced corticosterone.—cont'd

Stress-induced corticosterone levels are defined here as encompassing two related concepts:

(1) the circulating level that arises in response to life-threatening and unpredictable perturbations in wild individuals; and

(2) levels from blood samples taken after the bird has been exposed to a stressor for a specified time (typically 30 min). The capture and restraint/confinement conducted by researchers during a stress series is believed to mimic an acute natural stressor (though more naturalistic stressors can be used, e.g., Cockrem and Silverin, 2002), so is frequently used to induce stress-induced levels. Regardless of the stressor, the levels derived from this sample are assumed to reflect levels secreted by wild individuals. Birds can acclimate to stressors (see Romero, 2004), especially in captivity, so experience of the individual must be accounted for when drawing ecophysiological inference from stress-induced corticosterone levels.

reproductive investment and survival, providing a proximate (corticosterone-mediated) mechanism for life history evolution. Finally, field ecophysiological research conducted on wild avian models provides a richer understanding of free-living birds but imposes important challenges compared to laboratory studies, which will be addressed in Section 38.5, with a description of common methodological tools for assessing adrenocortical function in wild birds. For ease of reading, a final Section 38.6 contains a glossary of terms and abbreviations commonly used across this chapter.

38.2 Stress, energy, and glucocorticoids

The term "stress" can be misleading, and it is often misused in the ornithological literature. For example, it is relatively easy to find references to the "stress of reproduction" or the "stress of migration" in the literature, when authors are in fact referring to physiological demands of normally predictable LHSs that are not truly related to physiological stress. Prominent researchers on this topic assert that the use of this word says "virtually nothing about the underlying physiological or behavioral mechanisms" (McEwen and Wingfield, 2003b), and that "stress means whatever the author wants it to mean" (Romero, 2012). So what do we mean when using the term "stress"? As a polysemous word, depending on the context, authors may use "stress" to mean: (1) the stimulus that challenges *homeostasis* (i.e., *stressor*, *perturbation*), (2) the emergency response to perturbations (i.e., stress response), or (3) the chronic state of imbalance that follows overactivation of the adrenocortical axis (i.e., pathology, *chronic stress*). In the biomedical literature, this word remains ambiguous since it was first brought from the field of engineering by Cannon (1932) and Selye (1946). What alternative, unequivocal term could be used to avoid such confusion?

Modern ecophysiologists have made efforts to define and consolidate alternative and unequivocal terms (see Glossary in Section 38.6), leading to the recent introduction of "allostasis" and an accompanying set of terms to precisely define physiological responses to both normal life history conditions and unpredictable challenges, which are key aspects of this chapter. Allostasis is the process of maintaining homeostasis through change. This concept was introduced decades ago to redefine stress (Sterling and Eyer, 1988), but it only started to reach the ecophysiological literature after McEwen and Wingfield proposed the Allostasis Model (McEwen and Wingfield, 2003a). Through the key concepts of allostatic state, allostatic load, and allostatic overload, the model incorporates classic homeostasis in the context of an organism's lifecycle and in relation to individual experience and how the individual responds to ever-changing physical and social environments (i.e., within an ecological context; Figure 38.2; McEwen and Wingfield, 2010). This model uses the balance between energy input and energy requirements to predict when an animal should move away from the normal lifecycle into an emergency survival mode, and when a pathological imbalance would occur. The Reactive Scope Model is an offshoot of the Allostasis Model, but presents a different terminology for contextualizing the impact of stress in the body, as well as a new classification for the levels of the mediators (e.g., corticosterone in birds; see Figure 38.3) that allows the incorporation of a process known as "wear and tear." Combining traditional notions of stress and homeostasis with the more recent terminology of allostasis and allostatic load, the Reactive Scope Model addresses the mechanisms of response to perturbations and the roles of different mediators, including GCs. It is important to understand these two models and their associated terminology before we can understand the patterns of adrenocortical responses to stress and the underlying physiological mechanisms in birds, within an ecological and life history context.

- "Stress" is an unspecific term that may mean:
  (1) the stimulus that challenges homeostasis (i.e., stressor, perturbation),
  (2) the emergency response to perturbations (i.e., stress response), or

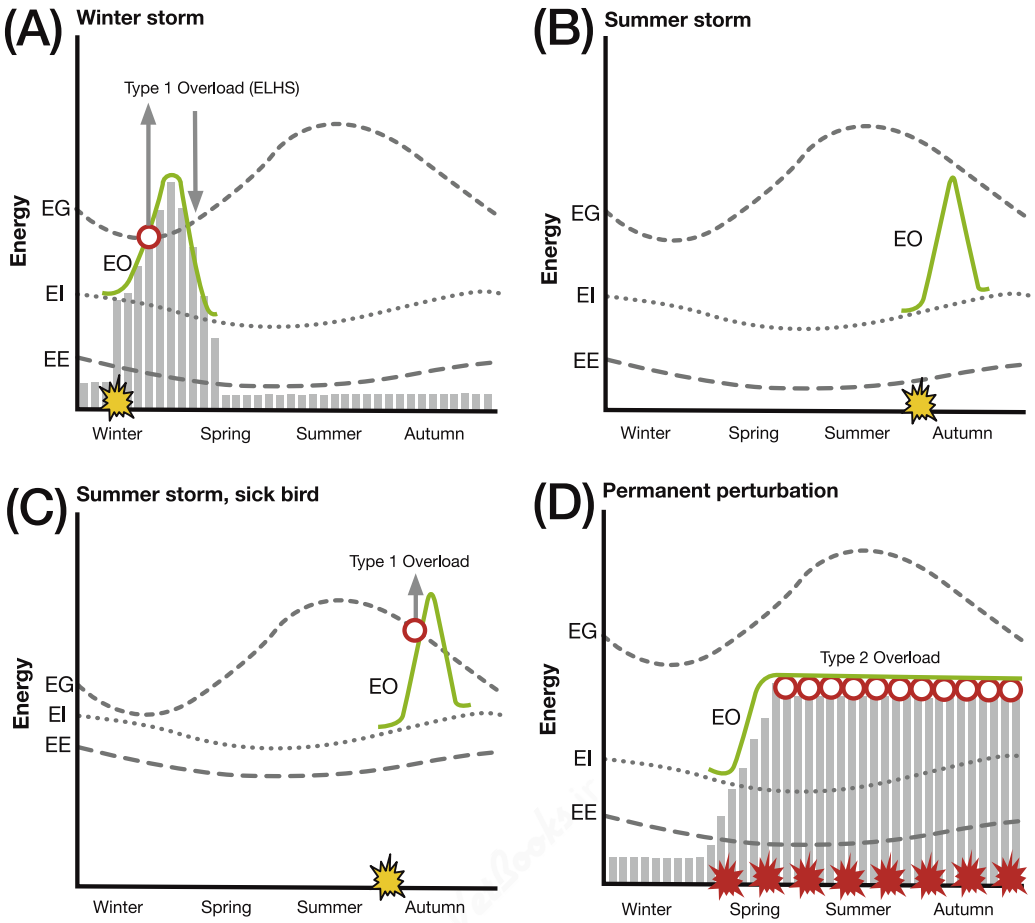

FIGURE 38.2 **The allostasis model.** The Allostasis Model provides a framework to understand the energetic requirements of organisms during their life, and predictions for when allostatic overload (*red circles*) would occur under a range of environmental, social, and individual-based scenarios. The y-axis represents potential nutritional requirements (including energy per se and nutrients) during 1 year (seasons in x-axis). The lines represent several energy components: EG (energy to be gained) represents the amount of energy in food available in the environment. In temperate areas, it is expected to rise in spring and summer and decline through autumn and winter when primary productivity is low. EE (existence energy) is the minimum existence energy (resting metabolism) required for basic homeostasis in any life history stage. It may decline in temperate spring and summer with ambient temperature. EI (ideal energy) is the extra energy required to go out, find food, process, and assimilate it under ideal conditions (when there are no perturbations) while performing seasonal routines (breeding, molting, migrating). It likely changes seasonally and for clarity we assume that it varies in parallel with EE. EO (energy following perturbation) is the additional energy required to go out, find food, process, and assimilate it under nonideal conditions. Allostatic load is the energy resulting from adding EE + EI + EO. In the figures, the *star* symbol defines when a perturbation (for example, severe weather) starts. Type 1 allostatic overload (panels A and C) occurs when allostatic load surpasses the energy available in the environment EG, promoting corticosterone elevations (*gray bars*, only shown in panels A and D for clarity) that trigger an Emergency Life History Stage (ELHS). One result is the suppression of other life history stages like migration or breeding, and bringing allostatic load below the level of EG. For example, the bird may suspend spring migration to obtain more food and only continue migrating when the perturbation ends. The bird can now survive the perturbation in positive energy balance and glucocorticoid elevations subside, avoiding pathologies associated with chronically high levels. Note that the same perturbation (for example, a severe storm) can result in Type 1 overload during winter but not in summer (compare panels A and B) when there is more food available (and EG > EE + EI + EO even during the perturbation). However, an individual heavily infected by parasites or with a permanent injury or chronic disease (panel C) would enter Type 1 allostatic overload facing the same summer storm because its intrinsic (disease-related) EE and EI levels are higher compared to a healthy bird (compare panels B and C). A second type of overload (Type 2 overload; panel D) can take place in situations where the energy available from the environment EG is not a limiting factor but a long-term perturbation (for example, climate change, captivity, permanent exposure to predators, permanent social challenge) triggers an allostatic state. The behavioral or physiological adjustments promoted by allostasis mediators (e.g., corticosterone) do not allow evading/coping with the continuing noxious stimuli (*red stars*). Corticosterone levels (*gray bars*) become chronically elevated or dysregulated, generating pathologies, and individuals would likely die early. Note that the individual must be unable to escape the perturbation in order for Type 2 allostasis overload to occur. In the figures, the levels of allostasis mediators (e.g., corticosterone) are indicated as gray bars only in the first and last panels (A and D) for simplicity, noting that their associations with energy levels (the metrics for all y-axes) are not necessarily linear. *Credit: Figures modified and expanded from McEwen and Wingfield (2003a) with permission.*

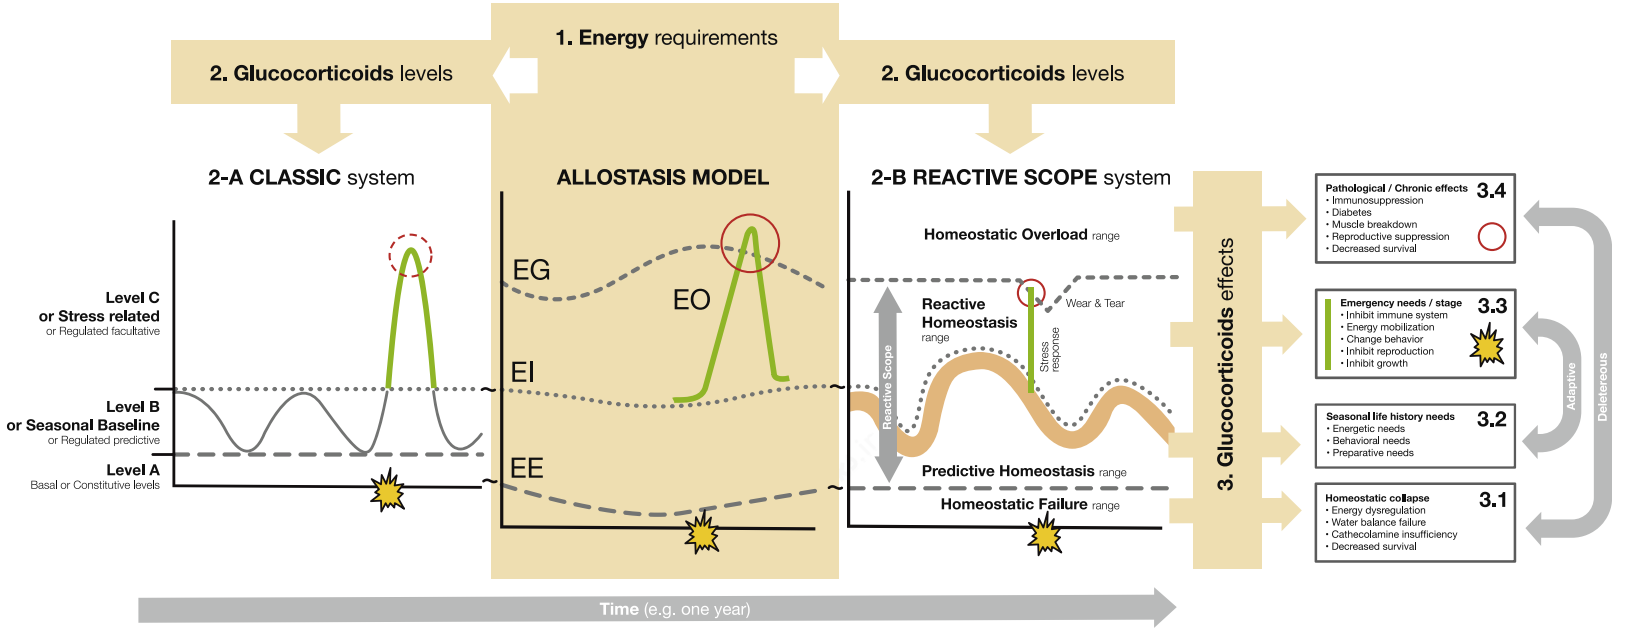

FIGURE 38.3 **Classification of corticosterone levels.** Classification of functional GC ranges according to the Classic system (panel 2A) and the Reactive Scope system (panel 2B). Both GC classification systems are presented in parallel to highlight the degree of overlapping and equivalence among system-specific terms (see main text and Section 38.6 for definitions), and in relation to the individual energy balance introduced by the Allostasis Model (panel 1). Energy requirements precede changes in GC levels, and thus the Allostasis Model is here presented as a central panel. Examples of GC effects on physiology and behavior (panel 3) are also presented in line with the corresponding GC ranges. Within any given chart, the x-axis represents the timeline (for example, 1 year), and the star symbol indicates exposure to a perturbation, which first results in increased energy demands (depicted as a *green line* in panel 1, implying increased allostatic load) and secondly in concomitant increases of GC levels reaching a range known as Level C or reactive homeostasis (*green lines* in panels 2A and 2B respectively). The perturbation may eventually bring the individual into negative energy balance (depicted as a *red circle* in panel 1, implying allostatic overload type I), and GC elevations will reach an upper range (*red circles* in panels 2A and 2B) potentially causing deleterious effects on body systems (panel 3, box 3.4). To avoid the damage associated to both the energy imbalance and the high GC levels, a facultative emergency life history stage is typically triggered (panel 3, box 3.3). If the negative energy balance subsides (because the perturbation extinguishes, or the individual relocates) GC levels return to a normal seasonal baseline known as level B or predictive homeostasis (in panels 2A and 2B, respectively) allowing resuming normal life history activities (panel 3, box 3.2). Note that the deleterious effects of GCs can occur both at very high and very low concentrations (panel 3, boxes 3.1 vs. 3.4). *Credit: Composite figure integrates graphs modified and expanded from several sources, including McEwen and Wingfield (2003a); Landys et al. (2006) and Romero et al. (2009).*

(3) the chronic state of imbalance that follows overactivation of the adrenocortical axis (i.e., pathology).

- Ecophysiologists are making ongoing efforts to define and consolidate alternative and unequivocal terms, leading to the recent introduction of the Allostasis Model and the Reactive Scope Model.

38.2.1 Allostasis: the concept and the model

Homeostasis (*sensu* Cannon, 1932) is the stability of physiological systems that are essential to life. As discussed in McEwen and Wingfield (2010), the concept of homeostasis is restricted to a few truly essential systems: pH, body temperature, glucose levels, and oxygen tension. In other words, those aspects of physiology that "keep us alive" (McEwen and Wingfield, 2003a). *Allostasis* is the process of achieving stability through change: it maintains homeostasis even though the set points and other boundaries of control may change with environmental conditions. Allostasis thus refers to those aspects of physiology that "help us adapt" (McEwen and Wingfield, 2010). Circulating GCs are major (but not the only) mediators of allostasis: additional mediators include catecholamines, cytokines, behavior, heart rate, blood pressure, and antibody titers (see Table 1 in Romero et al., 2009). GC levels can change markedly to help the body maintain homeostasis within narrow limits. To allow for this, GC levels fluctuate in daily and seasonal patterns (despite being equivocally called "stress" hormones), and also rise rapidly when a perturbation occurs. Free-living birds respond to potentially noxious stimuli (e.g., storms, social challenge, or human disturbances that reduce access to food and shelter) by increasing GC secretion, which facilitates foraging and gluconeogenesis. In addition, elevated GCs inhibit processes that are not essential to immediate survival (e.g., reproduction, migration) and increase physical activity. This allows an individual to move away from the perturbation or find shelter, as well as save energy by increasing night restfulness (Wingfield, 1994; Wingfield and Ramenofsky, 1999; Wingfield et al., 1998). When the body experiences altered and sustained activity levels of *allostasis mediators* (e.g., corticosterone), it enters an *allostatic state*, which can only be maintained for limited periods before damaging the body. The *Allostasis Model* (Figure 38.2) provides an ecological framework to understand when and how emergency responses are activated (reaching an allostatic state) through modeling the energetic requirements of organisms during their life, and in relation to the energy available in the environment. To understand the model, the following energy components need to be considered:

EG (energy to be gained): represents the amount of energy in food available in the environment. In temperate areas, it is expected to rise dramatically in spring and summer and then decline through autumn and winter when primary productivity is low.

EE (existence energy): is the minimum existence energy (resting metabolism) required for basic homeostasis in any LHS. It may decline with increasing ambient temperature (if it becomes easier to maintain body functions), e.g., in temperate spring and summer.

EI (ideal energy): is the extra energy required to go out, find food, process, and assimilate it under ideal conditions (when there are no perturbations) while performing seasonal routines (breeding, molting, migrating). It changes seasonally: it can follow EE and ambient temperature (for example, in a nonbreeding bird) or can increase during reproduction (spring-summer) and decrease during wintering. For clarity, in Figure 38.2A, it varies in parallel with EE.

EO (energy following perturbation): is the additional energy required to go out, find food, process, and assimilate it under nonideal conditions (following a perturbation). It is always higher than EE + EI. In Figure 38.2, the star symbol defines when the perturbation starts, setting the beginning point for elevations in EO energy demands.

Allostatic load can now be defined as the cumulative energetic requirements of the organism at a given time, and equals EE + EI + EO (although it is sometimes noted simply as EO). This concept relates to all the energy requirements in a broad sense (encompassing nutrients and all other potentially limiting resources), and it can be interpreted as a cost: the cumulative cost of being there, responding to the current situation whether it is predictable or not; or the "workload" of a particular moment (at certain times, an animal has to work harder—expend more energy to maintain homeostasis). A detailed definition of allostatic load in McEwen and Wingfield (2010) is "all of the energy and nutrients an organism needs to go about its daily and seasonal routines as the life cycle progresses, and to deal with unpredictable events from the physical and social environment that have the potential to be stressful." In the graphical representation, allostatic load fluctuates along a continuum with important transitional points (see red circles in Figure 38.2) that determine when the individual can cope with daily activities (seen as a cost, when is the load "affordable"?) and when it needs to trigger facultative physiological and behavioral responses evolved to reduce costs (when is the load unaffordable and becomes an overload?). In other words, transitional points determine when the individual enters overload and triggers an allostatic state.

The Allostasis Model proposes two different outcomes for *allostatic overload*. First, if energy demands exceed energy income and what can be mobilized from stores (i.e., if allostatic load surpasses EG), then Type 1 allostatic overload occurs. For example, breeding birds take

advantage of the increasing food abundance in spring to raise their broods. If inclement weather then increases the cost of maintaining homeostasis in addition to the demands of breeding, and at the same time reduces the food available to fuel this allostatic load, then a negative energy balance (overload) would result in a loss of body mass and the suppression of reproduction (see Wingfield et al., 1983 for empirical grounds). This negative energy balance is termed Type 1 allostatic overload, which leads to an allostatic state (increased levels of GCs), which then triggers physiological changes (use of lipid stores resulting in body mass loss) and behavioral changes (brood desertion). This response has been classically referred to as the ELHS and will be discussed in more detail in Section 38.3.3. Note for now, however, that short-term elevations of GCs may promote rapid physiological and behavioral changes, allowing a decrease of allostatic load below the EG level, before abandonment of the present LHS occurs. Only above a certain threshold (likely variable among individuals) would corticosterone trigger an ELHS (Wingfield and Romero, 2001). The final outcome of an allostatic state is normally survival because a positive energy balance can be reestablished: allostatic load will return to affordable levels when the individual relocates (or seeks refuge until the perturbations ends) and restores depleted condition through foraging. All of these actions are facilitated by the allostasis mediators (e.g., corticosterone levels, but also changes in behavior, hearth rate, blood pressure, cytokines, and antibody titers; see Romero et al., 2009), which are highly adaptive when elevated for a short period and then returned to normal (pre-perturbation) levels. Only in those circumstances when individuals are unable to avoid the perturbation after entering the ELHS is elevated corticosterone maintained for periods long to result in serious pathological effects and eventually death. The value of this Allostasis Model becomes more clear when we incorporate individual variation due to habitat quality, body condition, disease and parasites, reproductive state, experience, genetics, social status, and many other additional parameters. For example, because the energy available in the environment (EG) fluctuates (e.g., food is more abundant in spring than winter), a given perturbation will result in Type 1 allostatic overload faster at specific times of the year. This aspect is illustrated in Figure 38.2: the same storm (star symbol) promoting Type 1 allostatic overload in winter (panel (A)) fails to do so in summer (panel (B)) because there is sufficient energy in the environment to afford the increased allostatic load. However, an individual heavily affected by parasites or disease, or with a permanent injury (panel (C)), would enter Type 1 allostatic overload even in summer because its intrinsic (disease-related) energy requirement levels EE and EI are higher than average (in other words, its allostatic load was already elevated before the storm, and any additional EO load surpasses the energy available in the environment EG, rapidly resulting in overload). As an extreme example, habitats degraded by human transformation and climate change (Wingfield et al., 2017) often reduce food availability in the environment below the requirements for EE and EI. In the figures, the levels of allostasis mediators (for example, circulating corticosterone levels) are only indicated as gray bars in panels (A) and (D) for simplicity, but note that the metrics in the Allostasis Model refer to energy levels rather that the levels of any mediator. The relationships between energy requirement at a given moment and the level of a specific mediator are not necessarily linear because different allostasis mediators (e.g., GCs, cathecolamines, cytokines) act in concert and interact in complex physiological ways to meet allostatic demands (McEwen and Wingfield, 2010).

Second, another type of allostatic overload, qualitatively different from the Type 1 overload patterns described above, can arise in situations where energy from the environment (EG) is not limiting: then it is called Type 2 allostatic overload (see panel (D) in Figure 38.2). Here a long-term, rather than a short-term, perturbation (e.g., climate change instead of weather inclemency; captivity or permanent exposure to predators instead of a single predator chase; permanent social subordination instead of temporary social instability; see Section 38.3.3 for details) triggers an allostatic state, but concomitant elevations of GCs are unable to promote behavioral or physiological adjustments to cope with or to evade the noxious stimuli. For Type 2 allostatic overload to occur, the individual must be unable to evade the perturbation due to physical or social constraints. Corticosterone levels then become chronically elevated, generating pathologies despite adequate food resources (Type 2 overload occurs despite $EE + EI + EO < EG$; see Figure 38.2D). The effects on the body are similar to experimental exposure to high levels of exogenous corticosterone, and metabolic pathologies arise (e.g., hyperinsulinemia, hyperphagia, obesity). This situation is most likely to occur in vertebrates living in complex hierarchical systems (e.g., social primates), where subordinate (or depending on the specific system, sometimes dominant) status imposes heavy allostatic loads. However, it can also affect birds under certain conditions, such as (1) natural populations exposed to permanent habitat disturbances or climate change, (2) avian social systems where dominance structure predominates over food and shelter as a source of allostatic load (see review in Goymann and Wingfield, 2004), and (3) captive settings. The hormonal imbalances and metabolic costs imposed by Type 2 allostatic overload are high and likely result in chronic disease and premature death in the wild (e.g., birds with extreme fat stores are more likely to be depredated due to decreased maneuverability; Lind et al., 1999; Gosler et al., 2002), providing strong selection for the mechanisms limiting allostatic load.

However, in captive animals (and in human societies!), the selection pressure is not there, and pathologies can persist long-term.

In summary, the concept of allostasis (maintaining homeostasis through change) combines the energetic costs or demands associated with daily rhythms and LHSs (predictable) with those costs accompanying environmental perturbations and ecological and social challenges (unpredictable and either short- or long-term, see Section 39.3.1) into a continuum named allostatic load (see Figure 3 in Landys et al., 2006). Allostatic overload is then defined as either a short-term state in which the costs of the LHS and accompanying challenges (=allostatic load) exceeds the food resources available to provide sufficient energy (Type 1 allostatic overload), or a long-term state in which deleterious challenges are chronic and lead to a sustained allostatic state independent of seasonal changes in the environment (Type 2 allostatic overload). The terminology introduced by the Allostasis Model allows physiologists to replace the overused word "stress" by a set of distinct, unambiguous, and precisely defined terms that are being gradually incorporated into modern ecophysiological studies. However, an acknowledged weakness of the Allostasis Model is the use of energy as both the underlying mechanism and the universal metric (for a discussion of this topic see Walsberg, 2003; McEwen and Wingfield, 2003b; Romero et al., 2009; McEwen and Wingfield, 2010). This becomes a problem that is mainly a consequence of our current inability to measure individuals' energy demand (allostatic load) and environmental energy availability (EG) in free-living animals. Until we develop ways of measuring direct components of allostatic load (Porter et al., 2002; Ricklefs and Wikelski, 2002; Wilson et al., 2020), we will have to rely on the levels of allostasis mediators (e.g., circulating GCs) as best proxies to understand allostasis. Furthermore, the expected changes in corticosterone levels as a function of energy dynamics were only partially addressed in the original presentation of the Allostasis Model, and this will be the subject of the following subsection.

- Homeostasis is the stability of physiological systems that are essential to life, including pH, body temperature, glucose levels, and oxygen tension: those aspects of physiology that "keep us alive." In contrast, allostasis is the process of achieving homeostasis through change: those aspects of physiology that "help us adapt."
- The Allostasis Model provides a framework to understand the energetic requirements of organisms during their life, and in relation to the energy available. The model incorporates three concepts (allostasis, allostatic load, and allostatic overload) that allow replacing the overused and unambiguous word "stress":
  - Allostatic load is the cumulative energetic requirements of the organism in a broad sense (the "workload" in a particular moment), including predictable and unpredictable demands. Allostatic load fluctuates along a continuum, and transitional points determine when the individual can cope with daily activities and when it needs to trigger emergency responses aimed at reducing costs.
  - Type 1 allostatic overload is a short-term state of energy imbalance in which allostatic load exceeds the energy available from the environment plus the internal reserves.
  - Type 2 allostatic overload is a long-term state in which environmental or socially demanding challenges become chronic and exert deleterious effects on the individual, regardless of the energy available.
- The metric or "currency" for the Allostasis Model is energy. This represents a problem due to the difficulty of estimating energy demands and availability outside controlled conditions. However, energy management is achieved through changing levels of allostasis mediators (e.g., GCs, cathecolamines, cytokines, behavior, hearth rate, blood pressure, antibody titers) that can be measured accurately. The relationships between energy requirement at a given moment and the level of a specific mediator are not necessarily linear because different mediators act in concert and interact in complex ways.
- Corticosterone is the predominant GC in birds and a major allostasis mediator. Circulating corticosterone levels change in response to internal and external demands to manage energy balance. When the body experiences altered and sustained corticosterone elevations, it enters an allostatic state, which can only be sustained for limited periods before damaging the body.
- The Allostasis Model is a largely theoretical paradigm requiring empirical tests. However, it provides a framework for understanding when and how emergency responses are activated, and how individuals respond to changing physical and social environments.

38.2.2 Glucocorticoid levels

GCs are major allostatic mediators, meaning that they allow lifetime modulation of avian energy balance throughout changing internal and external conditions. Their role in gluconeogenesis explains much of their relevance as mediators, but they also act to facilitate morphological and behavioral changes and balance the immune system in ways that are crucial for individual fitness (see details in Chapter 33). The year-round dynamics of avian energy requirements and constraints introduced with the Allostasis Model provide a reference to describe expected changes in

GC levels (Figure 38.3). Because GCs can exert either "housekeeping" actions or devastating effects on the organism depending on their levels, it is critical to understand the range-descriptor terms and the specific terminology developed for this purpose. GCs can be "good and bad," "stress and antistress" (depending on the range), and an adequate term usage constitutes the only way to avoid confusion and to understand how opposing results regarding GC actions among studies are not necessarily contradictory. In fact, this paradox affects most allostasis mediators. The nomenclature describing GC ranges and functional thresholds differ, however, between what we will here call the *Classic System* and the *Reactive Scope System*. The two classifications are graphically presented in Figure 38.3 as two parallel panels (2A and 2B) and in relation to the Allostasis Model (but note that the latter refers to energy balance and not GC levels) for ease of comparison. As proposed by Wingfield et al. (1997) and further refined in Landys et al. (2006), the Classic System involves three hormonal thresholds (levels A, B, and C) and a set of corticosterone terms traditionally used (basal vs. baseline, constitutive vs. facultative, seasonal vs. stress related). The Reactive Scope System corresponds to a more recent classification given in the original proposal of a model (the Reactive Scope Model; Romero et al., 2009) that will be explained in the following section (Section 38.2.3). Although parallel terminologies may not help to explain the complexity of GC actions (the proposal of novel terms often generates controversy; McEwen and Wingfield, 2010), both systems ultimately agree in the following five conceptual ranges (one to five below) of increasing magnitude in circulating GC levels (Figure 38.3):

1. A pathological and physiologically unsustainable range where GC levels are too low for minimum homeostatic processes. This pathological range can be simulated by reducing levels of GCs through adrenalectomy (in mammals, Darlington et al., 1990) or chemical treatment (in birds, where adrenocortical cells are also located in the kidney tissue; see Chapter 33), and death rapidly occurs. In the Allostasis Model, this would be equivalent to an individual unable to meet the minimum energy requirements for existence (i.e., below EE level).
   a. In the Classic System, this range corresponds to GC concentrations below level A (this classification system does not have a specific place or level to represent a deadly physiological level or stage).
   b. In the Reactive Scope System, this is the GC range of *homeostatic failure.*
2. A minimum GC level allowing basic homeostatic processes (allowing meeting the existence energy demands EE in the Allostasis Model).
   a. In the Classic System, this range corresponds to GC concentrations within level (range) A, and corticosterone levels are termed basal or constitutive, (allowing "a physiological state A, representative of undisturbed animals at rest, in which hormone action maintains internal systems at a basal operating level to support the most fundamental requirements of life"; Landys et al., 2006).
   b. In the Reactive Scope System, this will be the lower end of (but already inside) the *predictive homeostasis range.*
3. A range where GC levels fluctuate according to predictable environmental changes, making it possible to cope with daily and seasonal routines of the life cycle (i.e., meeting ideal energy needs, EI, in the Allostasis Model).
   a. In the Classic System, this range corresponds to GC concentrations within levels (range) B and corticosterone levels are termed *seasonal baseline levels* or *regulated predictive level* (allowing a physiological state B where "hormone action maintains systems within a heightened operated range to support increasing demands—allostatic load, especially in association with predictable changes in the environment or life history"; Landys et al., 2006).
   b. In the Reactive Scope System, this will be the predictive homeostasis range, where GCs encompass normal circadian, daily, and seasonal changes. In the graphical representation of the Reactive Scope Model (Figure 38.3, panel 2B), the width of the orange colored area represents circadian variation (driven by predictable daily changes in light and dark; see, e.g., Dallman et al., 1987), while the convolutions of this thick line along 1 year reflect seasonal variation (predictable changes normally driven by photoperiod), which allow anticipation and progression of LHSs such as breeding (see, e.g., Romero, 2002). The thin line above the orange colored line represents corticosterone fluctuations in response to normal, and still predictable daily activities like foraging (using other terminology, "the circadian peak within the gray line corresponds to resting metabolic rate, while the thin line marks the active metabolic rate for that time of the year"; Romero et al., 2009).
4. An upper, facultative range of GC levels (superimposed above the normal circadian, daily, and seasonal fluctuations), where short-term elevations allow counteracting unpredictable changes in the environment, and either maintain or return the body to homeostasis (thus meeting the increased energy demands that follow perturbations: allostatic load EO).
   a. In the Classic System, this range corresponds to GC concentrations within level (range) C and

corticosterone levels are termed stress-induced, stress-regulated or regulated facultative (entering a physiological state C that "allow animals to survive threatening perturbations when allostatic load exceeds the immediate ability to cope, e.g., during encounters with a predator, infection, severe weather, energy storage and/or social instability"; Landys et al., 2006).

b. In the Reactive Scope System, this will be the *reactive homeostasis range*.

Both classification systems agree to term these facultative GC elevations as the "stress response," and link the physiological, morphological, and behavioral changes to a distinct ELHS (Wingfield et al., 1998), which will be presented in detail in Section 38.3.3. In panels 2A and 2B of Figure 38.3, the occurrence of a perturbation is depicted by a star symbol in the time line (x-axis), and concomitant GC elevations (the GC stress response) are represented with a thicker blue line (the same perturbation is also depicted in the central panel dedicated to the Allostasis Model with the predicted changes in energy demand EO, allostatic load, represented with a thicker green line). Note in the Reactive Scope Model (panel 2B), that the combination of predictive and reactive homeostasis ranges establishes the normal *reactive scope* for the individual, a concept that defines the upper and lower physiological constraints of a healthy animal and provides a name for the model, as we will explain shortly.

5. Finally, GC levels may reach a higher range where pathologies also develop. In the Allostasis Model, this would be equivalent to reaching Type 1 allostatic overload (when the energy demands exceed the energy available).

a. The Classic System (panel 2A) does not have a specific graphical notation for this range, likely because the development of pathology also involves a prolonged duration (time) of the GC elevations in a range that could still be indicative of typical *regulated facultative levels*. Prolonged GC elevations in this range are termed chronic GC levels. For ease of interpretation, the red circle in panel 2A depicts the highest GC concentrations that would lead to pathology if maintained for days.

b. In the Reactive Scope System, the upper GC levels would move into a homeostasis overload range (when corticosterone levels overpass the normal reactive scope above the upper end of the reactive homeostasis range). A key aspect in the Reactive Scope Model (and a conceptual novelty that was missing in both the Classic System and the Allostasis Model) is that the actual threshold for *homeostatic overload* can change within and between individuals in response to certain stimuli through a mechanism known as *wear and tear*. Therefore, the amplitude of the reactive scope is not a fixed trait in the individual. The effect of wear and tear is graphically represented in panel 2B, and its implications for reactive scope will be specifically discussed in the next section.

The absolute GC concentration defining each of these ranges varies between species (and even among populations within a given species, Wingfield and Romero, 2001), and GC actions on physiology and behavior are very different depending on the functional range (compare boxes 3.3 and 3.4 in Figure 38.3). On a more practical level, field endocrinologists typically collect blood samples from wild animals through standardized protocols such as the *stress series* (Box 38.1), which provides information about baseline and stress-induced GC levels. The simultaneous assessment of the conditions characterizing the same study subjects (e.g., health conditions, behavior, and environmental conditions) subsequently allows one to establish ecophysiological links. For simplicity, a direct association between circulating GC levels and GC actions (panel 3 in Figure 38.3) is often assumed. However, GC effects can be regulated at several levels (see Chapter 33, Wingfield, 2013b, Romero and Wingfield, 2016; Romero and Gormally, 2019), including at least (1) regulation of secretion and clearance rates, (2) regulation of transport (over 90% of circulating GCs are bound to carrier proteins, and only the remaining 10% constitute free and biological active hormone; Malisch and Breuner, 2010), (3) regulation of receptors (there are three types of receptors differing in affinities and exerting different effects on the organism), and (4) regulation of steroidogenic enzymes.

- GCs can exert housekeeping actions or devastating effects on the organism depending on what levels are involved (they can be "good and bad," "stress and antistress"). The absolute GC concentrations defining these ranges are species-specific.
- Two nomenclature systems (the Classic System and the Reactive Scope System) propose alternative terms to name GC ranges within adaptive and nonadaptive (pathological) levels.
- Healthy individuals show circulating GC levels within two narrow ranges below and above which serious pathologies occur:
  - Baseline levels fluctuate according to predictable environmental changes, allowing the individual to cope with daily and seasonal routines.
  - Stress-induced levels are facultative elevations (above seasonal baseline) that provide a means of

counteracting unpredictable changes in the environment. They are also termed the "stress response," and allow rapid physiological and behavioral changes characteristic of a distinct ELHS.

38.2.3 "Wear and tear" and the reactive scope model

Allostatic load (the "workload" to maintain homeostasis) is recognized as one the most relevant conceptual advances of the Allostasis Model (McEwen and Wingfield, 2003a). However, this concept needed to be further refined and expanded to incorporate additional body costs that were not explicitly acknowledged in the original formulation of the model. In particular, the elevation and maintenance of allostasis mediators incur a cost themselves. For example, the long-term behavioral and cardiovascular responses that characterize allostasis result in cardiovascular disease (Sapolsky, 2001), and GC elevations are known to exert a negative impact on the immune system, leading to a greater susceptibility to infections (Spencer et al., 2001). These costs are directly related to the allostasis mediators themselves and not to allostatic load per se, leading to the term "wear and tear": the cost of maintaining and using the physiological systems that mediate allostasis (Romero et al., 2009; Taff et al., 2018). The concept of wear and tear was introduced as a distinct attribute within a wider graphical interface, the *Reactive Scope Model* (Romero et al., 2009), which was proposed as a tool to characterize the physiological state of individuals across time, in response to perturbations, and according to the levels of mediators (not according to energy, which is the specific metric system of the Allostasis Model and generated ample criticism; Walsberg, 2003; Romero et al., 2009; McEwen and Wingfield, 2010). The Reactive Scope Model is therefore an extension (not a rebuttal) of the Allostasis Model and the seminal article leading to its formulation was supported by a review of the potential allostasis mediators and their effects at different ranges, including immune factors, cardiovascular responses, behavior, the central nervous system, and circulating GCs (Romero et al., 2009). For simplicity, only the later mediators (GCs; corticosterone) will be used here to explain wear and tear and the dynamics of the Reactive Scope Model across time and in response to perturbations. As we detailed in the previous section, the Reactive Scope Model also proposed a specific nomenclature to characterize the functional GC ranges (Figure 38.3, panel 2B). This new classification was justified to avoid confusion with other terms previously defined (what we called the Classic System in Figure 38.3, panel 2A), and circulating GC levels were presumed to exist in four ranges of increasing magnitude (i.e., homeostatic failure, predictive homeostasis, reactive homeostasis, and homeostatic overload). The combination of predictive and reactive homeostasis ranges establishes the normal reactive scope for the individual (which lies in between the upper and lower physiological constraints of a healthy animal, above and below which serious pathologies arise) and provides a name for the model (Figure 38.4).

In response to unpredictable perturbations, GC levels rapidly elevate outside the predictive range into the reactive homeostasis range. These elevations are graphically represented as rapid GC spikes (vertical bars in Figure 38.4), which counteract the negative effects of perturbations (depicted as numbered star symbols along the time line) through physiological and behavioral changes, and then quickly return to the predictive homeostasis range. This is the adrenocortical "stress response" aimed at maintaining homeostasis in the face of a perturbation. The sequence of perturbations experienced by a hypothetical model bird in Figure 38.4A indicates first that the magnitude of GC elevations depends on the type of perturbations. For example, the GC increase in response to perturbation 1 (e.g., a mild storm in winter) is significantly smaller than the elevations in response to perturbation 2 (a severe storm in winter). In these two examples, GC elevations remain within the reactive homeostasis range. In contrast, the same type of perturbation occurring at a different time of the year and even eliciting the exact same release of GCs can exert dramatically different effects on the individual. In Figure 38.4A, perturbations number 2 and 3 are two storms of similar quality (e.g., a severe storm occurring at the end of winter, and then again in early spring) eliciting similar GC elevations. However, only the latter causes pathology (red circle) as GC elevations reach the homeostatic overload range (GC spikes are represented now with a gray, rather than a green, bar to indicate pathological effects). A similar feature was previously suggested in the Allostasis Model with regards to an individual's likelihood of reaching states of negative energy balance at different times of the year, but some clarifications were needed. The Allostasis Model postulates that birds would be more resistant in winter because their energy requirements are lowest (winter perturbations should be stronger and demand more energy in order to reach allostatic overload Type 1; McEwen and Wingfield, 2003a), while the Reactive Scope Model postulates that birds are more resistant in winter because their GC *reactive homeostasis range* is wider (and thus reaching homeostatic overload would require a higher GC stress response, and likely a stronger perturbation; Romero et al., 2009). Energy demand (the currency of the Allostasis Model) and GC levels (the currency of the Reactive Scope Model) coincide in this example, as they both change in the same direction and result in deleterious effects, but this may not always be the case. As we pointed out, the task of maintaining GC levels in the reactive homeostasis range during a "stress response" itself incurs a cost known as wear and tear. Wear and tear can be defined

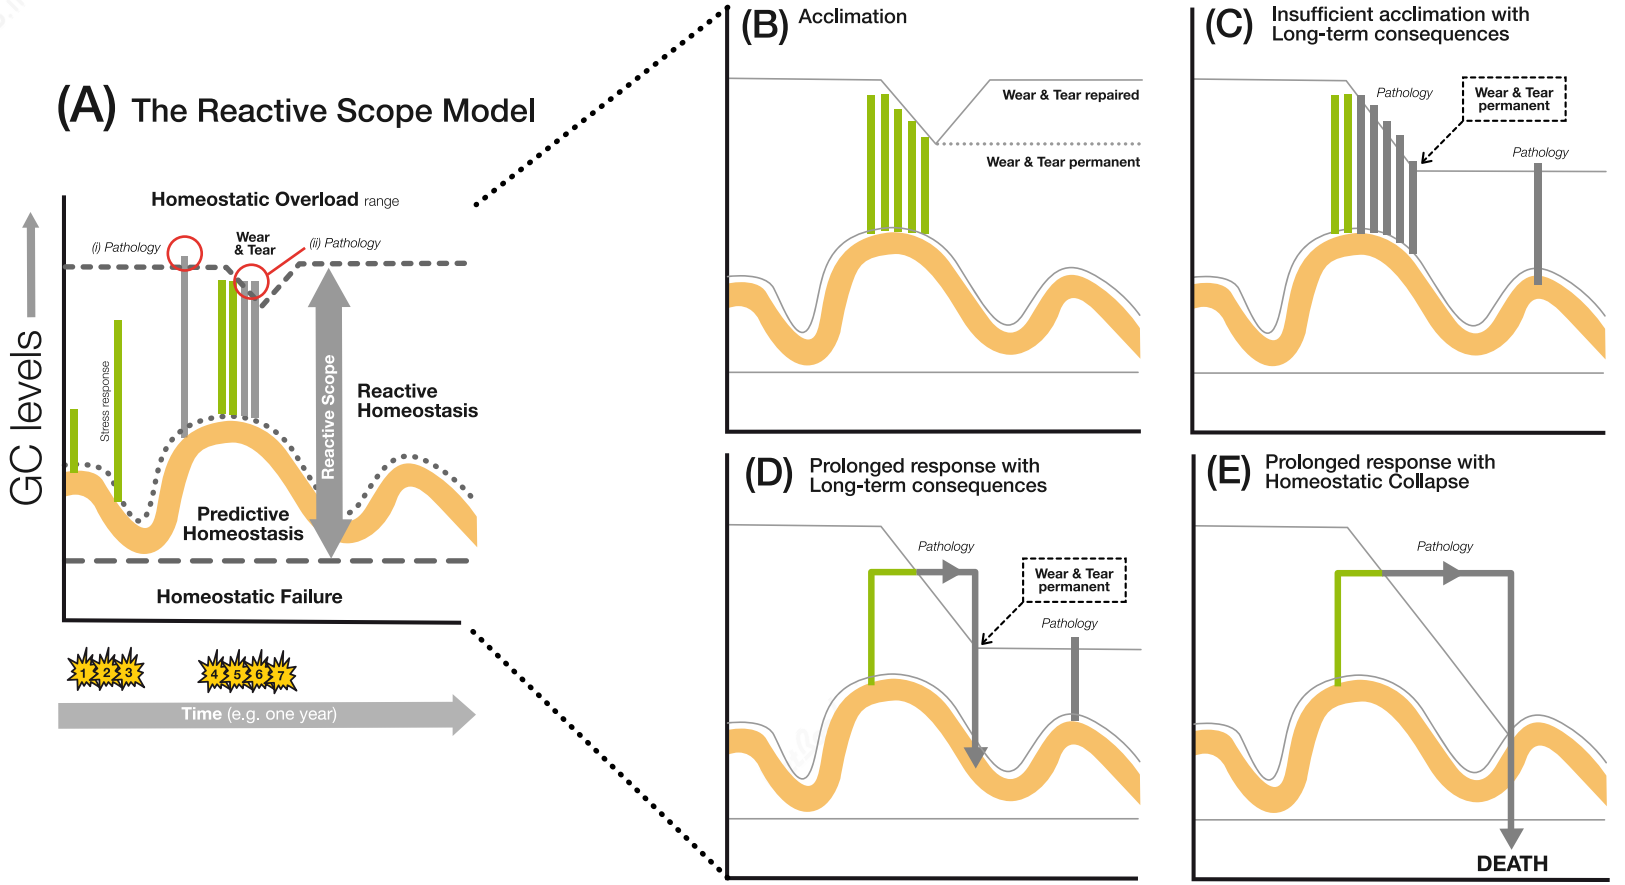

FIGURE 38.4 **The reactive scope model. Changes in circulating GC levels (y-axis) across time (x-axis) according to the reactive scope model.** Panel (A): GC levels exist in four nominal ranges: the predictive homeostasis range varies according to seasons and life history stages, and the reactive homeostasis range represents the facultative range of GC elevations in response to unpredictable perturbations. Both ranges combined define the normal reactive scope of the individual. Below and above this range, GC levels result in pathology (homeostatic failure and homeostatic overload ranges, respectively). In response to perturbations (numbered stars on x-axis), each vertical line represents both a rapid GC spike in the reactive homeostasis range and a rapid decrease when the perturbation ends. In panel (A), perturbation #2 is stronger than #1 and thus requires a stronger GC elevation to maintain homeostasis. Perturbations #2 and #3 are of similar strength, but occur at different times of year and only the latter results in GC levels extending into the homeostatic overload range (depicted as gray rather than *green bars*) and thus cause pathology. Perturbations #4 and #5 do not cause pathology, but repeated GC elevations exert "wear and tear" as depicted by a progressive decrease in the threshold between reactive homeostasis and homeostatic overload (thereby decreasing the reactive scope of the individual). Wear and tear implies that the GC response to subsequent perturbations #6 and #7 will generate pathology. In this example, wear and tear is rapidly repaired and there are no long-term consequences to the ability to respond to future perturbations (the reactive scope becomes normal after the last perturbation, #7). Panel (B) depicts acclimation. Repeated responses to stressors exert wear and tear but the animal habituates or acclimates when GC elevations decrease over time. Since GC levels never cross the threshold of homeostatic overload, pathology does not develop (note that all the bars are green). The accumulated wear and tear can be repaired once the stressor ends (*upper solid line*), or alternatively remain permanent (*lower dashed line*). Panel (C) depicts an insufficient acclimation with long-term consequences. Here the animal acclimates to a repeated perturbation but despite GC elevations progressively decrease, they enter the GC homeostatic overload range and pathology develops (denoted with *gray bars*). The threshold of reactive homeostasis could be repaired, but in this example, wear and tear exerts permanent effects, increasing susceptibility to future perturbations. As a consequence, even a moderate GC elevation elicited to face the last perturbation in this panel (C), enters the homeostatic overload range and generates pathology. Panel (D) presents an example of long-term exposure to a perturbation (e.g., chronic social stress, habitat degradation). Long-term exposure elicits prolonged GC elevations (note that the green bar now indicates extended GC secretion), which also exert wear and tear. When the sustained increase in GC levels extends above the adjusted threshold (where the green bar turns gray), pathology resulting from the elevated GCs themselves appears. Once the perturbation ends, GCs return to the predictive homeostasis range, but in this example, wear and tear becomes permanent as it likely occurs under social stress. Consequently, a later response to perturbation pushes GCs immediately into the homeostatic overload range. Panel (E) presents an extreme example of long-term exposure to perturbations. It implies that GC elevations remain in the homeostatic overload range for long periods, generating long-term pathology and accumulating continuous wear and tear. Once the threshold between GC reactive homeostasis and homeostatic overload ranges intersect with the predictive homeostasis range, GC levels collapse into the homeostatic failure range, turning pathology into death. *Credit: Figure modified and expanded from Romero et al. (2009) with permission.*

as the cumulative cost of maintaining GC levels within the reactive homeostasis range, and this cost has a consequence: a decrease in the threshold level between the reactive homeostasis range and homeostatic overload (see decreased threshold after perturbations 4 and 5 in Figure 38.4A). Note that the concept of wear and tear is different from the concept of pathology: in the latter, GCs themselves are causing damage, whereas in the former the likelihood of GCs causing damage increases. To illustrate this conceptual difference, compare the effect of perturbation 3 with the effects of perturbations number 4 and 5 in Figure 38.4A: only the former perturbation 3 positively generates pathology. Wear and tear can therefore be also interpreted as a gradual decrease in the ability to cope with perturbations. As the individual continues to respond to sequential or prolonged perturbations, GC elevations repeatedly enter the reactive homeostasis range, and the ability to counteract further stressors diminishes. At some point, the elevated GCs will cross a threshold and will start to create problems themselves. It is very important to note that, through wear and tear, GC levels can enter the homeostatic overload range even though their concentrations may not have changed. In other words the Reactive Scope Model proposes two ways of reaching homeostatic overload: either GC levels extend beyond the normal reactive scope, or GC levels remain in the reactive homeostasis range for an extended period, but wear and tear "shrinks" the reactive scope of the individual. Both scenarios are graphically depicted in Figure 38.4A. In response to perturbation 3, GC levels elevate above the normal reactive scope of the individual, entering the homeostatic overload range and generating pathology. Later that year, the same individual is exposed to perturbations number 4 and 5, which trigger GC elevations within the reactive homeostasis range. These perturbations do not cause pathology per se because concomitant GC elevations do not reach the homeostatic overload range. However, they exerted wear and tear on the individual, increasing susceptibility to enter homeostatic overload in response to subsequent perturbations (in fact, perturbations number 6 and 7 trigger GC elevations similar in magnitude to perturbations 4 and 5, but only the former cause pathology as the reactive scope range "shrunk"; see Figure 38.4A). In healthy individuals, wear and tear can be repaired after the perturbations end, but it could also remain for life, imposing a permanent decrease of the reactive scope of the individual and a permanent susceptibility to pathologies (the two options are represented within Figure 38.4B). Wear and tear and its graphical representation is an alternative way to express the concepts encompassed by allostatic load. For examples and detailed explanations of the physiological mechanisms underlying wear and tear, see Romero et al. (2009). Modeling wear and tear the way explained above illustrates why equivalent GC responses might be adaptive early, but cause problems later. It also illustrates why animals will be more resistant to stress-related pathologies during some LHSs compared to others. The model also suggests some evolutionary implications. For example, the authors propose that the slope of wear and tear in a specific individual could be determined empirically, because the threshold separating reactive homeostasis from homeostatic overload is equivalent to the maximal GC secretion of the normal reactive scope (Romero et al., 2009). Maximum GC secretion in a young, healthy, naïve bird could be determined experimentally (for example, through exogenous adrenocorticotropic hormone (ACTH) treatment; see Section 38.5.2), providing the actual limit of reactive homeostasis. Then, if a moderate perturbation is experimentally applied repeatedly to the animal for a short period, acclimation may occur (e.g., Walker et al., 2006) and the magnitude of the response will decrease (a visual example is provided as panel (B) in Figure 38.4). As long as pathological symptoms do not appear, thereby revealing that the individual has entered the homeostatic overload range, the acclimation over time will occur and the slope of wear and tear will be manifested as a time-related decrease in GC secretion. As we already mentioned, there are situations where repeated GC elevations cause permanent changes to the individual's physiology, and this can be illustrated by a permanent decrease in the reactive homeostasis range (e.g., in Figure 38.4C, the decreased reactive scope implies that this individual will have a lifelong increased susceptibility to pathologies). Also, the examples above only depict scenarios of repeated short-term perturbations followed by episodic spikes of GC into the reactive homeostasis range. These scenarios would be equivalent to Type 1 overload in the Allostasis Model (McEwen and Wingfield, 2003a,b). However, a single long-term perturbation may similarly cause prolonged GC elevations, a situation that was named Type 2 overload in the Allostasis Model and required separate conceptual explanations (McEwen and Wingfield, 2003a,b). With the graphical proposal of the Reactive Scope Model and the associated concept of wear and tear, the upper end of the reactive homeostasis range is simply expected to show a long-term (permanent) decrease in response to long-term perturbations, as depicted in panel (D). The graphical models for the response to both (1) repeated short-term perturbations (panels (A)–(C) in Figure 38.4) and (2) prolonged perturbations like subordinate social status or habitat degradation (panels (D) and (E)) are very similar under the Reactive Scope Model, and the dichotomy between Type 1 and Type 2 overloads is no longer necessary according to Romero et al. (2009). For example, low social status may impose a long-term cost to subordinate individuals compared with dominants (the reverse situation may also occur depending on the dynamics of the specific social system; Goymann and Wingfield, 2004), leading to what has been classically

termed "chronic social stress." In the Reactive Scope Model, this is depicted in Figure 38.4D (social conflict elicits a prolonged adrenocortical response, likely "shrinking" the reactive scope of individuals). In all of the examples above, we presented scenarios where the repeated/prolonged GC responses eventually end. However, the model predicts that as long as a prolonged GC response remains in the homeostatic overload range, wear and tear should continue to occur (Figure 38.4E). The threshold between *predictive homeostasis range* and homeostatic overload will decrease, until actually becoming lower than the predictive homeostasis range itself. In this situation, very low GC levels will fall into the homeostatic failure range, where normal homeostasis cannot be maintained, and death should follow. The Reactive Scope Model further provides predictions for how long GC levels can remain in the homeostatic overload range until collapse will occur. Examples of chronic malnutrition, changes in social status, and lifelong allostatic changes resulting from early life experiences are provided in the original formulation of the Reactive Scope Model (Romero et al., 2009), establishing comparisons to the Allostasis Model and highlighting the benefits of an alternative interpretation for scenarios that generate enormous interest for both biomedical researchers and ecologists. The Reactive Scope Model provides, for example, a new framework to understand the concept of eustress (Selye, 1976), and those changes that occur during development that can reset an animal's reactive scope resulting in lower (rather than higher) vulnerability to enter homeostatic overload later in life, a concept that challenges traditional models (Saino et al., 2005). Finally, note that despite the fact that considerable empirical grounds led to the formulation of both the Allostasis Model and the Reactive Scope Model, these are still today largely theoretical paradigms, requiring experimental demonstration in free-living animals under diverse ecological scenarios (Romero, 2012; DuRant et al., 2016).

- The Reactive Scope Model is an extension of the Allostasis Model and is presented as a graphical tool for characterizing the physiological state of individuals according to the levels of mediators (e.g., circulating corticosterone titers) rather than energy levels.
- The combination of the two adaptive corticosterone ranges of a healthy animal (i.e., predictive and reactive homeostasis ranges) form the normal reactive scope of the individual. Corticosterone levels above and below the reactive scope cause serious pathologies. Therefore, the reactive scope defines the upper and lower physiological constraints of a healthy individual.
- In response to unpredictable perturbations, GC levels rapidly elevate into the reactive homeostasis range during a "stress response." Even when GC elevations do not reach homeostatic overload to cause pathology, as the individual continues to respond to sequential or prolonged perturbations GC levels will exert wear and tear.
- Wear and tear is defined as the cost of maintaining and using the physiological systems that mediate allostasis and can be graphically depicted as a decreased threshold level between the reactive homeostasis range and homeostatic overload (and therefore a decreased reactive scope).
- Wear and tear implies a gradual decrease in the ability to cope with perturbations. This concept is different from pathology: GCs themselves are not causing damage, but increase the likelihood of damage due to a progressively decreased reactive scope. Wear and tear illustrates why equivalent GC responses might be adaptive early, but cause problems later.
- The Reactive Scope Model proposes two ways of reaching homeostatic overload: (1) either GC levels extend beyond the normal reactive scope and cause pathology; or (2) GC levels remain in the reactive homeostasis range for an extended period, but wear and tear "shrinks" the reactive scope of the individual, increasing the likelihood of pathology.
- The Reactive Scope Model, like the Allostatis Model, is still a largely theoretical graphical tool requiring empirical demonstrations.

38.3 Adrenocortical response to environmental change

A cornerstone question for evolutionary biologists and field endocrinologists is: How do birds respond and adapt to an ever-changing environment? There is a large amount of evidence that the mechanisms by which birds perceive potential challenges and transduce this information into neuronal and endocrine responses are fundamentally different when facing predictable versus unpredictable environmental events (Wingfield, 2013a). In this section, we will characterize the unpredictable events of the environment (the perturbations), especially those that disrupt the normal life cycle, and will summarize the adrenocortical responses that allow adaptive orchestration of facultative physiological and behavioral mechanisms aimed at maximizing fitness. The frequency and severity of disturbances is expected to increase dramatically during the coming decades through the concerted action of climate change and anthropogenic pressures, imposing severe and novel challenges for many biota through exposure to rapidly changing conditions never experienced in the preceding millennia (Sergio et al., 2018). This subject is critically relevant for basic and conservation-oriented research because human-induced perturbations can generate similar adrenocortical

responses to natural stressors and the individuals' inability to cope will likely precede many extinction processes.

38.3.1 Predictable versus unpredictable environmental change

As we have previously pointed out, some seasonality in climatic, biological, and social conditions exists to different degrees in all avian habitats, and birds have evolved mechanisms to organize their life cycles in synchrony with other individuals and the predictable environment. Internal and external (temperature, photoperiod, rainfall, social interactions) environmental cues allow anticipatory adjustments of major life history events (Wingfield, 2008). Individuals can thus prepare for energetically demanding times of year such as a cold and rainy winter or a hot and dry season, and GC levels will fluctuate within a baseline range. Regardless of how challenging local conditions may appear to the human eye, GCs do not elevate into stress-induced levels in response to the predictable environment: such conditions are not perturbations from the bird's perspective. For example, American goldfinches (*Carduelis tristis*) do not elevate GC levels in winter despite exposure to severe weather and temperatures below −20°C (Dawson et al., 1991), and adult king penguins (*Aptenodytes patagonica*) fast for weeks, relying on their fat stores during the austral winters without necessarily increasing circulating GCs (Cherel et al., 1988). Extreme cold and lack of food constitute, within certain limits, the normal environmental conditions under which these two species evolved their life cycles. However, there is no habitat subjected to perfectly foreseeable changes. Sudden severe storms outside the expected season, attacks from predators or dominant individuals, human disturbance, and parasites or disease are generally not predictable and have the potential to disrupt the life cycle of the individual, potentially causing death. Unpredictable events in the environment are generally termed perturbations or stressors. These could be characterized in the light of the Allostasis Model described earlier (Section 38.3.1), across a gradient of increased energy demands (allostatic load), and their effects (allostasis) in terms of GC secretion and subsequent adjustments of LHSs, which should depend on the energy available to each particular individual at each particular moment (see Figure 3 in Landys et al., 2006). The fact than some types of perturbations eventually bring the individual into allostatic overload makes a qualitative difference for the role of circulating GCs in behavior and physiology, as will be discussed below. A widely accepted classification for the types of perturbations is provided by Wingfield (2013a; see also Wingfield and Romero, 2001), who proposes discriminating between labile (short-term, transient) and permanent (long-term, modifying) perturbation factors. *Labile perturbation factors* (*LPFs*) are in turn roughly divided into two major groups: *indirect LPFs* (lasting seconds to a few minutes) and direct LPFs (lasting minutes to hours). The formulation for this classification takes into account the duration of the unpredictable stimuli, the actual duration of the adrenocortical response, and its resulting effects on the normal progression of the individual's life cycle (all of these factors combined). Figure 38.5 synthesizes information about these parameters and provides examples for ease of interpretation of the text below.

- The mechanisms by which birds perceive potential environmental challenges and transduce this information into endocrine responses are fundamentally different when facing predictable versus unpredictable events.
- Regardless of how challenging local conditions may appear to the human eye, birds' circulating corticosterone levels do not elevate into stress-induced levels in response to the predictable environment.
- Unpredictable and potentially noxious events in the environment are termed perturbations (or stressors), resulting in stress-induced corticosterone elevations.
- Perturbations can be classified as either (1) LPFs (short-term, transient) or (2) permanent perturbations (long-term, also called modifying factors). LPFs can in turn be classified in two major groups: indirect LPFs (lasting seconds to a few minutes) and direct LPFs (lasting minutes to hours).
- This classification takes into account the duration of the unpredictable stimuli, the duration of the associated adrenocortical response, and the resulting effects on the normal progression of the individual's life cycle.

38.3.2 Indirect, labile (short-term) perturbations

Indirect LPFs are very short-lived perturbations, lasting seconds to a few minutes and have little or no long-term effects on an individual (as long as it manages to rapidly survive the sudden exposure to noxious stimuli). Examples may include a predator chase, a conspecific agonistic interaction, the loss of nest/offspring to a short severe storm, or a brief human disturbance. Here a "flight or fight" response is typically triggered with little or no elevation of GCs into the reactive homeostasis range, and resumption of normal activities (e.g., social behavior, renesting) takes place within minutes to hours (Figure 38.5). The *flight or fight response* implies stimulation of the cholinergic sympathetic fibers that innervate the chromaffin tissue of the adrenal, causing the local release of acetylcholine, which triggers the release of predominately epinephrine in the blood. This rapid allostatic response promotes increased heart rate, vasodilation of arterioles in skeletal muscle, general venoconstriction, relaxation of bronchiolar muscles, pupilar dilation,

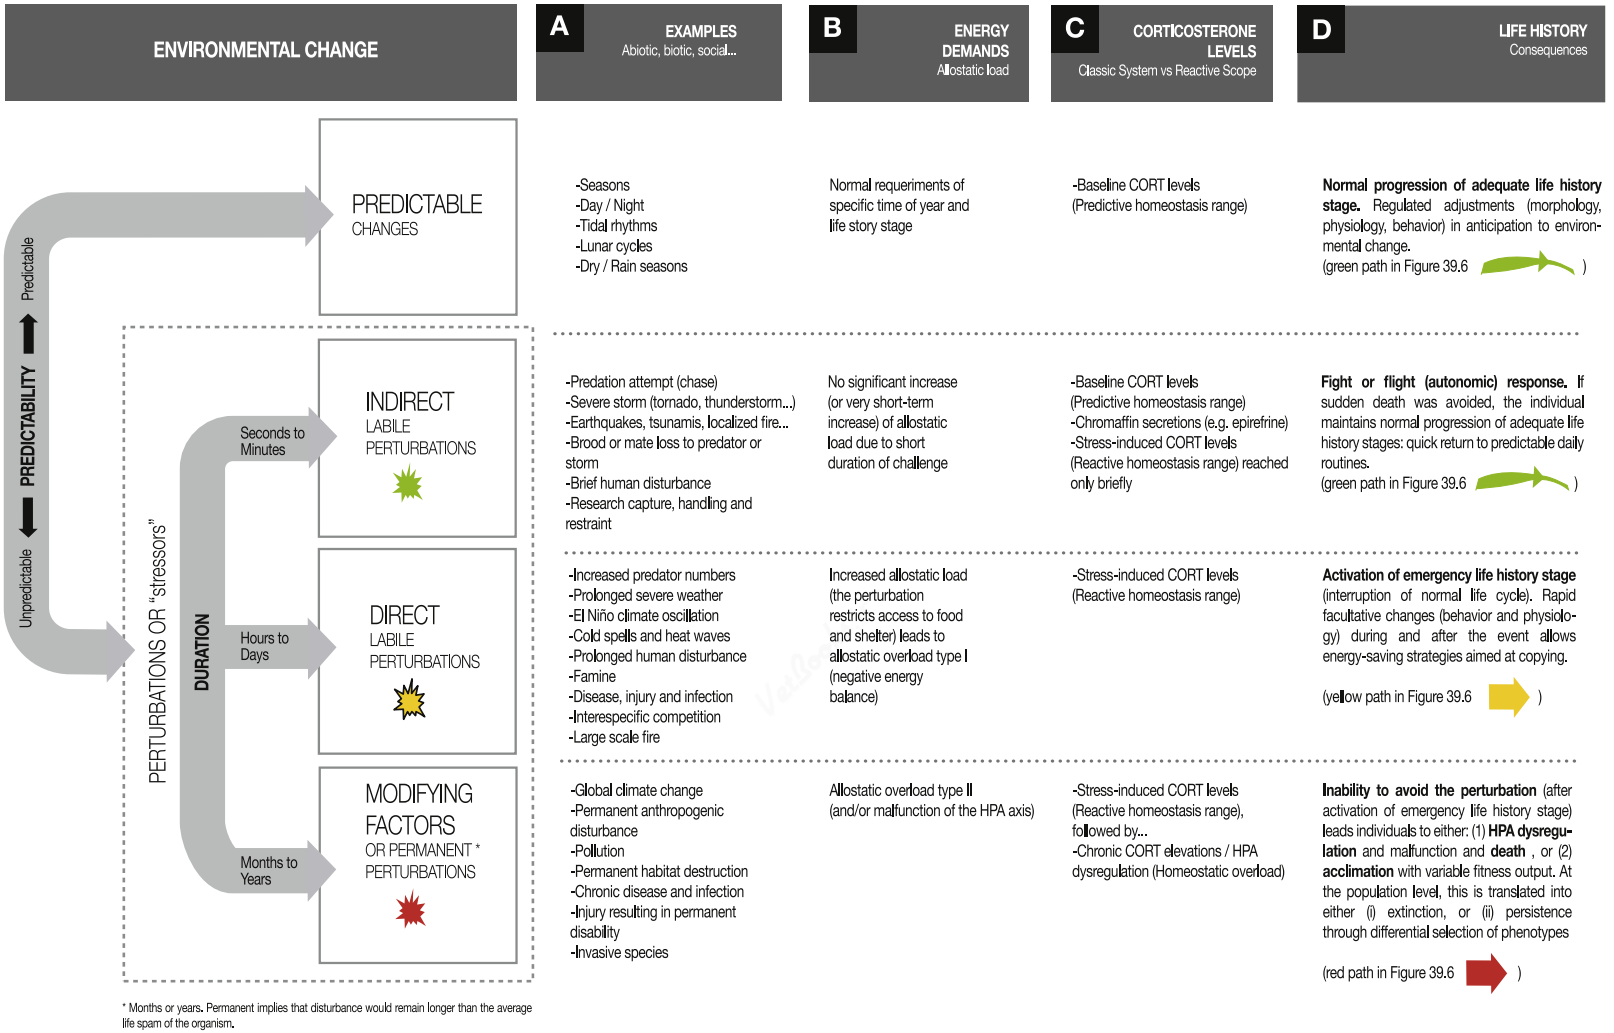

FIGURE 38.5 **Environmental change and individual responses.** Characterization of environmental change and corresponding energy, adrenocortical and life-history responses. Environmental changes can be predictable, or otherwise are termed "perturbations" or "stressors" (column A lists potential examples). Perturbations can be classified as either labile (short-term, transient) or permanent (long-term, *modifying factors*). Labile perturbation factors (LPFs) are in turn roughly divided into two major groups: indirect LPF (lasting seconds to a few minutes) and direct LPF (lasting minutes to hours). The formulation for this accepted classification takes into account not only the duration of the unpredictable noxious stimuli but also the energy demands (allostatic load) imposed on the individual (column B), the actual elevation of GC titers (column C), and the resulting effects on the normal progression of the individual's life cycle (column D). The fact that some types of perturbations may bring the individual into allostatic overload makes a qualitative difference for the actions of circulating glucocorticoid, which may trigger an emergency life history stage (adaptive response) aimed at avoiding the perturbation, or create permanent damage if the individual does not habituate to permanent stressors. *Credit: Figure created by the authors of this chapter after Wingfield (2013a), expanded to incorporate biotic and social examples from other sources and to implement concepts from the Allostatis Model and the Reactive Scope Model.*

piloerection, and (very importantly) mobilization of liver glycogen and free fatty acids (Axelrod and Reisine, 1984; Romero et al., 2009). Only if the perturbation persists beyond the first few minutes will the adrenocortical response be activated. Then an elevation of *corticotropin* (ACTH) secretion from the anterior pituitary (adenohypophysis) will trigger the increase of circulating GC levels into the reactive homeostasis range (Figure 38.1; see details for the complete cascade of hormonal secretions in Chapter 33). Sustained elevation of GCs into stress-induced levels marks the short-term response. At this point, the individual will require additional energy resources to cope with the noxious stimuli. Even though the perturbation is still short-term or labile, after a few minutes, it will only be considered indirect if the individual readily resumes its normal life cycle when the perturbation is over. For example, the experimental capture, restraint, and serial blood sampling protocol that is routinely applied to quantify adrenocortical responses in wild birds (Section 38.5.1; Box 38.1) typically lasts 30 to 60 min. Birds during this protocol elevate circulating GCs into stress-induced levels, but they typically resume normal activities (e.g., nest attendance) within minutes following release. Capture and blood sampling would not be considered an indirect LPF according to its duration and associated GC elevations (allostatic responses need to go beyond the flight or fight, autonomic response), but this event does not qualify as a direct perturbation (see below), provided a fast resumption of normal life cycle activities and no apparent energy imbalance.

- Indirect LPFs are short-lived, lasting seconds to a few minutes and have little or no long-term effects on an individual. Examples include short predator chases, agonistic interactions, the loss of nest/offspring to a short severe storm, and brief human disturbance.
- Indirect LPFs elicit a flight or fight response largely mediated by the sympathetic nervous system, with little or no elevation of GCs into stress-induced levels. Resumption of normal activities takes place within minutes to hours.

38.3.3 Direct, labile (short-term) perturbations and the "emergency life history stage"

Direct LPFs are perturbations lasting hours or days, imposing high-energetic demands and resulting in a temporary disruption of the normal life cycle (for example, resulting in brood desertion). Potential examples include exposure to prolonged severe weather, strong intra- or interspecific competition for food or shelter, increased number of predators, reduced food resources, pollution, and prolonged human disturbance (Figure 38.5A). The cumulative allostatic load brings the individual into negative energy balance (allostatic overload Type 1), and the individual redirects physiology and behavior into a facultative mode known as the *ELHS* (Wingfield et al., 1998). Figure 38.6 illustrates a sequence of life history events of a model avian species. Under normal conditions (in the absence of perturbations), the life cycle of a bird is composed of a finite number of *LHSs*: winter or nonbreeding, breeding, and moult (depending on the species there could be more, and include, for example, migration). The temporal sequence of LHSs varies from species to species and each stage is expressed at a particular time of year for which it has evolved to maximize fitness (Jacobs and Wingfield, 2000). Each LHS has a varying number of unique substages (for example, the breeding stage involves gonadal maturation, courtship, ovulation, etc.) following a specific "one-way" sequence. The development of each stage and the sequential transitions between stages are regulated by endocrine secretions, which follow predictable environmental cues such as the annual photocycle and allow adequate stage-specific changes in physiology, morphology, and behavior in anticipation of energy demands (i.e., as dictated by the predictable portion of environmental change). In contrast, exposure to a direct LPF (represented with a yellow star symbol) can occur at any time and it will trigger a facultative "emergency stage" (the ELHS) at any point of the life cycle. The substages within an ELHS are remarkably consistent in all bird species studied to date, and serve first to redirect the individual into a survival mode and then to allow it to return to the normal LHS once the perturbation passes. The behavioral and physiological components that make up the substages of an ELHS (Wingfield and Kitaysky, 2002; Wingfield and Romero, 2001) are:

1. Deactivation of territorial behavior or social hierarchies in the home range of a group.
2. Adoption of one of the following alternative strategies: (A) "leave it" strategy: movement away from the direct LPFs; (B) "take it" strategy: switch to an alternate set of energy-conserving behavioral and physiological traits; or (C) "take it at first, and then leave it" strategy: switch to energy-conserving mode first, and then move away if conditions do not improve.
3. Once a strategy has been adopted, mobilization of stored energy (fat and protein) to fuel movement away, or finding refuge and endure while sheltering.
4. Finally, once the direct LPF passes (or the individual evades), the individual must settle in an alternative habitat if an appropriate site is located or return to the original site and resume the normal sequence of LHSs (returning to the most appropriate for that time of year, whether it is the same as before the perturbation or any other; see thin green arrows in Figure 38.6).

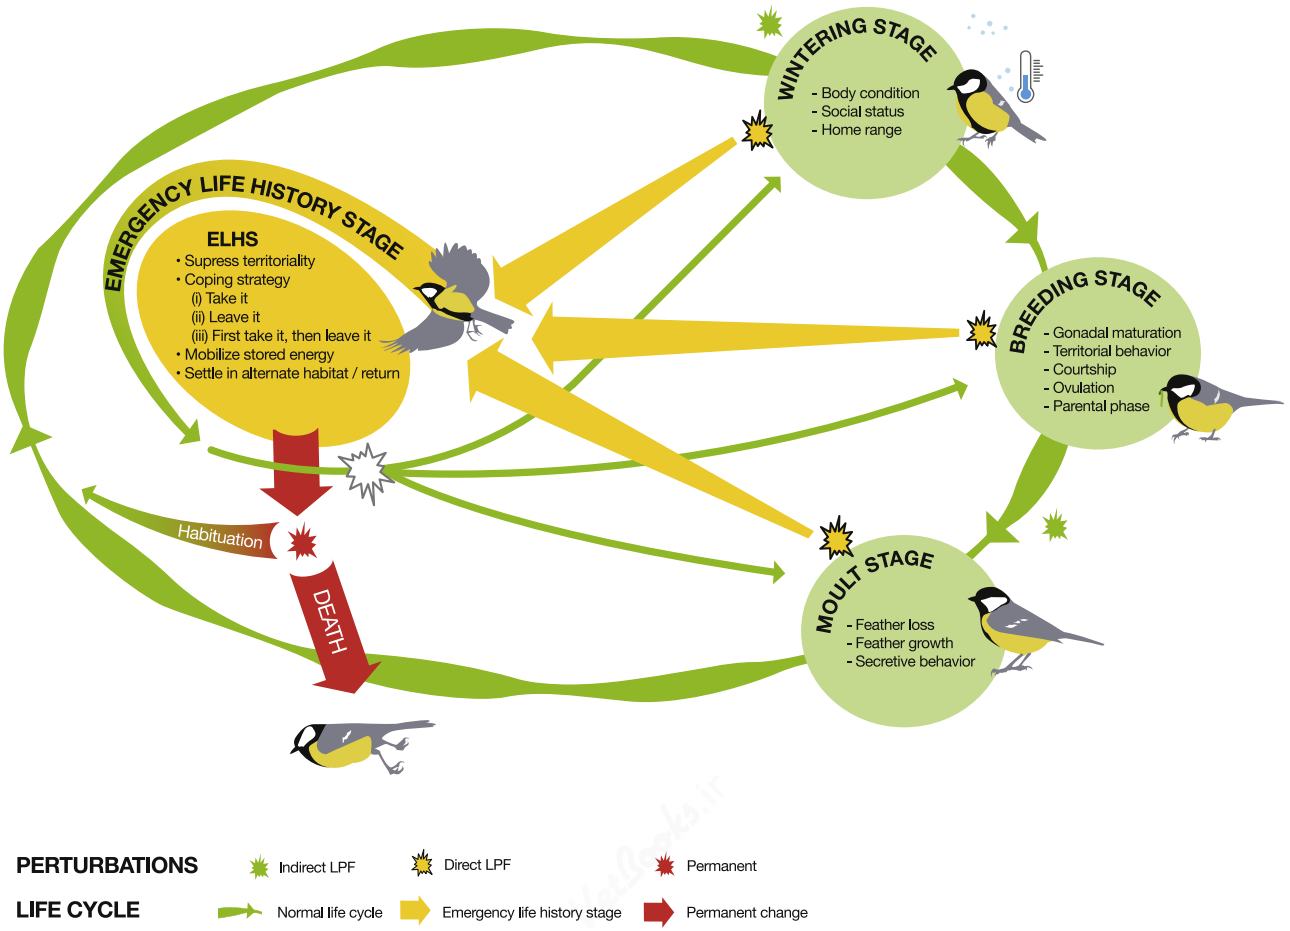

FIGURE 38.6 **The emergency life history stage.** Schematic representation of the facultative emergency life history stage (ELHS) within the life cycle of a hypothetical model avian species. The normal cycle is composed of a finite number of life history stages (LHSs) (*green boxes*) occurring in a specific, nonreversible, sequence (one-way path of *arrows*). This sequence has evolved to maximize individual fitness, and each LHS occurs at specific times of the year, when and where the environmental and social conditions are likely most adequate to use the energy available for specific life tasks. Each LHS is composed of a number of substages in a preset sequence (e.g., breeding stage: gonadal maturation, territory acquisition, etc.). Unpredictable perturbations of different magnitudes and duration (*star symbols*) may occur at any time of the year. When overcoming a perturbation requires a relatively small energy investment (e.g., response to a short predator chase), they are termed indirect labile perturbations (*green stars*), which trigger the autonomous "flight or fight" response, result in short-term or no elevations of circulating GC and allow the individual to continue its normal life cycle. However, labile perturbations may last hours or days (e.g., increased predator numbers) and demand larger energy investments for survival. They are then termed direct labile perturbations (*yellow stars*), and trigger considerable elevation of GC levels above the normal baseline into stress-induced levels. These perturbations redirect the individual's life cycle into a facultative ELHS (yellow path) aimed at coping with the increased allostatic load and survival at the expense of temporarily suppressing the normal life cycle. The marked GC elevations (see the thicker width of the *dashed yellow arrows*) promote dramatic changes in physiology and behavior, including the use of lipid and protein stores as energy to survive while sheltering or moving away (e.g., during irruptive avian migrations). Once the perturbation is over or the individual relocates, circulating GC levels return to baseline range and the individual returns to the most appropriate LHS, which may or may not be the one when the perturbation occurred (see the thinner width of the *green arrows* as they return to the *green boxes*). Perturbations, however, may not always subside (e.g., habitat destruction, climate change) eventually becoming long-term or permanent (*red stars*). If the individual cannot avoid a permanent perturbation, long-term or chronic GC elevations (*red path*) can cause deleterious effects on the organism and eventually result in death. Alternatively, individuals may habituate to the perturbation, but fitness and normal progression of LHSs would only be achieved if GC function returns to normal levels. *Credit: Figure modified and expanded after Wingfield and Kitaysky (2002).*

Such dramatic changes in behavior and physiology can occur within minutes to hours of exposure to direct LPFs, and a combination of laboratory experiments and field studies indicates that the elevation and maintenance of GC levels above seasonal baseline, and into stress-induced levels, underlies this facultative ELHS (Figure 38.6). A few examples follow (for additional examples, see Wingfield and Romero, 2001; Wingfield and Kitaysky, 2002; Wingfield et al., 2011; Wilsterman et al., 2020). Young but not adult European blackbirds (*Turdus merula*) migrated southwards when exposed to a severe weather event (direct LPF) in Germany that resulted in snow and ice covering their winter feeding grounds. The energy demanded by digging for food likely exceeded the EG, but

only among unexperienced, first year individuals. As predicted, the group of young, unexperienced birds that left the regular wintering areas showed concomitant elevations of circulating corticosterone levels compared to nonmigrating adults (Schwabl et al., 1985). There are similar studies linking unusually severe winter weather (a direct LPF) to elevated corticosterone levels and irruptive migrations (a "leave it" ELHS strategy) in ground-feeding birds because the snow covering food resources may impose an unpredictable and considerable increase to allostatic load. North America, dark-eyed juncos (*Junco hyemalis*) showed significantly higher plasma corticosterone levels during a severe snowstorm compared to before or after it; circulating GC levels were highest when home ranges were abandoned and lower when the birds found refuge after the storm (Rogers et al., 1993). In contrast, Harris's sparrows (*Zonotrichia querula*) became inactive to ride out a severe winter storm (a "take it" strategy), but also showed concomitant elevations of circulating corticosterone (Rohwer and Wingfield, 1981). Note that the influences of inclement weather on the ELHS depend upon the severity of the storm and when it occurs. Considering studies during the reproductive season, white-crowned sparrows (*Zonotrichia leucophris pugetensis*) delay the onset of breeding without elevating corticosterone levels if severe weather occurs before egg laying. This suggests that storms early in the season do not qualify as LPFs, and that they rather act as supplementary information (predictive environmental change) to fine-tune gonadal development. Alternatively, it is possible that the energy demands for that time of the year were low compared to the energy available in the environment plus the body reserves, allowing individuals to cope with a perturbation without triggering GC elevations above baseline range. However, during incubation and chick brooding, the additional energetic costs associated with these normal LHSs increase vulnerability to perturbations, and equivalent severe storms result in elevated corticosterone levels and the abandonment of nest and territory, which are typical examples of a "leave it" strategy within the ELHS (Wingfield, 1984). Because sex roles during reproduction impose different allostatic loads for males and females in many bird species, we may also expect that a given LPF should differentially trigger corticosterone elevations and an ELHS depending on the energy invested by each sex in each substage. For example, territory acquisition is largely a male role in raptors. Male black kites (*Milvus migrans*) likely face higher allostatic loads compared to females at the start of the breeding season, and they showed higher corticosterone elevations in response to the experimental LPF of capture and restraint (Blas et al., 2011). Allostatic load should be even higher among young males because they rely on the competitive displacement of an older male to initiate breeding; as expected, corticosterone levels following capture and restraint were higher in young compared to older males. This pattern was reversed among females, because young, floating individuals incur neither the allostatic loads of competition for territories nor the energy demands for egg formation: young females showed the lowest levels of corticosterone after exposure to capture, handling, and restraint and likely the lowest susceptibility to trigger an ELHS in response to perturbations (Blas et al., 2011). The effect of sex roles on the susceptibility to LPF has also been suggested in white-crowned sparrows. Severe weather may affect females more than males during the incubation period because males do not incubate, but a storm during the fledging phase would affect males more, as their parental effort is at its highest point (Wingfield, 1984; Wingfield et al., 1983). Here it is worth mentioning that although some LHSs and substages are energetically demanding (e.g., territory acquisition, incubation, and brooding), they are totally predictable and do not generate GC elevations into the reactive homeostasis range per se. However, because these life cycle activities increase allostatic load, they can generate a greater susceptibility to elevate GCs into stress-induced levels after exposure to unpredictable perturbations (and therefore a greater susceptibility to enter ELHS). The examples above indicate that stress-induced GC elevations underlie activation on the ELHS, but additional field and laboratory experiments (many of which include experimental manipulations of systemic GC titers) have allowed a more precise characterization of GC actions on the particular behavioral and physiological traits that make up the substages of an ELHS. We will briefly comment on some of these GC actions occurring within stress-induced range (i.e., those that accompany life-threatening perturbations). However, it is important to note that GC actions at the lower range that characterizes daily and seasonal life processes (that is, within baseline levels) can modify the same traits in different and even opposite ways. These aspects are thoroughly reviewed elsewhere (Landys et al., 2006; Wingfield and Romero, 2001). Major GC actions at stress-induced levels include:

1. Increased protein catabolism and gluconeogenesis: Administration of exogenous GCs to mimic stress-induced levels induces protein loss and muscle atrophy in a variety of avian species. For example, domestic fowls (*Gallus gallus*) respond to corticosterone treatment showing a rapid elevation of plasma uric acid, a byproduct of amino acid breakdown (Saadoun et al., 1987). In house sparrows (*Passer domesticus*), corticosterone implants decrease the mass of pectoralis muscles, but differentially promote catabolism of the soluble (sarcoplasmatic) protein fraction rather than contractile (myofibrilar) components, which allows maintenance of flight capabilities (Honey, 1990). By making available amino acids, reactive GC levels

support increased allostatic load through indirect provisioning of intermediates for the citric acid cycle and substrates for hepatic gluconeogenesis.

2. Increased availability of lipid energy from adipose tissue stores (Dallman et al., 1993): Stored triglycerides may be released as free fatty acids, through either an increase of triglyceride breakdown or a decrease in the rate of re-esterification. In addition, elevated GCs seem to support enzymatic mechanisms that allow delivery of fatty acids to working tissues (Mantha and Deshaies, 2000; Landys et al., 2006, and citations therein). Note that artificial elevation of GC levels may also result in increased fat depots when the experimental animals are in positive energy balance (Wingfield and Silverin, 1986).
3. Decreased body mass: Exogenous corticosterone elevations inhibit weight gain in, for example, house sparrows and rufous hummingbirds (*Selasphorus rufus*) (Honey, 1990; Hiebert et al., 2000). Mass loss might be a consequence of the two metabolic effects described above (increased energy mobilization) plus a decreased maintenance of structural tissues.
4. Modulated locomotor activity: For example, white-crowned sparrows show a rapid increase in activity after corticosterone ingestion (Breuner et al., 1998). This effect likely depends on GC concentration: while moderate elevations promote intense activity (a "leave it" ELHS strategy), very high doses may actually stimulate inactivity (a "take it" strategy; Wingfield and Ramenofsky, 1999). In addition, energy availability seems to modulate this response: while corticosterone implants increase activity in fasting birds, they decrease activity when food is ad libitum (Astheimer et al., 1992). Both the dose- and the context-dependent effects of GC elevations match the expected behavioral responses under an ELHS: when the LPF does not reduce food resources, it may be adaptive to "take it," but if the perturbation persists then a reduction of the available energy (food) would trigger higher GC elevations and a "leave it" strategy aimed at searching for energy somewhere else. GC effects on locomotor activity may be particularly relevant in avian species adapted to severe habitats such as deserts or high latitudes, which show irruptive movements in response to LPF (Wingfield and Ramenofsky, 1997). Note, however, that seasonal GC levels are typically elevated during those LHSs that demand high-physical activity such as migration and dispersal (Landys-Ciannelli et al., 2002; Belthoff and Dufty, 1998), but these effects occur within baseline range.
5. Increased food intake: Although some studies propose that GCs regulate feeding rate in a permissive capacity (Dallman et al., 1993), recent research suggest that this effect is mediated through a threshold action of GC receptors rather than by the extent of GC elevations above the seasonal baseline (see details in Landys et al., 2006). There is ample correlational evidence that foraging activities are normally highest during the times of day when baseline GC levels are maximal (e.g., López-Jiménez et al., 2016a), and that feeding intensity can be shifted by corticosterone manipulations (Dallman et al., 1993), but again, these effects occur within baseline range.
6. Suppressed territorial and reproductive behavior: For example, male song sparrows (*Melospiza melodia*) reduce territorial aggression when treated with exogenous corticosterone (Wingfield and Silverin, 1986). Similarly, free-living pied flycatchers (*Ficedula hypoleuca*) decrease the rate of feeding nestlings when treated with exogenous corticosterone (bringing a concomitant decrease in nestlings' body condition and survival), and even cease all reproductive activities (abandoning the nest and the acquired territories) when given high-dose GC implants (Silverin, 1986).
7. Increased night restfulness: Exogenous corticosterone administration in captive white-crowned sparrows and pine siskins (*Spinus spinus*) result in a uniformly low-oxygen consumption pattern, with an estimated 20% energy savings overnight compared with controls (Buttemer et al., 1991). However, similar treatment applied to other species yielded contradictory results (Palokangas and Hissa, 1971), likely because GC-induced gluconeogenesis also affects metabolic rate and thus oxygen consumption (Jimeno et al., 2018). Corticosterone administration to rufous hummingbirds results in nocturnal torpor, a form of seeking refuge ("take it") strategy that these birds acquire through decreasing body temperature (Hiebert et al., 2000).

Summarizing, GC elevations into the stress-induced range, which are typically several-fold higher than the seasonal baseline, allow critical changes in physiology and behavior aimed at coping with LPFs and thus have adaptive value in maximizing survival and lifetime reproductive success, even at the cost of a temporary suppression of the life cycle. Once the direct LPF is over or the individual relocates, circulating GC levels normally decrease back to baseline range and the individual returns to the most appropriate LHS, which may or may not be the one when the perturbation occurred. Perturbations, however, may not always subside and eventually they may become long-term or permanent (for example, habitat destruction and climate change). Then, they are termed modifying factors.

- Direct LPFs last hours or days, impose high-energetic demands (allostatic load), and result in a temporary disruption of the normal life cycle. Examples include exposure to prolonged severe weather, intraspecific

competition, increased predation pressure, reduced food resources, and prolonged human disturbance.

- The cumulative allostatic load imposed on the individual brings a negative energy balance (allostatic overload Type 1), and the individual redirects physiology and behavior into a facultative LHS known as the ELHS. Such an emergency stage is largely driven by the elevation and maintenance of GC levels above seasonal baseline and into stress-induced levels.
- Stress-induced corticosterone elevations range during an ELHS promote (1) increased protein metabolism and gluconeogenesis, (2) availability of lipid energy from adipose tissue stores, (3) decreased body mass, (4) changes in locomotor activity and foraging, (5) suppression of territorial and reproductive behavior, and (6) increased night restfulness. These corticosterone-mediated changes in physiology and behavior have adaptive value, maximizing individual fitness at the cost of a temporary suppression of the life cycle.
- Once the direct LPF is over or the individual relocates, circulating GC levels normally return to baseline range and the individual returns to normal LHSs.

38.3.4 Permanent (long-term) perturbations or "modifying factors"

Modifying factors are *permanent perturbations* lasting months to years (they are termed "permanent" because the disturbance may remain longer than the average lifespan of the organism), when they impose high-energetic demands upon the individual and result in a permanent disruption, even disintegration of the normal life cycle (Wingfield and Romero, 2001; Wingfield, 2013a). Potential examples include chronic disease and infection (e.g., high-parasite load), injury resulting in permanent disability, global climate change, and sustained anthropogenic disturbance (Figure 38.5A). The cumulative allostatic load imposed on the individual may bring a negative energy balance, leading to death if a prior activation of the ELHS did not result in evasion of the perturbation (for example, when relocation was not possible). Here the sustained long-term GC elevations into stress-induced levels exert wear and tear (see Section 38.2.3), resulting in deleterious effects on critical body systems, including inhibition of gonadotropin secretion and cessation of reproductive function (e.g., delay of puberty onset, gonadal involution), suppressed secretion of growth hormone (e.g., stress-induced dwarfism), complete breakdown of the skeletal muscle (e.g., suppressed flight and movement capabilities), suppression of T-lymphocyte response to infections (increasing susceptibility to disease), severe neuron loss in the hippocampus through impaired glutamate and calcium regulation, and decreased generation of arachidonic acid (for a review of effects, see Sapolsky, 1996; Wingfield and Romero, 2001; Romero et al., 2009). In contrast to the highly adaptive GC responses that characterize the ELHS, chronic GC elevations lack adaptive value Wingfield et al., (2017). Note also that, at a given point, chronic GC exposure will bring a disruption of the HPA axis, and the deleterious effects on the organism may occur even if the long-term perturbation subsides and the energy available in the environment becomes above the energy needs of a healthy individual (this will be equivalent to *allostatic overload Type 2*, to a critically reduced reactive scope generated by wear and tear, or to the ecological scenarios of social stress that we have already mentioned). Pollution is also considered a type of modifying factor, but its impact on avian adrenocortical function has been subjected to scarce research and there is a great need for field investigations (Baos et al., 2006; Baos and Blas, 2009; Meillère et al., 2016). A critical point regarding the effects of modifying factors is that not all the individuals within a population perceive and respond to perturbations in the same way. As a consequence, under particular scenarios (which should depend on the species and the type of perturbation), it is possible that even a drastic initial response to modifying factors (e.g., disappearance of a fraction of the population through death or emigration) is followed by a recovery through differential selection of the more tolerant phenotypes (Blas et al., 2007; Cockrem, 2007). In other words, perturbations may become selective pressures, potentially allowing adaptation. For example, burrowing owls (*Athene cunicularia*) living in urban environments showed reduced stress-induced corticosterone levels compared to rural conspecifics (Palma et al., 2020). These results suggested that only individuals expressing low HPA axis responses can thrive in cities. Population persistence could occur provided that (1) there exists some genetic variability in the response to stress, whereby specific genotypes do not activate adrenocortical responses to that specific perturbation; (2) individuals acclimate to that particular perturbation, progressively reducing their adrenocortical responses and surviving without permanent activation of the HPA axis; or (3) epigenetic effects (e.g., maternal programming) reduce the impact of the perturbation through modifying the offspring's adrenocortical responses. Unintentional artificial selection on HPA axis traits has been suggested during capture, initial acclimation, and captivity in two bird species with several invasive populations originating from the international trade in wild-caught pets: the African weavers (*Ploceus melanocephalus*) and (*Euplectes afer*) (Baños-Villalba et al., 2021). The initial acclimation and captivity that followed capture favored the differential survival of individuals with reduced feather corticosterone levels, potentially influencing the invasiveness and impact of introduced populations, and the success of biological

invasions (a global problem with large negative impacts on ecosystems and human societies).

- Permanent perturbations (also called modifying factors) last months or years, imposing high-energetic demands and resulting in a permanent disruption of life cycles. Potential examples include chronic disease and infection, global climate change, and sustained anthropogenic disturbance (e.g., urbanization and habitat destruction).
- After the initial activation of the ELHS, inability to evade the perturbation implies that the cumulated allostatic load will bring the individual into a negative energy balance, and death may follow.
- The sustained long-term GC elevations exert wear and tear, reaching the homeostatic overload range and resulting in deleterious effects on critical body systems, including (1) inhibition of gonadotropin secretion and cessation of reproductive function, (2) suppressed secretion of growth hormone, (3) complete breakdown of the skeletal muscle, (4) suppression of immune system, and (5) neuronal death.
- Modifying factors can lead to population extinctions. However, population persistence through local adaptations could also potentially occur if genetic variability and phenotypic plasticity in the response to stress allow a differential survival of stress-resistant individuals.

38.4 Phenotypic plasticity and selection on the stress response

Avian speciation has taken place under contrasting environmental scenarios (e.g., from deserts to poles), and adrenocortical responses have evolved in parallel, shaped by the prevailing perturbation factors and likely explaining the strong interspecies variability. Within a given species, different subspecies, races, morphs, and even populations have been reported to differ in the patterns of adrenocortical secretion (Wingfield and Romero, 2001). On the one hand, such variability reveals a genetic basis that controls HPA function and, for example, has allowed humans to domesticate wild animals and generate phenotypes with reduced corticosterone reactivity through artificial selection (Keith et al., 1973; Satterlee et al., 2000; Løtvedt et al., 2017). In addition to such genetically determined patterns, the adrenocortical response to stress shows a strong phenotypic plasticity. For example, the environmental conditions experienced early in life can prime lifelong differences in the patterns of adrenocortical responses, revealing epigenetic patterns that may be adaptive (Love et al., 2013; Jimeno et al., 2019). Furthermore, individuals often show the ability to modulate their adrenocortical response according to the specific requirements characterizing different LHSs, thereby maximizing the cost-benefit balance associated with the actions of corticosterone on behavior and physiology (Lendvai et al., 2007; Walker et al., 2015). Phenotypic plasticity is also manifested when repeated exposure to the same perturbations provoke gradual changes in adrenocortical function, revealing that experience-related patterns occur through acclimation, and highlighting the close connection between cognition (i.e., an individual's perception of a potential threat) and the adrenal response (Cyr and Romero, 2009). Overall, the HPA axis shows all the features of a trait subjected to natural selection (Love et al., 2013; Cockrem, 2013; Hau et al., 2016): large individual variation (Williams, 2008; Cockrem, 2013), repeatability under consistent conditions (Ouyang et al., 2011; Rensel and Schoech, 2011), heritability (comparable to that of other physiological traits; see Béziers et al., 2019 and references therein), and actual response to artificial selection (Satterlee and Johnson, 1988; Evans et al., 2006). It should be noted that the components of the HPA axis (i.e., baseline and stress-induced) may not be equally heritable, and the stress response likely shows greater adaptive potential (Jenkins et al., 2014; Homberger et al., 2015; Béziers et al., 2019).

- The HPA axis shows all the features of a trait subjected to natural selection: large individual variation, repeatability under consistent conditions, heritability, and response to artificial selection.
- Superimposed on genetically determined patterns, individuals show phenotypic plasticity in their responses to stress.

38.4.1 The stress response during development

Young birds display highly variable HPA responses during development (reviewed in Blas and Baos, 2008). On the one hand, interspecies differences reflect the wealth of variability in developmental strategies within the altricial-precocial spectrum (Figure 38.7A; Starck and Ricklefs, 1998). Although precocial species such as mallards (*Anas platyrhynchos,* which hatch with sight, covered with down, and can thermoregulate, locomote, and feed independently from parents) can elevate circulating corticosterone in response to human handling 1 day after hatching (Holmes et al., 1990), altricial species such as northern mockingbirds (*Mimus polyglottos*, which hatch blind, almost naked, and unable to thermoregulate or locomote) show little HPA response to the same stimuli during the first few days posthatch (Sims and Holberton, 2000), indicating a "*stress hyporesponsive period*." On the other hand, within a given developmental mode and species, HPA responses gradually increase as the individual grows and develops. For example, white storks (*Ciconia ciconia*), a semialtricial species, show very moderate GC responses to capture and handling until 20 days posthatching (Figure 38.7B), but the same type of experimental stimuli gradually elicit more

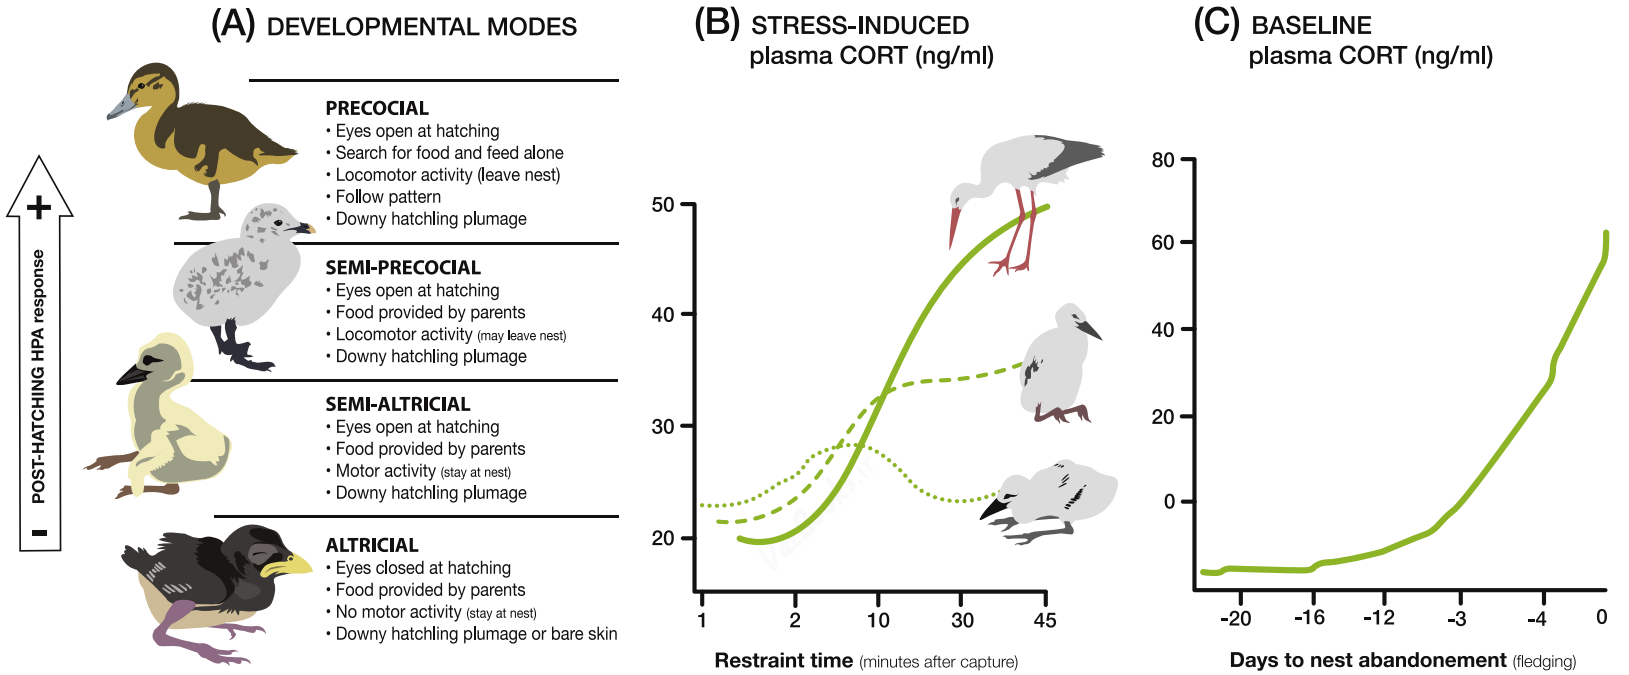

FIGURE 38.7 **The stress response during development.** Panel (A). Avian developmental modes span a gradient defined by two extremes: precocial and altricial species. Altricial species (e.g., Passeriformes, a house sparrow, *Passer domesticus*, in the drawing) hatch with closed eyes, lack of feather coat, have reduced motor capabilities, and are unable to thermoregulate or forage without parental care. Precocial species (e.g., Anseriformes; a mallard, *Anas platyrhynchos,* in the drawing) hatch in an advanced developmental stage, with open eyes, a feather coat, and independent foraging and locomotor capabilities. Intermediate developmental modes include semialtricial (e.g., a white stork, *Ciconia ciconia*) and semiprecocial species (e.g., a yellow-legged gull, *Larus michahellis*). The ability to respond to environmental and social perturbations through HPA function (e.g., ability to elevate corticosterone in response to capture and handling) increases across the developmental gradient of hatchlings: altricial species show a stress hyporesponsive period characterized by inability to show glucocorticoid elevations until days following hatching, while altricial species show robust HPA responses within 1 day posthatch. Panel (B). *Developmental changes in HPA function:* Within a given species (e.g., white storks), HPA function progressively increases during ontogenic development. The figure shows circulating corticosterone levels (*y*-axis) during the 45 min following capture and restraint (stress-induced levels) for three nestlings aged 24, 40, and 60 days old. Panel (C). *Transition from nestling to fledging stages*: Circulating baseline corticosterone levels are typically elevated shortly before hatching, fledging, and during dispersal, allowing birds to meet the increasing energy demands associated with ontogenic transitions. The figure shows baseline circulating corticosterone in thin-billed prion (*Pachyptila belcheri*) chicks, relative to the observed time of fledging ("0" on the x-axis). Note maximum corticosterone levels during the day prior to departure. *Credit: Composite figure based on Blas and Baos (2008), Blas et al. (2006a), Quillfeldt et al. (2007).*

robust corticosterone secretions as birds grow older, reaching maximal corticosterone secretion (resembling typical adult-like responses) near fledging (Blas et al., 2006a). In altricial passerines, a variety of species exhibit little or no stress-induced corticosterone response when youngest and the response gets progressively stronger throughout development (Rensel et al., 2010; Bebus et al., 2020).

The *Developmental Hypothesis* proposes that the patterns of maturation of HPA responses within and across species evolved to balance the costs and benefits of GC actions with the individual's progressive ability to overcome environmental perturbations (Blas and Baos, 2008). Two proximate hypotheses have been put forward to explain these patterns of age-related development on the ability to respond to stressors (Torres-Medina et al., 2019). On the one hand, a gradual growth and improved sensitivity of the HPA axis tissues may result in an increased ability to secrete corticosterone in response to stressors ("maturation hypothesis"). Alternatively, an age-related attenuation of the negative feedback system could gradually result in the developing bird being able to secrete increasingly more corticosterone as it grows older ("negative feedback attenuation hypothesis"). Limited experimental evidence to date supports the maturation hypothesis in semialtricial species (Torres-Medina et al., 2019), but more work is needed with species exhibiting different modes of development.

Regardless of the proximate mechanism, an inability to mount robust responses during initial developmental stages avoids exposure to high and prolonged GC levels, which reduces growth and impairs thyroid function and cognitive and competitive abilities (Schwabl, 1999; Kitaysky et al., 2003; Hayward and Wingfield, 2004). However, as the individual grows, its ability to show stress-induced responses acquires a critical adaptive value. For example, corticosterone elevations in nestling black-legged kittiwakes (*Rissa tridactyla*) at mid-developmental stages (15–20 days old) facilitate begging and aggression (Kitaysky et al., 2001, 2003), two behavioral responses highly advantageous to cope with food shortages early in life despite being still dependent on parental care.

In addition to a progressive, developmental increase in the ability to trigger robust HPA responses, baseline GC levels typically show age-related changes that serve to regulate ontogenic transitions across vertebrate taxa (reviewed in Wada, 2008). Baseline GC elevations promote maturation of critical organs and possibly control both the ability to hatch and the timing of fledging. For example, baseline corticosterone levels peaks around hatching in domestic fowls (*Gallus domesticus*; Carsia et al., 1987) and graylag geese (*Anser anser*; Frigerio et al., 2001), and exogenous corticosterone administration in turkey (*Meleagris gallopavo*) embryos two days before hatching significantly increases hatching success (Wentworth and Hussein, 1985). In white storks, baseline corticosterone levels increase prior to fledging (Corbel and Groscolas, 2008), and similar patterns have been found in American kestrels (*Falco sparverius*; Heath, 1997), pied flycatchers (Kern et al., 2001), canaries (*Serinus canaria*; Schwabl, 1999), thin-billed prions (*Pachyptila belcheri*; Quillfeldt et al., 2007), and Laysan albatross (*Phoebastria immutabilis*; Seabury and Breuner, 2005). Interestingly, baseline corticosterone elevations at the time of nest departure may be related to the species requirements to perform the first flights, and thus nest location. Avian species nesting on the ground (e.g., snowy owls, *Bubo scandiacus*) or in low brush (e.g., northern mockingbirds) do not perform their first flights until a few days following nest departure, and the later transition is not associated with baseline corticosterone elevations (Romero et al., 2006; Sims and Holberton, 2000). In contrast, avian species nesting in cavities or higher substrates (high trees, cliffs) perform their first flights as they abandon the nest, and typically show increased baseline corticosterone levels (e.g., cavity nesting American kestrels, Heath, 1997; screech-owls *Otus* sp., Belthoff and Dufty, 1998; or burrow-nestling thin-billed prions, Quillfeldt et al., 2007; see Figure 38.7C). Furthermore, corticosterone levels elevate before and during the activity periods in fledging screech-owls (Belthoff and Dufty, 1998), suggesting a role of this hormone in natal dispersal. Corticosterone elevations during avian development may thus serve to meet with the increasing energy demands *(allostatic load)* associated with ontogenic transitions including hatching, fledging, and dispersal (Wada, 2008).

- Avian developmental modes range across a gradient defined by two extremes: altricial and precocial.
- The stress response of hatchlings increases across the developmental gradient: while altricial species show a "stress hyporesponsive period" characterized by an early inability to show GC elevations, precocial species show robust HPA responses soon after hatch.
- Inability to show robust responses early during development allows avoiding exposure to high and prolonged GC levels, which reduce growth and impair thyroid function, cognitive and competitive abilities.
- The Developmental Hypothesis proposes that the patterns of maturation of HPA responses evolved to match the costs and benefits of GC actions with the individual's progressive ability to cope with perturbations (e.g., increased behavioral performance and parental independence).
- Baseline corticosterone levels increase prior to hatching, fledging, and during dispersal, making it possible to meet the increased energy demands (allostatic load) associated with ontogenic transitions.

38.4.2 Maternal effects

Studies in humans, laboratory models, and birds indicate a profound effect of the quality of parental care and the perinatal environment experienced early in life on offspring's HPA function and associated behavioral responses (McGowan and Szyf, 2010; McGowan et al., 2011; Jimeno et al., 2019). GC actions during development exert permanent organizational effects on the individual, with a stronger impact on performance (fitness: reproduction and survival), compared to reversible activational effects of the same hormones when the endocrine systems are already developed (Williams, 2008). In birds, developmental exposure to high GC levels can occur prenatally (i.e., maternally mediated changes or *in ovo* composition, e.g., Almasi et al., 2012) and also postnatally or *ex ovo* (e.g., through variation in the amount of offspring care: food provisioning, shelter, social competition; see Blas and Baos, 2008 for a review), and has the potential to translate ecological and environmental conditions into permanent offspring responses through a process termed maternal programming (Figure 38.8A and B, reviewed in Love et al., 2013). As a consequence, mothers can "prime" lifelong responses in offspring through exposure to high or low levels of GCs, resulting in a permanent modification of HPA function (Hayward and Wingfield, 2004; Love et al., 2005; Saino et al., 2005; Love and Williams, 2008; Spencer et al., 2009) that will likely affect the ability to cope with ecological perturbations. Such priming can be highly adaptive and allow animals to adjust to changing environments because exposure to a low level of perturbations early in life often result in individuals that are better able to cope with exposure to higher levels of perturbations on subsequent occasions (a process known as hormesis; Constantini et al., 2010). Note that these adaptations occur epigenetically: the genetic composition in the offspring can be the same, but the expression of different genes in response to perturbations and GCs during development will result in different phenotypes. For example, cross-fostering the biological offspring between mothers that provide high and low care can permanently reverse offspring's HPA response in laboratory animals (Francis et al., 1999).

The fitness of the phenotypes modified through maternal programming is expected to be context-specific, and determined by the environmental conditions encountered after development, and how much they resemble natal conditions (*Maternal-Match Hypothesis*; Love et al., 2013). In those situations when the early priming was a reliable predictor of the offspring's future environment, maternal programming is expected to increase offspring and even maternal fitness (Figure 38.8B). However, if maternal signaling was a poor predictor of offspring's future environment, the programming would exert negative (maladaptive) effects on the offspring ("thrifty phenotypes"; Hales and Baker, 1992). The Maternal-Match Hypothesis (Love et al., 2013) is a paradigm proposed to refine the broader Environmental-Match Hypothesis (Sheriff et al., 2009, 2010, 2011a). Although these hypotheses require testing in wild birds, there is evidence for a number of environment-maternal-offspring connections mediated through corticosterone, which constitute the pillars for maternal programming summarized in Figure 38.8:

1. *Environmental and social conditions affect GC levels in adult birds, including reproducing females.*

For example, increased risk of predation (Hawlena and Schmitz, 2010; see Clinchy et al., 2013 for a review on the "ecology of fear"), unpredictable changes in food availability (Kitaysky et al., 1999a,b, 2007; Shultz and Kitaysky, 2008), human disturbance (Thiel et al., 2008; Zhang et al., 2011), and social competition consistently promote plasma GC elevations in females that may be forming eggs, laying, or brooding offspring. Therefore, the potential for GC transfer into eggs and developing young exists. Yet, in laying hens (*Gallus gallus domesticus*), unpredictable food restriction (Janczak et al., 2007) and ACTH challenge that raised plasma levels of corticosterone (Rettenbacher et al., 2005) both failed to increase corticosterone in egg yolk. So, while it is possible that maternal stress results in a transfer of corticosterone into eggs in wild birds, more research is needed to investigate this and potential alternate mechanisms (Sheriff et al., 2011b).

2. *Environmental and social conditions affect offspring GC levels (in ovo and developing birds).*

Although the precise mechanism whereby circulating GCs are transferred from the mother to the eggs requires additional research (Groothuis et al., 2005), positive correlations between maternal (plasma) and egg (yolk) levels have been shown in European starlings (*Sturnus* vulgaris; Love et al., 2005) and barn owls (*Tyto alba*; Almasi et al., 2012). Additional studies have reported a concomitant increase in egg GC levels in response to maternal exposure to environmental challenge (barn swallows, *Hirundo rustica,* Saino et al., 2005; European starlings, *Sturnus vulgaris,* Love et al., 2008; song sparrows, *Melodia melodia,* Travers et al., 2010), including predation pressure and social conditions. For example, solitary breeding females of the semicolonial European starling deposit higher egg GC levels (Love and Williams, 2008), and reduced female condition often results in decreased food provisioning rates to nestlings, elevating posthatching GC levels (Love et al., 2004; see Angelier et al., 2007b, 2009 for seabirds). Single

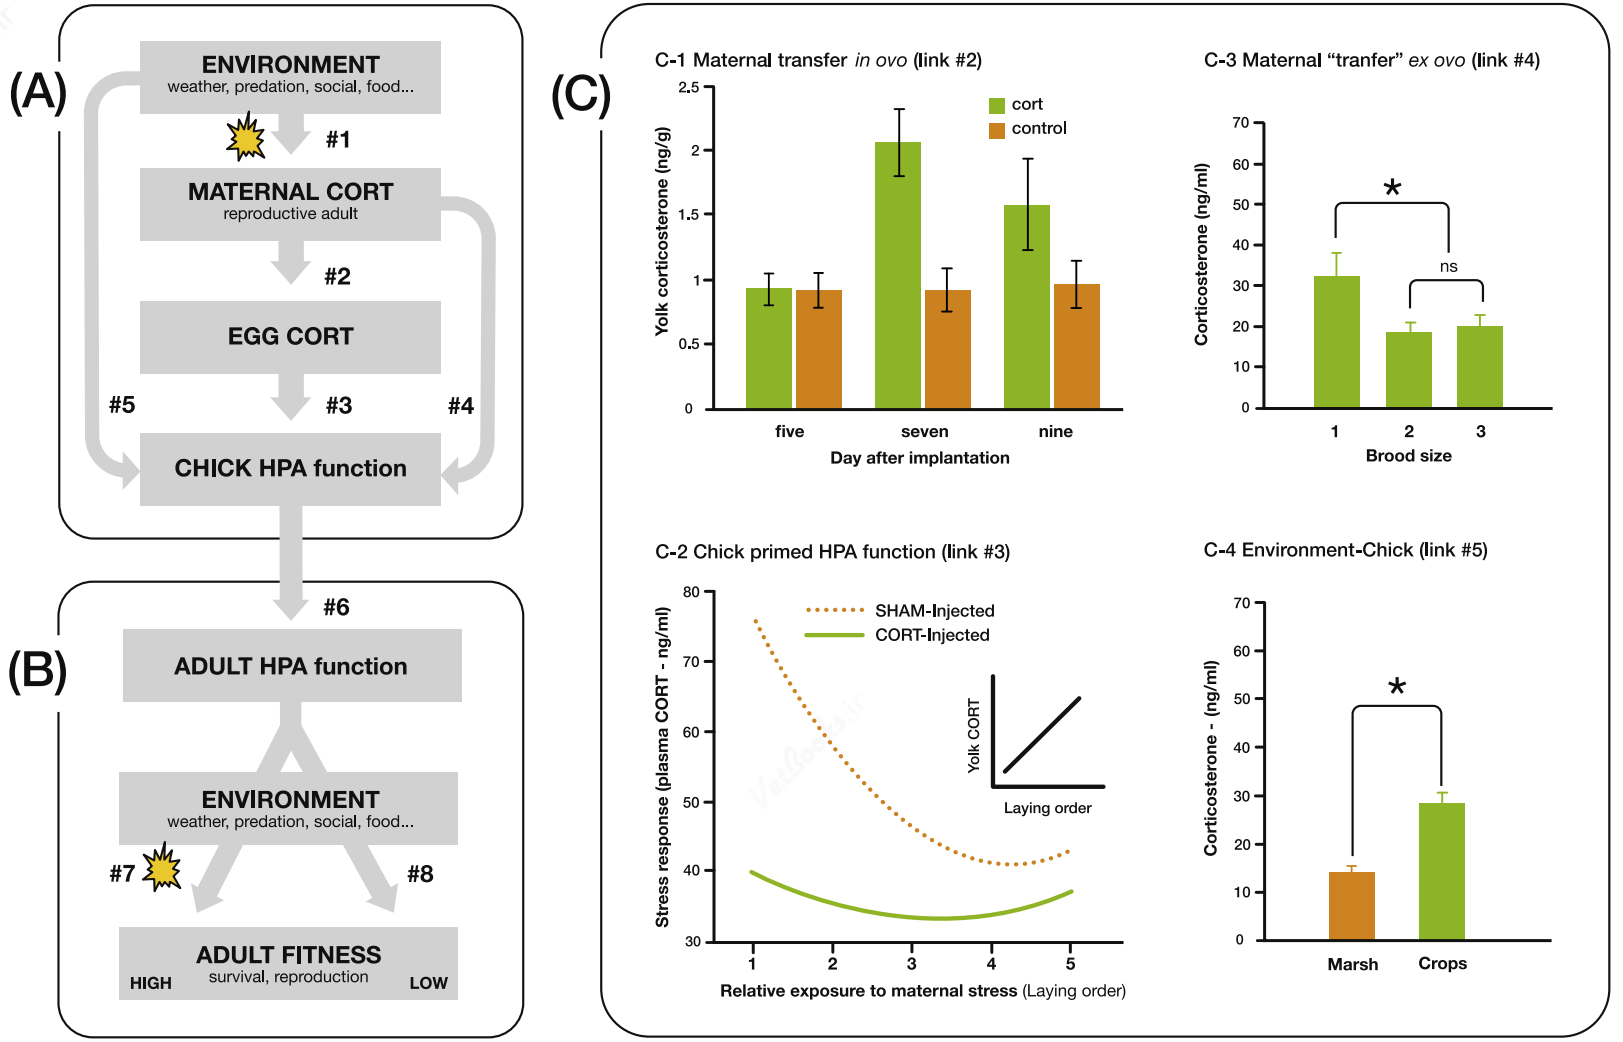

FIGURE 38.8 **Maternal effects.** Panel (A). Summary of the proposed mechanisms whereby environmental perturbations transduce into permanent changes of the hypothalamic–pituitary–adrenal (HPA) axis function in developing birds, through maternal effects (maternal programming). Environmental perturbations (star symbols) activate the HPA axis of reproducing, adult female birds (#1). Maternal stress in prelaying and laying females result in high levels of corticosterone (or other hormones) being deposited in the eggs (#2), and these will hatch nestlings developing a "primed," permanent modification of their HPA response (#3). Subsequently, variability in maternal care such as reduced attendance of nestlings and food provisioning, or increased within-brood social conflicts, can elicit further corticosterone elevations in the developing nestlings (#4). Because parental care cannot completely buffer environmental perturbations, these may also exert a direct effect on nestlings' corticosterone levels (#5) and contribute to permanent modifications of the HPA axis. The "priming" of HPA responses experienced by growing birds during development can be long-lasting, and the resulting adult phenotypes will show a permanent epigenetic modification of their response (#6). Panel (B). *The Maternal-Match Hypothesis:* Depending on the GC exposure that birds received during development (a function of maternal hormones, parental care, and natal environmental conditions; see Panel A, above), different phenotypes of HPA function will result. For example, the same pair of birds in different years could produce offspring that are high-versus low-HPA responders. Phenotypes may differ in the amount of corticosterone secreted in response to standardized perturbations, and therefore in the ability to cope with environmental challenge later in life. The maternal-match hypothesis proposes that the fitness of each phenotype will be determined by the environmental conditions encountered after development. In those situations when the early "priming" was a reliable predictor of the offspring's future environment (#7; note the same star as #1 in Panel A), offspring fitness will increase. However, if maternal signaling was a poor predictor of offspring's future environment, as may be the case with human-induced rapid environmental change, offspring fitness will be reduced (#8). Panel (C). *Examples illustrating maternal effects: C1*: Corticosterone implants in female Japanese quail (*Coturnix coturnix japonica*) significantly increased the concentrations of corticosterone in the yolk of eggs laid seven and nine days after implantation. This figure illustrates arrow #2 in panel A. *C2*: Relative responsiveness of the HPA axis (stress-induced plasma corticosterone) in fledging, free-living European starling (*Sturnus vulgaris*) in relation to natural variation in exposure to maternal stress (note that yolk corticosterone naturally increases across laying order; see insert and Love et al., 2008). The stress response of nestlings was further decreased when the eggs had been previously treated with exogenous corticosterone (*continuous line*) compared to controls (*dotted line*). This figure illustrates *arrow* #3 in panel (A). *C3*: Nestling white storks (*Ciconia ciconia*) showed higher baseline corticosterone when they were singletons, reared in nests that suffered a strong brood reduction (insufficient parental care), compared to nestlings from two- and three-chick broods. This figure illustrates *arrow* #4 in panel (A). *C4*: Baseline corticosterone in nestling white storks were higher when reared in the less productive environment (crop fields) compared to nestlings reared beside wetlands (marsh), where food availability is higher. This figure illustrates *arrow* #5 in panel (A). *Credit: Composite figure based on Hayward and Wingfield (2004); Love et al. (2013); Blas et al. (2005), and Blas and Baos (2008).*

chicks in white storks nests are the result of partial hatching failure and brood reduction (indicating insufficient parental care), and show higher circulating GC levels (baseline range) compared to nestlings from two- and three-chick broods (Figure 38.8, panel C3; Blas et al., 2005).

3. *Environmental challenge and elevated GC levels in developing offspring (in ovo, and posthatch) generate long-term differences in HPA function, behavior, and performance.*

For example, in nestling black-legged kittiwakes (*Rissa tridactyla*), experimental food restriction during development results in sustained elevations in 30-day-old chicks (Kitaysky et al., 1999a,b), and experimentally elevated corticosterone levels promote begging and aggression (Kitaysky et al., 2001) but result in long-term impairment of cognitive abilities persisting at least 8 months later (Kitaysky et al., 2003). In European starlings (*Sturnus vulgaris*), reduced maternal provisioning rates increase fledglings' adrenocortical responsiveness (Love and Williams, 2008). Within a given clutch, maternal GC levels (deposited in egg yolks) sequentially increase (Love et al., 2008), and the subsequent HPA responses of nestlings are negatively correlated with *in ovo* GC exposure (Figure 38.8, panel C2). The latter association can be further enhanced by exogenous administration of GC in the eggs, which results in fledglings showing the lowest HPA responses (Love and Williams, unpublished data in Love et al., 2013). Somehow opposing results have been reported in Japanese quail *Coturnix coturnix japonica*, where experimentally elevated plasma corticosterone in laying females is transferred to egg yolk (Figure 38.8, panel C1), but the hatched chicks (which grow at a slower rate) display higher, rather than lower responsiveness of the HPA axis as adults (Hayward and Wingfield, 2004). Unfortunately there is a lack of studies in wild birds monitoring whether such changes in HPA function, behavior, and performance persist in the phenotypes after fledging, but a negative relationship between stress-induced corticosterone levels in nestlings and survival into adulthood was found in wild, unmanipulated white storks (Blas et al., 2007). Studies that have manipulated corticosterone in early life as a proxy for environmental challenge provide additional insights into long-term effects. For example, experimental elevation of corticosterone in postnatal female zebra finches (*Taeniopygia guttata*) resulted in reduced incubation effort when they were adults (Spencer et al., 2010), and experimental dietary restriction and elevated corticosterone during development resulted in adults with significantly shorter and less complex songs (Spencer et al., 2003). In house sparrows, early-life corticosterone manipulation was associated with depressed baseline and stress-induced concentrations of corticosterone at all stages of life, through adulthood (Grace et al., 2020).

Maternal programming has been proven to be an adaptive (GC-mediated, epigenetic) mechanism bridging maternal and offspring environment to explain, for example, the cyclic population dynamics of wild mammals (see Sheriff et al., 2009, 2010, 2011a). Whether this mechanism also applies to wild birds urgently requires additional field research under contrasting environmental scenarios and in association with long-term monitoring of the individual's performance and HPA function. Human-induced rapid environmental change has a strong potential to make maternal programming maladaptive when it results in variable environmental conditions that mothers are not able to predict (Donelan et al., 2020). Thus, the likelihood that offspring are "primed" for the novel environments they are likely to face will be low, which may present a problem for all vertebrate populations, particularly of endangered species.

- Actions of GCs during development exert permanent organizational effects on individuals.
- Developmental exposure to GCs occur prehatch (*in ovo*: during egg formation), and posthatch (*ex ovo*: according to the amount of maternal and paternal care).
- GC transfer from mothers to offspring has the potential to translate ecological and environmental conditions into permanent offspring responses through a process termed "maternal programming."
- Such "priming" can be highly adaptive and allow animals to adjust to changing environments.
- The fitness of the modified phenotypes is likely context specific and determined by the environmental conditions encountered after development (Maternal-Match Hypothesis). Human-induced rapid environmental change has the potential to make maternal programming maladaptive.

38.4.3 Modulation of the stress response

The ELHS (Figure 38.6 and Section 38.3.3) redirects energy investment away from normal activities into a survival mode. Such an energy shift (mediated through corticosterone elevations) can be highly adaptive in most circumstances, but the individual also incurs important costs. In fact, life history theory postulates that organisms are continually facing trade-offs in the allocation of a limited quantity of resources/energy between competing functions (Stearns, 1992). For example, breeding birds must trade off energy and resources between current reproductive investment and survival (which determines future reproduction). Whether an individual should allocate more resources to one or the other life history trait depends on the relative importance in maximizing lifetime fitness, and natural selection has likely filtered optimal decisions. This is a core argument for widely accepted models on the cost of reproduction (Williams, 1966), leading to the

proposal of the "*Brood Value Hypothesis*" (Heidinger et al., 2006; Lendvai et al., 2007; Lendvai and Chastel, 2008; Angelier et al., 2020). The Brood Value Hypothesis proposes that the stress response should be modulated as a function of the relative importance of the current reproductive attempt; when the value of the current reproduction is relatively high, the stress response should be mitigated to ensure that the current breeding attempt is not compromised. This hypothesis has found empirical support in numerous field studies, within and across species. For example, maximum corticosterone in response to capture and restraint in red-legged partridges (*Alectoris rufa*) declines from the prelaying to the laying stage, suggesting an adaptive down-modulation of adrenocortical responses as the value of reproduction increases (Figure 38.9A; J. Blas and T. Marchant, unpublished data). The first experimental demonstration that individuals can flexibly modulate their stress response with respect to the reproductive value of their brood was performed in free-living house sparrows. By means of an experimental increase or reduction of clutch size during the nestling period, Lendvai et al. (2007) found that parents tending enlarged clutches responded less strongly to a stressor than those tending reduced clutches (Figure 38.9B). In addition, they examined whether individuals responded less strongly to a stressor as the breeding season progressed and future reproductive opportunities declined. The stress response decreased with breeding date during the birds' first breeding attempt, but it remained constant during their second breeding attempt. The same line of reasoning applies to interspecies comparisons: avian species breeding in northern latitudes have limited opportunities to renest due to a short breeding season; as predicted by the Brood Value Hypothesis, they show attenuated stress responses compared to southern populations/species, which have a longer reproductive season and thus more possibilities to breed within the same year (Silverin et al., 1997; O'Reilly and Wingfield, 2001; Breuner et al., 2003; but see Wingfield et al., 1995a). Similarly, older individuals have progressively reduced breeding opportunities, making it adaptive to increase reproductive effort as they age ("Terminal Investment Hypothesis": Clutton-Brock, 1984; Velando et al., 2006). Consistent with the Brood Value Hypothesis, older birds show attenuated secretion of GCs in response to challenges (Heidinger et al., 2006), although this pattern may not always occur (Angelier et al., 2007a). The response to stress has been shown to be reduced in the sex providing the most parental care (Wingfield et al., 1995b; O'Reilly and Wingfield, 2001; Holberton and Wingfield, 2003), during the specific breeding substages requiring higher parental investment (Meddle et al., 2003; see Figure 38.9A), and even within a given substage (e.g., brooding) as offspring quality or quantity increases (Lendvai et al., 2007; Lendvai and Chastel, 2008; Viblanc et al., 2016). A phylogenetic comparative analysis on 34 wild avian species found that those with a higher value of the current brood relative to future breeding mounted weaker corticosterone responses during acute stress (Figure 38.9C), and that females in the species with more female-biased parental care had weaker corticosterone responses (Bókony et al., 2009). Collectively, correlational, experimental, and comparative evidence suggest that modulation of the stress response

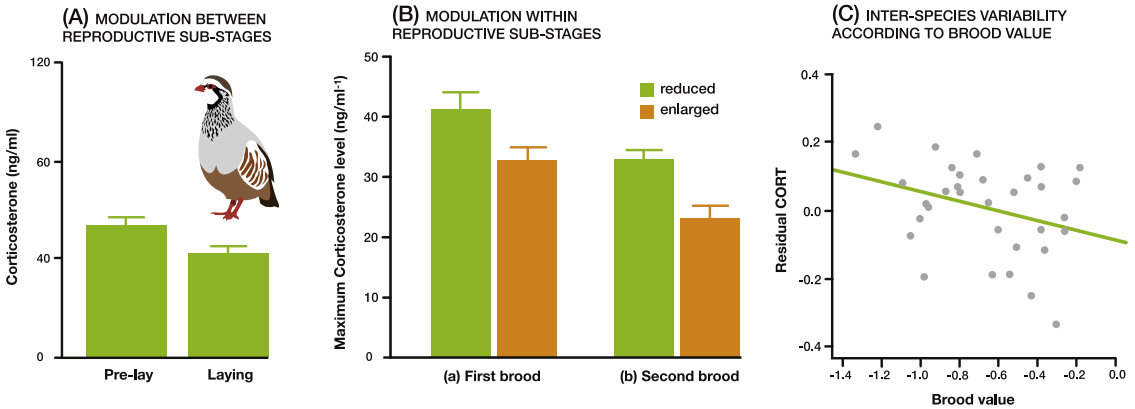

FIGURE 38.9 Modulation of the stress response during reproduction. Panel (A). Maximum corticosterone in response to capture and restraint in captive red-legged partridges (*Alectoris rufa*), across breeding substages. Stress-induced corticosterone declined as birds started laying eggs, suggesting an adaptive down-modulation of hypothalamic−pituitary−adrenal (HPA) responses as the brood value increases. Panel (B). Maximum corticosterone titers (stress-induced levels) in free-living house sparrows (*Passer domesticus*) as a function of a manipulation of brood size (number of nestlings) performed in the (a) first and (b) second breeding attempt of a year. Experimentally increased broods elevated the brood value to adult birds, which down-modulated their HPA responses. Panel (C). Residual, maximum corticosterone titers (peak plasma level controlled for baseline and breeding latitude) in relation to brood value in 34 wild avian species. Brood value expresses the putative importance of current reproduction as LOG [clutch size/(clutch size × broods per year × average reproductive life span)]. *Credit: Composite figure based on J. Blas and T.A. Marchant, unpublished data; Lendvai et al. (2007), and (2009).*

functions as a physiological mediator for the adaptive allocation of energy and resources between current and future reproduction. Importantly, these studies point to a particular hormonal mechanism, the HPA axis function, as the physiological basis for life history trade-offs, indicating that HPA function and GC secretion may be a target of selection just like other traits (Bókony et al., 2009; Hau et al., 2016; and see Bonier and Martin, 2016).

- Individuals can flexibly modulate their stress response with respect to the reproductive value of their brood (Brood Value Hypothesis).
- The intraindividual patterns of modulation are consistent with interspecies differences in stress responses, suggesting similar underlying ecological constraints. Avian species breeding in northern latitudes have limited opportunities to renest due to short breeding seasons, and show attenuated stress responses. Females in avian species showing female-biased parental care have weaker corticosterone responses.
- Modulation of corticosterone secretions makes it possible to trade off energy and resources between current reproductive investment and survival, providing a proximate mechanism for life-history evolution.

38.5 Field methods to study adrenocortical function

Our current understanding of avian adrenocortical function is to a large extent based on experimental studies performed in laboratory conditions using captive birds. This allows researchers to control a considerable number of variables known to affect *HPA* function (e.g., photoperiod, temperature, food and water, social interactions, status, age, sex, and LHS). Captive birds are easily accessible for repeated sampling and trait manipulations, and most lab facilities have readily available infrastructure to obtain, process, and store the collected samples in repeatable conditions.

However, laboratory settings impose a considerable bias when extrapolating results to the real world (Fusani et al., 2005; Calisi and Bentley, 2009). To start with, only a few avian species can be kept in captivity for experimentation, limiting research conclusions to specific species or phylogenetic groups (e.g., poultry species), and even to specific breeds whose HPA system has been voluntarily or involuntarily modified through artificial selection (Keith et al., 1973; Satterlee et al., 2000). When a wild bird is brought to captivity for experimentation, the capture and transfer to the laboratory typically exerts effects on the HPA axis (Dickens et al., 2009) which may continue throughout captivity (Fischer and Romero, 2019), and captivity-related changes in density and/or social structure can act as additional acute stressors (Dufty and Wingfield, 1986; Nephew and Romero, 2003). Furthermore, the artificial settings of captivity are unable to replicate the richness of natural stimuli and their complex interactions, and the recorded physiological and behavioral responses likely represent a minimum diversity compared to what occurs in natural habitats, when birds are exposed to real ecological scenarios (Fusani et al., 2005; Fusani, 2008). For example, wild *Passerine* species show reduced hippocampal volume, lower levels of circulating testosterone, and contrasting responses to pharmacological treatment when brought to captivity (Wingfield et al., 1990; Smulders et al., 2000; Canoine and Gwinner, 2002). Results across a range of bird (and mammal) species strongly indicate that deprivation of environmental and social cues can dramatically modify neuroendocrinological and behavioral responses and can produce contrasting information compared to studies in natural environments (Calisi and Bentley, 2009).

The past 50 years have witnessed an increasing number of behavioral endocrinologists focusing their research on wild species under natural settings, largely following the pioneering work of John Wingfield (Wingfield and Farner, 1975, 1976, 1993) who implemented methods to quantify hormones in small blood samples, avoiding the need for killing the study subjects and establishing the discipline of *Field Endocrinology*. Working in the field imposes at least five important challenges compared to laboratory settings (Fusani et al., 2005; Fusani, 2008) and has led to the use of alternative, noninvasive tools to monitor endocrine parameters (Bortolotti et al., 2008; Sheriff et al., 2011b). First, wild birds inevitably differ in nutritional condition, social status, LHS, and many other factors whose variability should be taken into account during the design of a field experiment, the collection of samples, and the subsequent statistical treatment of data. Second, catching wild birds may take a considerable amount of effort, and the trapping method should be carefully chosen to avoid additional interferences on adrenocortical function. For example, the use of visual decoys and playbacks may facilitate capture, but using social stimulation as "bait" also stimulates rapid hormone secretions (e.g., elevating testosterone levels, Wingfield and Wada, 1989), potentially effecting GC levels (Charlier et al., 2009). Even the use of passive trapping methods like mist netting should be carefully supervised because the capture event itself is a stressor, and the time elapsed until sampling need to be standardized, controlled for, or at least meticulously recorded (see Section 38.5.1 and Box 38.1). Third, sample sizes are often reduced compared to laboratory studies ($N \leq 10$ are not uncommon) due to the difficulty of capturing wild birds and also to minimize the impact on wild populations. Whenever possible, repeated measures designs are advisable to increase the statistical power, although recapturing the same individuals may not be always possible as individuals learn avoidance behaviors. Collaborative projects can overcome this issue by sharing data to increase sample sizes and

improve inferences, especially across large geographic areas (e.g., Fairhurst et al., 2015a, b; Knight et al., 2019), but strict methodological standards must be implemented. Fourth, because conditions can be primitive when working in field or remote locations, specific logistics may be required for sample processing and transportation. For example, the separation of plasma from blood samples for subsequent determination of corticosterone levels may require using a battery- or manually operated centrifuge, while plasma preservation, storage, and transport in frozen conditions may require handling dry ice or liquid nitrogen in specific containers adapted for field and travel (details in Fusani et al., 2005). The use of alternate tissues can overcome this issue but cannot replace blood sampling for studying HPA functioning or responses to acute stressors (see Section 38.5.4.1). Fifth, and finally, special care should be taken regarding the ethical and legal considerations associated with the manipulation of wild birds (Fair et al., 2010), aimed and minimizing potential impacts on the well-being of study subjects and the viability of natural populations.

All the constraints and the special considerations above imply that a first step for any field study of avian adrenocortical function requires a carefully planned experimental design. Environmental stochasticity (unpredictable events) occur frequently during field studies (Sergio et al., 2018), and this may actually result in "natural experiments" that provide unique opportunities to understand the role of adrenocortical function in birds, for example, during inclement weather (Wingfield et al., 1983), social conflict (Goymann and Wingfield, 2004), famine conditions (Kitaysky et al., 1999a,b), and pollution accidents (Baos et al., 2006; Baos and Blas, 2009). Below we will summarize common field techniques that are frequently used for assessing adrenocortical function in wild birds, some of which have been developed or largely implemented in recent years (laboratory techniques aimed at quantifying GC levels have been reviewed elsewhere; see, e.g., Sheriff et al., 2011b).

- Translocation and captivity are known to affect the HPA axis in birds. Deprivation of environmental and social cues can modify avian neuroendocrinological and behavioral responses, preventing the extrapolation of results from laboratory studies to the real world.
- Field endocrinologists focus their research on wild species under natural settings, but face important challenges during sample collection, processing, and transportation. These have led to the development of alternative and noninvasive tools to monitor endocrine function.
- Field research requires carefully planned experimental designs and special care to minimize impacts on the well-being of individuals and the viability of natural populations.
- Environmental stochasticity often results in "natural experiments" that provide unique opportunities to understand the role of the stress response in avian ecology and evolution.

38.5.1 Obtaining adequate blood samples: capture and restraint protocols and the "stress series"

Field endocrinologists face an obvious methodological difficulty when collecting samples aimed at assessing HPA function in wild animals: an adequate baseline blood sample containing GC levels truly indicative of the individual's "unstressed" conditions should not be affected by the investigator disturbance. However, the trapping and capturing activities that necessarily precede blood sampling are typically perceived by wild birds as real predation attempts (Scheuerlein et al., 2001; Canoine et al., 2002). Although many behavioral and neuroendocrine components of the "fight-or-flight" response occur within seconds (e.g., epinephrine/norepinephrine elevations accompanied by escape behaviors and alarm calls), the elevation of circulating corticosterone levels typically shows a 2–3 min delay (Romero and Reed, 2005). This short timeframe constitutes, in many field situations, a feasible period for obtaining a first blood sample in situ. This can be done through venipuncture of the wing (brachial) vein using a sterilized needle and collecting blood drops in heparinized microhematocrit tubes (e.g., one or several 50 μL tubes) or using heparinized syringes that also allow accessing the leg or jugular veins. These procedures are generally harmless provided adequate training and observing the recommended blood sampling volume limitations according to body size (Fair et al., 2010; though see Brown and Brown, 2009). Following capture and initial collection of a baseline blood sample, birds should be kept in cloth bags or immobilized with cloth corsets, allowing adequate ventilation but preventing injury if the bird struggles. Birds should also be placed in a safe place, sheltered from direct negative effects of weather, and their vision deprived (large birds may require using falconry hoods, Blas et al., 2010). It is very important to follow a strict capture, handling, and restraint protocol because subsequent collection of additional blood samples at predefined intervals of time (for example, 10, 30, and 45 min postcapture, Blas et al., 2006a) will allow the characterization of GC elevations at the individual level during a "*stress series*" (Box 38.1; Figure 38.10A). Researchers can therefore transform/adapt their normal capture and sampling activities into standardized experimental protocols that will allow establishing formal group comparisons in a repeatable manner within and across studies (for example, in relation to age, sex, and body condition). The timing and number of sampling

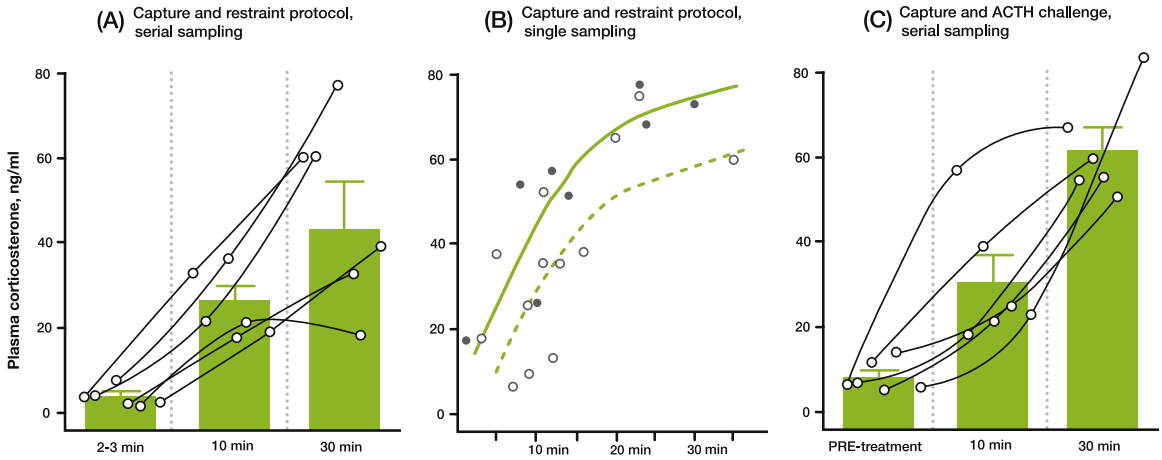

FIGURE 38.10 Protocols for assessing the "stress response". Panel (A). *Capture and restraint with repeated blood sampling*: Plasma corticosterone levels in nestling black kites (*Milvus migrans*) after standardized capture, restraint and serial bleeding of the same individuals (one line per individual, $N = 6$ birds) at three fixed times (x-axis). The green bars in the background represent mean and standard error (S.E.) per sampling episode. Panel (B). *Capture and restraint with single blood sampling*: Plasma corticosterone levels in adult male black kites after standardized capture, restraint, and collection of one single sample per individual (*single dots* are independent individuals). The *solid and dashed lines* indicate logistic regression estimates for nonbreeding (*black dots*) and adult breeding birds (*white dots*). Panel (C). *Capture and restraint with adrenocorticotropic hormone (ACTH) challenge and serial blood sampling*: Plasma corticosterone levels in nestling black kites after standardized capture, restraint and intravenous injection of ACTH. Serial blood sampling was performed before and after (10 and 30 min) treatment (one line per individual, $N = 6$ birds). ACTH injections were performed within 2 min from capture for ease of comparison with the corticosterone responses shown in Panel (A). The green bars in the background represent mean and S.E. per sampling episode. *Credit: Composite figure based on L. López et al., unpublished data; J. Blas et al., unpublished data; and Blas et al. (2011).*

intervals will depend on research objectives and logistical practicality. In some field situations, it may not be possible to obtain rapid samples from all the individuals in unstressed/baseline conditions (e.g., when the trapping method involves simultaneous capture of many birds; Blas et al., 2011) or collect repeated samples from the same individuals (e.g., in small species or during early developmental stages, when blood volume is highly limited; Fairhurst et al., 2013b). In all the cases, it is still critical to keep accurate records of the times elapsed from capture to blood sampling each individual, and GC responses can be subjected to group comparisons through regression analyses (Figure 38.10B).

- Capturing wild birds stimulates their stress response. Consequently, baseline corticosterone levels are normally assessed in blood samples obtained within 2−3 min postcapture. Additional blood samples will allow characterizing the *adrenocortical response to stress* at the individual level ("*stress series*").
- Blood sampling requires keeping meticulous records of the times elapsed from capture to blood sampling for each individual. Samples can be collected at predefined intervals of time or along a continuum, but a standardized *capture, handling, and restraint protocol* is required to establish group comparisons.

38.5.2 Quantifying the strength and sensitivity of adrenocortical responses

Although the *handling and restraint protocol* accompanied by serial collection of blood samples (Box 38.1) is a widely used method for assessing adrenocortical function in wild birds, the resulting GC elevations may be affected by perception differences among and within individuals (Romero, 2004). For example, wild penguins exposed to human presence show moderate GC elevations following the same capture and restraint protocol that triggers strong adrenocortical responses in unexposed conspecifics (Walker et al., 2006), suggesting habituation to human presence (Cyr and Romero, 2009). Similarly, acclimation was proposed to explain why parrots that were bred in captivity had attenuated corticosterone responses compared to wild-caught parrots (Cabezas et al., 2013). The reverse outcome may also occur when predator-naïve species learn that humans can be a potential danger, resulting in gradually stronger GC responses (Rödl et al., 2007). For these reasons, field studies may benefit by incorporating additional research methods to characterize adrenocortical function regardless of perceptional biases (see Canoine et al., 2002). For example, the sensitivity and the robustness of an individual's adrenocortical response can be estimated by means of administration of two commercially available

drugs followed by the collection of blood samples to monitor concomitant, short-term (e.g., within 30–90 min) changes in endogenous GC levels (Figure 38.10C).

The adrenals' *maximal ability or capacity* to secrete GC can be experimentally assessed through intravenous, intramuscular, or intraperitoneal administration of exogenous adrenocorticotropin (ACTH). Porcine ACTH is commercially available for research purposes, and it is known to elicit corticosterone release in the avian adrenals (Astheimer et al., 1994; Wasser et al., 1997; Rich and Romero, 2005). The commercial product is normally provided lyophilized, requiring suspension in an injectable isotonic solution (Ringer's solution). Dosage choice and injection volumes can be assessed according to previous references, and a pilot study using a small sample size (e.g., four to six birds) would allow selecting the minimal dose eliciting maximal response (*adrenal saturation*) and the optimal postinjection time for the subsequent collection of blood samples. Unfortunately, ACTH degrades at room temperature or following thaw–freeze cycles, requiring the preparation of aliquots maintained frozen until a few minutes before injection.

The *robustness* of an individual's adrenocortical response can be characterized through exogenous (intravenous, intramuscular, or intraperitoneal) administration of *dexamethasone* (*DEX*). DEX is a synthetic GC that competes with endogenous corticosterone for binding receptors in the brain, and artificially stimulates negative feedback (Dallman et al., 1992). Because DEX does not bind to the antibodies commonly used in radioimmunoassays (RIAs), a decrease of endogenous GC levels can be monitored by performing serial collection of blood samples within a relatively short period (e.g., 30, 60, and 90 min) after chemical challenge, allowing standardized comparisons among experimental groups (Torres-Medina et al., 2019). Negative feedback is a critical component of HPA function, as a failure in this system can lead to persistent elevated corticosterone levels that lengthen and strengthen the overall stress response (Romero, 2004), potentially resulting in stress-related disease (Sapolsky, 1992; Romero and Wikelski, 2010). Contrary to ACTH, commercial DEX solutions are generally stable at room temperature, and because it is a common anti-inflammatory drug, the product is easily accessible in veterinary clinics.

- Individual experience can affect HPA functioning (e.g., through acclimation), and methods are available to characterize adrenocortical function regardless of perceptional biases.
- The individual's *maximal capacity* to secrete GCs can be experimentally assessed through ACTH injections, followed by serial collection of blood samples and quantification of corticosterone elevations.
- The *robustness* of an individual's adrenocortical response can be characterized through exogenous administration of DEX, a synthetic GC that competes with endogenous corticosterone and stimulates negative feedback.

38.5.3 Phenotypic engineering

One of the best ways to explore whether and how traits of organisms are currently adaptive is to manipulate them experimentally and compare the relative fitness of altered and unaltered individuals. This method has been termed *phenotypic engineering*, and it is a powerful tool in field endocrinology studies (Ketterson et al., 1996; and see Bonier and Martin, 2016). For example, one could manipulate body condition and monitor the effects on circulating hormones (Figure 38.11A). More often, field endocrinologists are interested in a continuous manipulation of the individual's hormone levels (over the course of a few days or weeks) in order to assess the effects on physiology, morphology, behavior, and performance (Figure 38.11B and C). Repeated administration of a substance (e.g., daily injections) is impossible in most field conditions because focal individuals avoid being regularly recaptured. Consequently, field researchers rely on subcutaneous implant devices to deliver the target substance (e.g., corticosterone, DEX) more or less continuously. Depending on the chemical properties of the target substance and other considerations (including the researcher's budget), this can be achieved through three types of subcutaneous implant devices (described below; see also Fusani, 2008). With the required training, the associated surgical procedures are simple, fast, and minimally invasive: after applying local anesthesia (e.g., external or subcutaneous lidocaine solution between the wings, the lower neck, or the upper leg area where the implant will be placed) and superficially cleaning the area with a cotton swab impregnated in povidone-iodine solution (alcohol should be avoided), a small incision using a sterile scalpel allows subsequent insertion of the implant device with sterile forceps. The skin is subsequently closed using a small dab of tissue adhesive (for smaller incisions/birds; Fairhurst et al., 2013b) or surgical stitches (for larger ones; Blas et al., 2006b).

1. ***Silicone implants***: Silastic medical grade tubing (Dow Corning, Inc.) can be filled with crystalline hormone and the two ends closed with silicone glue. After subcutaneous insertion, the substance diffuses through the semipermeable walls for a variable period determined by the length of the tube, the thickness of the walls, the amount of drug, and its lipophilic nature. Although this inexpensive technique can be useful for highly

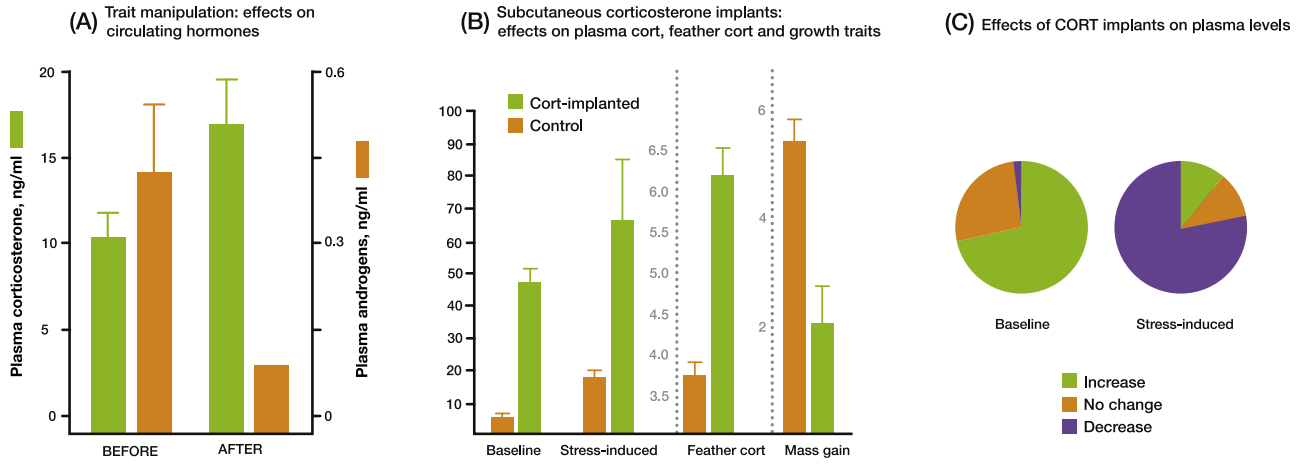

FIGURE 38.11 Phenotypic engineering influences levels of corticosterone. Panel (A). *Effects of trait manipulations on circulating hormones*: Plasma levels of baseline corticosterone ("CORT"; left axis, *green bars*) and androgens (right axis, *orange bars*) before and after an experimental food restriction that caused a decrease in the body condition of adult male red-legged partridges (*Alectoris rufa*). Bars indicate means and standard error (S.E). All plasma samples were collected 3 min postcapture. Panel (B). *Effects of sustained corticosterone manipulations on plasma CORT, feather CORT, and body mass*: Plasma corticosterone levels (ng/mL), feather corticosterone levels (pg/mm), and body mass gain (g) in nestling tree swallows (*Tachycineta bicolor*) subcutaneously implanted with time-release corticosterone pellets or drug-free control pellets (*green and orange bars* respectively) on day 7 posthatch. Baseline blood samples were collected within 2−3 min following capture, and stress-induced blood samples were collected after 30 min of restraint (all samples collected 3 d after implanting). The feathers were growing during the experimental period, and were collected on day 15 posthatch. Body mass change was estimated between days 7 and 11 posthatch. All bars indicate means and S.E. Panel (C). *Directions of the effects of CORT implants on plasma CORT levels*: A review of 50 published experiments revealed that baseline CORT levels generally increase whereas stress-induced CORT levels generally decrease following the use of subcutaneous CORT implants in birds. *Credit: Composite figure based on Pérez-Rodriguez et al. (2006); Fairhurst et al. (2013b), and Torres-Medina et al. (2018).*

lipophilic hormones such as testosterone (Blas et al., 2006b), silastic implants have low permeability for hydrophilic substances such as corticosterone (Kinel et al., 1968). In addition, *continuous* release does not mean *consistent* release (see Fusani, 2008). The choice of perforating the tube or leaving one end open causes a fast release of the hormone and thus inability to maintain a sustained elevation within or between individuals (Newman et al., 2010), which may confound experimental results. Despite such problems, this has traditionally been the most common method of manipulation in studies on wild birds, with a prevalence of 50% across the experiments performed during the last two decades (Torres-Medina et al., 2018).

2. ***Osmotic pumps***: Osmotic minipumps (Alzet, Durect Corporation, Cupertino, CA, USA) allow for up to four weeks of *continuous and consistent* hormone release independent of its solubility (e.g., Soma et al., 2000; Fusani et al., 2005). This method provides high repeatability (Fusani, 2008) but has received a rather marginal use (*ca.* 6% of avian experiments involving corticosterone implants; Torres-Medina et al., 2018), possibly because it is relatively expensive (Fusani, 2008).
3. ***Time-release pellets***: Innovative Research of America (Sarasota, Florida, USA) manufactures pellets for the most common hormones and antihormone drugs as well as placebo (vehicle only) pellets (Figure 38.11B and C). The hormone is included in a cholesterol matrix that is slowly reabsorbed when placed subcutaneously. Although commercial pellets are relatively expensive, it is not necessary to recapture the animal to remove any experimental device after the study, providing a considerable advantage compared to silicone implants and osmotic pumps. The frequency of use of this method is 44% across corticosterone implant studies on birds, with a growing tendency observed during the last two decades (Torres-Medina et al., 2018). Caution should be taken regarding dosages and expected release times (Müller et al., 2009; Fairhurst et al., 2013b); the duration of effects is typically limited to the first third of the theoretical period, making it advisable to perform pilot studies with repeated blood sampling sessions for each study model and throughout the supposedly effective (theoretical) period advertised by the manufacturer (Torres-Medina et al., 2018).

Note that the effects of corticosterone implants on baseline levels show a quadratic association with experimental dose across bird species, and decreased plasma levels may occur at both high and low-implant doses (Torres-Medina et al., 2018). Furthermore, continuing hormonal treatment for longer than a few days or 1 week can also result in endogenous readjustment of the individual's endocrine system (evolved to maintain homeostasis). Therefore, long-term administration of an exogenous hormone may result in reduced endogenous

production through negative feedback, and eventually in a regression of endocrine glands. These effects may last longer and be opposite to the intended initial manipulation (Fusani, 2008), potentially confounding the interpretation of results. Indeed, a review of 50 studies that used subcutaneous corticosterone implants found that 72% of experiments increased baseline corticosterone levels, but 78% of experiments reduced stress-induced corticosterone levels (Figure 38.11C; Torres-Medina et al., 2018). Thus, while target effects on baseline hormone levels can be expected (though by no means guaranteed), delivering the hormone using implants frequently produces stress-hyporesponsive phenotypes, which can be problematic for studies measuring downstream variation in other biological traits. Given our current gaps of knowledge regarding the effects of corticosterone implants on avian physiology, it is recommended that researchers (1) perform dose-effect pilot studies, (2) conduct a stress series to assess the consequences to both baseline and stress-induced corticosterone levels, and (3) improve the resolution and duration of blood sampling protocols aimed at assessing effective duration of implants and associated responses (Torres-Medina et al., 2018). Finally, it should be noted that experimental augmentation of GC levels generally reduces fitness across species (Bonier and Cox, 2020).

- One method to explore how endocrine traits are adaptive is to alter them experimentally and compare the fitness of altered and unaltered individuals ("phenotypic engineering").
- Field endocrinologists rely on subcutaneous implant devices to deliver the target substances (e.g., corticosterone) more or less continuously. Depending on the chemical properties of the target substance, this can be achieved through silicone implants, osmotic pumps, or time-release pellets.
- Hormonal treatment for longer than a few days, or that produce supraphysiological levels, may result in a reduced endogenous production, including hyporesponsiveness to stressors. Caution should be taken to avoid potentially confounding results, including downstream biological effects.

38.5.4 Corticosterone and its metabolites in tissues other than blood

Quantifying circulating (plasma) corticosterone levels is the best way to characterize individual adrenocortical status at a particular moment, and to understand how the HPA system works mechanistically and in relation to acute stressors. However, blood levels are instantaneous measurements, and the circulating GC titers within a given individual show dramatic temporal fluctuations according to the immediate internal and external circumstances (e.g., social, environmental, daily rhythms). Field avian researchers face a challenge when trying to establish associations between long-term metrics, such as fitness and individual adrenocortical function, because GCs at a particular instant in time (a blood sample) hardly represent the long-term allostatic responses of an individual. Likewise, studies addressing the environmental causes of individual GC physiology may find it unrealistic to expect an instantaneous GC measurement to reflect the complexity of patterns of GCs secreted in response to suites of stressors experienced over time.

Establishing robust ecophysiological associations would require repeatedly sampling the same individuals across time, space, and/or large samples sizes. Such tasks are difficult to accomplish in field scenarios, explaining, in part, why GC-fitness associations are rarely reported and remain generally elusive to ecological studies (Breuner et al., 2008; Bonier et al., 2009; Crespi et al., 2013; Dantzer et al., 2014). In addition, obtaining blood samples requires capturing live birds, which can introduce a potential artifact of the investigator disturbance on the results (Table 38.1) and raises ethical concerns related to the well-being of the individuals and the conservation of wild populations (Sheriff et al., 2011b). Studies using blood to measure ecophysiological associations over large spatial scales (e.g., effects of climate change or habitat degradation) or in relatively inaccessible species face logistical challenges. This may be solved by sampling blood during periods of the annual cycle when large numbers of individuals from across the landscape are more easily accessible (e.g., on migration), but physiological and environmental conditions at the time of sampling may bear little resemblance to the conditions relevant to fitness. For these and other methodological and logistical reasons summarized in Table 38.1, field researchers may choose alternative biological samples to study adrenocortical function in wild birds, such as feathers and excreta.

38.5.4.1 Feathers

The discovery (Bortolotti et al., 2008, 2009a) and independent confirmation (Lattin et al., 2011; Koren et al., 2012; Fairhurst et al., 2013b; Jenni-Eiermann et al., 2015) that corticosterone can be quantitatively determined in feathers has provided a minimally invasive and retrospective means of measuring avian GC physiology (Romero and Fairhurst, 2016). Outstanding methodological issues aside (reviewed in Romero and Fairhurst, 2016), the measurement of feather corticosterone can produce novel ecophysiological insights, and feathers provide excellent flexibility in the field. Not surprisingly, this technique has gained popularity in the past 10 years with behavioral ecologists and conservation physiologists. Evidence suggests that, with proper validation and careful interpretation,

TABLE 38.1 Summary of methodological advantages and disadvantages associated with the use of blood, feathers, and excreta samples for assessing adrenocortical function in wild birds.

	Blood samples (corticosterone, CORT)	Feather samples (corticosterone, CORT)	Excreta samples (glucocorticoid metabolites, GCMs)
Trapping and capture required	**Yes**	**Depends on context** Capturing is optional. Feathers can be collected after natural molt (e.g., near nest site) or from dead/museum specimens.	**Depends on context** Capturing is optional. Direct field observation may be required to collect fresh samples and assign bird identity.
Potential for researcher interference on results	**High** Blood GC levels increase 2–3 min postcapture. Variability in handling and restraint affects circulating corticosterone in the collected samples.	**Negligible** Even if capture is applied for sampling, the potential effect would only affect currently growing feathers (and even then may only be negligible on overall feather corticosterone levels). Only longer-term perturbations (such as captivity) would affect corticosterone levels in growing feathers.	**Low** If capture is applied, time until defecation may elevate excreta GCM levels (the extent of interference depends on the frequency of defecations and the species' metabolism).
Training required to obtain samples	**Yes** Proper blood sampling techniques require initial training	**Minimal** Proper collection of feathers from live birds requires minimal training. No training needed to collect feathers during natural molt in the field, or from research specimens, though collecting feathers from the latter may require following specialized (museum) protocols.	**No** Training not required. Fresh excreta can be collected in the field, or after restraining captured birds in cloth bags.
Time scale (of adrenocortical activity) reflected in samples	**Short** minutes (possibility of accurate, short-term characterization of adrenocortical responses).	**Medium-long** Days to weeks or months (depending on feather growth duration). Adult birds may have feathers grown at different times and in different locations. Feather morphology allows discrimination of different portions grown across consecutive days.	**Medium-short** Minutes to hours (timeframes depend on the actual delay between feeding and excretion in any given sample).
Logistics for sample collection and initial processing	**High** Venipuncture and blood sampling require using syringes or sterilized needles and microhematocrit tubes (preferably heparinized). Plasma should be separated from whole blood through centrifugation (field centrifuge, pipettes, tubes, etc., required).	**Low** Plastic or paper bags or envelopes. Samples should be kept as dry as possible to avoid mold.	**Medium-low** Excreta samples can be collected in vials or plastic bags.
Logistics for sample preservation, storage, and transport	**High** Coolers are required to preserve blood samples fresh until centrifugation within the same day. Storage and transport requires freezing (freezer, dry ice, or liquid nitrogen, and specific containers).	**Low** Feathers can be stored in paper envelopes or plastic bags at room temperature.	**Medium-high** Considerable microbial degradation requires freezing samples immediately. Alternatively, samples can be preserved in alcohol, dried in an oven or lyophilized.

Continued

TABLE 38.1 Summary of methodological advantages and disadvantages associated with the use of blood, feathers, and excreta samples for assessing adrenocortical function in wild birds.—cont'd

	Blood samples (corticosterone, CORT)	Feather samples (corticosterone, CORT)	Excreta samples (glucocorticoid metabolites, GCMs)
Possibility of subsampling to characterize timeframes	**No** Single samples cannot be divided temporally. Additional blood sampling is required to analyze time-related patterns (e.g., capture and restraint series).	**Yes** Feathers can be clipped and subsampled to select portions grown across different days.	**No** Subsampling should be avoided. GCMs are not uniformly distributed within a sample. Undigested materials can cause interference with final results.
Retrospective potential	**No** Circulating corticosterone reflects current adrenal activity and therefore has very little retrospective potential.	**High** GCs are incorporated in the feather structure during growth, but birds maintain the same feathers for months or years (depending on the feather tract and the species' molt patterns), allowing retrospective analyses (e.g., feathers collected this year can reflect circulating corticosterone levels of a previous year when they were grown).	**Low** Excreted CM reflects secretion, metabolism, and excretion during a variable period (minutes to hours) prior to deposition, allowing for short-term retrospective analyses (for example, researchers may decide to collect samples minutes to hours after a storm or a bout of aggressive interactions, and focal individuals can be chosen *post hoc*).
Discrimination between baseline and stress-induced GC levels	**High** Capture and restraint (and serial blood sampling) allows assessing baseline and stress-induced corticosterone levels in the individual. An evaluation of the internal (e.g., nutritional), environmental, and social conditions is required to determine whether initially collected samples represent true baseline.	**Low** Feather corticosterone integrates the amplitude and duration of circulating corticosterone levels during a growth period. Interpretation of results should take into account the potential variation in both baseline and stress-induced levels within and between feather samples.	**Low** Excreta GCMs integrate the amplitude and duration of circulating corticosterone levels between food ingestion and excreta deposition. Interpretation of results should take into account the potential variation in baseline and stress-induced levels within and between excreta samples.

Differences in laboratory assay methods required for the quantification of corticosterone or corticosterone metabolites levels in each type of sample should also be taken into account.

feather corticosterone can be a useful biomarker of allostasis, with applications to evaluate potential impacts of human activities on avian health and well-being (e.g., Fairhurst et al., 2015b; Sergio et al., 2015; Expósito-Granados et al., 2020; Baños-Villalba et al., 2021; Grunst et al., 2020).

Although the precise proximate mechanism requires additional study, there is solid evidence using radiolabeled hormone that circulating (systemic) corticosterone is gradually deposited (likely through diffusion) into the growing feather structure primarily during cell differentiation in the blood quill (Jenni-Eiermann et al., 2015). The corticosterone remains sequestered within the feather keratin structure, rather than being externally deposited (for example, through preen gland secretions; Bortolotti et al., 2008; Lattin et al., 2011; Jenni-Eiermann et al., 2015; Will et al., 2019), and can persist for at least 150 years (Fairhurst et al., 2015a). Robust experimental evidence shows that feather corticosterone reflects allostatic load (Johns et al., 2018) and can correlate with both baseline and stress-induced measurements of plasma GC levels (Figure 38.11C; Fairhurst et al., 2013b; Jenni-Eiermann et al., 2015). Moreover, feather corticosterone values mirror lifetime changes in reproductive success and survival rates (López-Jiménez et al., 2017). Collectively, this evidence supports a clear connection between energetic balance, circulating plasma levels of corticosterone, and the levels of corticosterone that are ultimately deposited in feathers. However, researchers should avoid using feather corticosterone as a proxy for plasma levels because a relationship between the two is likely to occur only when the latter reflect sustained HPA activity (Fairhurst et al., 2013b). Feather corticosterone should instead be viewed as a separate and alternate measure of GC physiology (Romero and Fairhurst, 2016).

The growth rate of feathers implies that the period over which researchers can assess an individual's GC levels is days or weeks, rather than minutes or hours. This represents a considerable methodological advantage for field studies, as feather corticosterone levels likely reflect a more representative and ecologically meaningful time scale of individual allostatic responses, including responses to the collective environmental perturbations experienced during feather growth. In the years since the technique was first described, feather corticosterone levels have been shown to correlate with individual fitness and performance (Figure 38.11B and C; Bortolotti et al., 2008; Koren et al., 2012; Fairhurst et al., 2012b, 2013a; Kouwenberg et al., 2013; Harms et al., 2015; López-Jiménez et al., 2017; Ramos et al., 2018; Monclús et al., 2020), quality-dependent traits (Bortolotti et al., 2009b; Mougeot et al., 2010; Kennedy et al., 2013; Grava et al., 2013; Fairhurst et al., 2014), and environmental conditions (Fairhurst et al., 2011, 2012a, 2013a; Carrete et al., 2013; Legagneux et al., 2013; López-Jiménez et al., 2016b; Treen et al., 2015; Messina et al., 2020). Moreover, correlations between measures of feather corticosterone in one period of the annual cycle and downstream biological traits in a subsequent period have provided insights into carry-over effects (*sensu* Harrison et al., 2011) in a variety of avian taxa, including seabirds (Crossin et al., 2013; Fairhurst et al., 2017), waterfowl (Harms et al., 2015; Hansen et al., 2016), songbirds (Boves et al., 2016; Latta et al., 2016; Imlay et al., 2019; Messina et al., 2020), and raptors (Monclús et al., 2020). Given the obvious utility of feather corticosterone for studying ecophysiology, and its flexible means of assessing GC levels retrospectively, feather corticosterone shows promise as a biomarker (Romero and Fairhurst, 2016). It is worth mentioning that the evidence for GC-fitness relationships has been mixed in birds (Bonier et al., 2009), but this is the norm in vertebrates (Dantzer et al., 2014) and is to be expected with any measure of GC physiology.

There is debate as to how best to express feather corticosterone levels, but the vast majority of studies correct corticosterone values by feather length (i.e., CORT/mm is the unit). This is because corticosterone is likely deposited in a time-dependent way and length best reflects time during feather growth (Bortolotti et al., 2008, 2009a; Bortolotti, 2010; Jenni-Eiermann et al., 2015). To account for effects of feather mass on feather corticosterone values (Romero and Fairhurst, 2016), which can be problematic in studies where poor nutritional condition and high levels of corticosterone can affect feather mass, alternate correction approaches have been proposed (Will et al., 2019). Researchers should also be aware that results from different analytical techniques are not comparable, and GC measurements derived from enzyme immunoassays (EIAs) and assay kits are overall less repeatable than those from in-house assays and RIAs (reviewed by Schoenemann and Bonier, 2018). This has important implications because EIA kits are increasingly popular for measuring feather corticosterone. As with all techniques for analyzing hormones, proper validation is paramount and reporting all appropriate QA/QC parameters is critical when publishing data (Buchanan and Goldsmith, 2004).

Feathers can be used to assess changes in HPA activity across short- or long-term scales. For example, because daily feather growth can be determined through visual examination of growth bands (one pair of dark/light bands is typically grown every 24 h; Jovani et al., 2010), by clipping and subsampling different feather portions, it is possible to assess changes in GC levels across the few days or weeks required to complete feather formation. This approach has limitations, as sectioning and analyzing small feather segments may present methodological problems (Romero and Fairhurst, 2016; Ganz et al., 2018). Alternatively, a complete feather could be used to assess GC activity over a longer period of days or weeks, depending on the total amount of time required to grow each feather type. Because birds regularly replace all body feathers in a species-specific molting sequence, different feathers from the same individuals allow assessing HPA activity at different times of the year and at different locations (Carrete et al., 2013). However, researchers should make all appropriate validations of the repeatability of feather corticosterone measures in feathers from the same or different tracts before comparing values (Harris et al., 2016), as repeatability is likely to be species- and context-dependent. Combining multiple feathers for analysis introduces additive variation that can easily obscure effects of interest, and even "symmetrically" molting feathers may grow over slightly different time periods, reflecting different ecophysiological conditions and, thus, produce different feather corticosterone values. Therefore, standardizing feather samples as best as possible can help reduce unwanted variation (see Romero and Fairhurst, 2016).

The analysis of GC levels can be combined with other intrinsic markers in the same sample to provide additional ecophysiological context. For example, combining feather corticosterone and stable isotope analysis can establish the detailed spatial-temporal dynamics of adrenocortical function (Fairhurst et al., 2013a), and contaminant levels can provide toxicological context (Meillère et al., 2016). Sample storage, transport, and preservation do not require freezing, and feathers can be stored in plastic bags or paper envelopes at room temperature. The analysis of feather hormones has the unique advantages of allowing for experimentation and sampling at any time of the year with minimal investigator-induced impacts and offering a large retrospective potential (Table 38.1). For example, molted feathers can be collected without disturbing wild birds, and

museum specimens can be used (Kennedy et al., 2013; Fairhurst et al., 2015a; reviewed in Romero and Fairhurst, 2016). Considering these benefits, feather corticosterone may well provide the ultimate noninvasive physiological measure of adrenocortical function in birds (Romero and Fairhurst, 2016). As with any biomarker, continued research and validation are essential (Madliger et al., 2018).

- Circulating corticosterone is deposited in growing feathers, remaining sequestered within the keratin structure and allowing a retrospective assessment of adrenocortical activity.
- Feather corticosterone levels are best expressed as pg/mm because length reflects time during feather growth. The slow growth rate allows inferring an individual's exposure and response to environmental perturbations across days or weeks (rather than minutes or hours).
- Feather plucking induces regrowth, allowing for experimentation with minimal investigator-induced artifacts. In addition, feathers are naturally replaced in a specific molt sequence, allowing noninvasive, long-term monitoring of adrenocortical function.
- Different feathers from a captured individual or a museum specimen allow inferring adrenocortical activity at different times of the year and at different locations.
- Depending on sampling, feather corticosterone provides a minimally- or noninvasive physiological measure of adrenocortical function. Appropriate validations and tests of repeatability are essential to interpreting and comparing feather corticosterone values.

38.5.5 Corticosterone metabolites in droppings (excreta)

Circulating corticosterone levels can be also traced using bird "droppings," the excretory products including urine and feces (both are normally mixed in the cloaca prior to excretion; Klasing, 2005). This can be done using either a homogenate of the entre dropping (Washburn et al., 2003) or collecting only the fecal portion (Hirschenhauser et al., 2005). However, it is very important to point out that there are no native GCs in excreta samples (Touma and Palme, 2005): GCs are extensively metabolized in the liver and excreted into urine (via the kidneys), or into the gut (via the bile ducts), undergoing further chemical modifications by the intestinal flora (Palme, 2005; Palme et al., 2005). This process results in complex and varied excreted *glucocorticoid metabolites* (*GCMs*) whose proportion and structure depends on the species and its metabolism at the time of dropping production (Goymann et al., 2006). Importantly, this requires a proper validation study to ensure that the final levels of the analyzed by-product (GCMs) reliably reflects the original GC levels (e.g., corticosterone) in the circulatory system of the research model (Millspaugh and Washburn, 2004; Goymann, 2005; Palme et al., 2005). Because excreta samples are also subjected to considerable microbial degradation after defecation (Möstl et al., 1999, 2005), samples should be collected fresh and preserved immediately. Samples can be frozen, which is preferable (Sherriff et al., 2011b), preserved in alcohol, or dried in an oven (Wasser et al., 1997; Khan et al., 2002; Terio et al., 2002); the choice of method will determine whether GCMs are expressed as per wet or dry mass (these two values may correlate; Wasser et al., 2000). It is also important to avoid excreta subsampling (GCM may not be uniformly distributed with a sample) and remove undigested materials if differences in diet among samples are observed, because both factors may introduce considerable interference into results.

Collecting samples of previously excreted samples in the field is noninvasive (see Table 38.1), but obtaining fresh samples implies the need to perform observations of marked/controlled individuals to monitor defecation events either visually (Wasser et al., 1997) or through remote spatial tracking (Thiel et al., 2008). Alternatively, birds can be trapped and restrained until defecation occurs (Garamszegi et al., 2012). Whether the stress caused by capture and manipulation affects excreta GCM levels depends on the frequency of defecations and the species' metabolism (Palme et al., 2005), making it advisable to keep detailed records of the times from capture to sample collection and preservation, and restrict the analyses to those samples collected within a short time after capture (for example, within 5 min: Garamszegi et al., 2012). GCM levels in droppings are assumed to reflect an integrated average of three processes: GC secretion, metabolism, and excretion. Although it is debated whether GCMs best represent baseline or stress-induced GCs, it is more likely that they reflect overall GC levels in circulation within a variable period of time (Sheriff et al., 2011b).

The noninvasive nature of excreta sampling procedures makes it a very suitable substrate for a wide array of applications in animal welfare and conservation biology (for reviews, see Millspaugh and Washburn, 2004; Busch and Hayward, 2009). For example, GCMs have been used to study avian adrenocortical function in relation to behavior (Lucas et al., 2006; Carere et al., 2003) and habitat quality (Wasser et al., 1997), to understand the effects of anthropogenic perturbations in natural environments (Thiel et al., 2008; Blickley et al., 2012), to determine responses to handling in captive endangered species (Glucs et al., 2018), and monitor responses to instrumentation for tracking movements (Latty et al., 2016).

- Adrenocortical activity can be monitored analyzing avian excretory products (bird "droppings"). However, *excreta samples do not contain native corticosterone*.

- Before excretion, circulating GCs are chemically transformed into GCMs, whose proportion and structure depends on the avian species. As a consequence, proper validation studies are required before assuming a direct association between circulating corticosterone titers and excreted GCM levels.
- Excreta sample collection is noninvasive and provides a suitable substrate for the study of avian adrenocortical activity, particularly in animal welfare and conservation contexts. Because bird "droppings" are subjected to microbial degradation, it is important to control the times from defecation to sampling.

Glossary of terms

ACTH corticotropin; adrenocorticotropic hormone.

Acute levels (of corticosterone) (also termed stress-regulated levels or regulated facultative levels). Corticosterone levels within the reactive homeostasis range.

Adrenocortical response physiological response to a stressor involving the hypothalamic–pituitary–adrenal (HPA) axis and culminating with the release of glucocorticoids (e.g., corticosterone) from the adrenal glands (Section 38.5.1) (Figure 38.1).

Allostasis mediators processes and body systems allowing allostasis (e.g., glucocorticoids, corticosterone, cytokines, cathecolamines, hearth rate, blood pressure, antibody titers) (Section 38.2.3).

Allostasis Model theoretical paradigm and framework to understand when and how animals activate emergency ("stress related") responses through modeling their energetic requirements across life and in relation to the energy available. Using energy as study metrics, the model introduces the key concepts of allostasis, allostatic state, allostatic load and allostatic overload (Section 38.2.1) (Figures 38.2 and 38.3).

Allostasis process of maintaining stability (i.e., homeostasis) through change. It refers to those aspects of physiology that "help us adapt." This concept is gradually replacing one of the meanings of the ambiguous term "stress" (Section 38.2.1) (Figures 38.1–38.3).

Allostatic load cumulative energetic requirements of the organism in a broad sense (the "workload" to maintain homeostasis in a particular moment), including predictable and unpredictable demands (Section 38.2.1) (Figures 38.2 and 38.3).

Allostatic overload type 1 short-term, deleterious state of energy imbalance in which allostatic load exceeds the energy available from the environment plus the internal energy reserves. As a response, individuals typically acquire an allostatic state (e.g., sustained corticosterone elevations) leading to the emergency life history stage ELHS (Sections 38.2.1 and 38.3.3) (Figures 38.2 and 38.3).

Allostatic overload type 2 long-term, deleterious state in which environmental or socially demanding challenges become chronic (e.g., social stress, captivity) and the sustained corticosterone elevations generate pathologies, regardless of the energy available (Sections 38.2.1 and 38.3.4) (Figure 38.2).

Allostatic state altered and sustained activity levels of allostasis mediators (e.g., elevated corticosterone), which can only be maintained for limited periods before damaging the body (Section 38.2.1) (Figure 38.2).

Basal corticosterone levels (also termed constitutive levels). Minimum levels allowing basic homeostatic processes. Minimum levels allowing a physiological "state A" representative of undisturbed animals at rest (Section 38.2.2) (Figure 38.3).

Baseline corticosterone levels (also termed seasonal baseline levels, regulated predictive levels or predictive homeostasis range). A range where corticosterone levels fluctuate according to predictable environmental changes, allowing the individual to cope with daily and seasonal routines of the life cycle but being insufficient to cope with unpredictable perturbations. Baseline levels allow a physiological "state B" where hormone actions maintain systems within a heightened operated range to support allostatic load (Section 38.2.2) (Box 38.1) (Figure 38.3).

Brood Value Hypothesis hypothesis proposing that birds can flexibly modulate their adrenocortical response according to the value of their brood (as the brood value increases, the adrenocortical response decreases) (Section 38.4.3) (Figure 38.9).

Capture, handling, and restraint protocol (also termed capture and handling) standardized method for capturing, handling, and restraining wild birds in repeatable conditions, required to establish adequate comparisons of their adrenocortical response. This protocol is frequently accompanied by the collection of a stress series (Section 38.5.1) (Box 38.1).

Chronic stress pathological state characterized by a malfunctioning of critical body systems as a consequence of prolonged or repeated exposure to perturbations. Allostatic overload type 2 (Figure 38.3).

Classic System traditional nomenclature describing corticosterone ranges and functional thresholds. This classification system combines three hormonal thresholds (levels A, B, and C) and a set of contrasting terms including basal and baseline, constitutive and facultative, seasonal and stress-related (Section 38.2.2) (Figure 38.3).

CORT corticosterone.

Corticosterone a steroid hormone and the primary avian glucocorticoid (see also "glucocorticoids").

Corticotropin (ACTH) adrenocorticotropic hormone. Hormone produced by the anterior pituitary (in response to hypothalamic signals) that stimulates the release glucocorticoids in the adrenal glands (Section 38.5.2) (Figures 38.1 and 38.10).

Developmental Hypothesis hypothesis proposing that the patterns of maturation of adrenocortical responses within and between avian species evolved to match the costs and benefits of glucocorticoid actions with the individual's progressive ability to cope with perturbations (e.g., increased behavioral performance and parental independence) (Section 38.4.1) (Figure 38.7).

DEX dexamethasone.

Dexamethasone (DEX) synthetic glucocorticoid that competes with corticosterone for binding sites and stimulates negative feedback (Section 38.5.2) (Figure 38.11).

Direct LPFs (direct labile perturbation factors) short-lived perturbations lasting hours or days, imposing high energetic demands and resulting in activation of the emergency life history stage (ELHS) temporary disrupting the normal lifecycle (Section 38.3.3) (Figures 38.5 and 38.6).

ELHS emergency life history stage.

Emergency life history stage (ELHS) facultative life stage activated in response to direct labile perturbations, and driven by the

elevation and maintenance of glucocorticoid levels above baseline titers (i.e., into the reactive homeostasis range or stress regulated levels). During an ELHS, birds change their behavior and physiology to maximize survival at the cost of temporarily suppressing their normal lifecycle (Section 38.3.3) (Figures 38.2 and 38.6).

Field Endocrinology emerging scientific discipline aimed at studying the interplay between the endocrine system and the environment, using wild animals in their natural habitats as study models (Section 38.5).

Flight or fight response physiological and behavioral responses to short-term perturbations, mediated by the sympathetic nervous system with little or no elevation of glucocorticoids (Section 38.3.2) (Figure 38.6).

GCMs glucocorticoid metabolites (Section 38.5.5) (Table 38.1).

GCs glucocorticoids (Figure 38.1).

Glucocorticoid metabolites the products of glucocorticoid metabolism; typically measured in blood, saliva, and body excretions (e.g., avian excreta, or "droppings"). (Section 38.5.5)

Glucocorticoids (GCs) (also misleadingly termed "stress hormones" for short) steroid hormones produced in the adrenals and released in response to ACTH. GCs are major allostasis mediators in vertebrates, control carbohydrate, fat and protein metabolism and their circulating levels change in response to internal and external demands to manage energy balance. The predominant GC in birds is corticosterone (Figures 38.1 and 38.3).

Homeostasis stability of the physiological systems essential to life. This concept is often restricted to a few truly essential systems such as pH, body temperature, glucose levels, and oxygen tension. Homeostasis refers to those aspects of physiology that "keep us alive" (Section 38.2.1) (Figures 38.1 and 38.4).

Homeostatic failure pathological state characterized by unsustainably low levels of corticosterone, insufficient to maintain homeostasis and resulting in death. Term associated with the Reactive Scope Model (Sections 38.2.2 and 38.2.3) (Figures 38.3 and 38.4).

Homeostatic overload pathological state characterized by abnormally elevated levels of corticosterone that disrupt normal body functions. The actual threshold for homeostatic overload can change within and between individuals in response to certain stimuli through a mechanism known as wear and tear (Sections 38.2.2 and 38.2.3) (Figures 38.2 and 38.4).

HPA axis hypothalamic−pituitary−adrenal axis (Figure 38.1).

Indirect LPFs (indirect labile perturbation factors) short-lived perturbations lasting seconds to a few minutes and inducing a flight or fight response with little or no elevation of glucocorticoids into the reactive homeostasis range (Section 38.3.2) (Figures 38.5 and 38.6).

Labile perturbation factor (LPF) short-term perturbation. According to their duration, labile perturbations can be classified as either direct (direct LPF) or indirect (indirect LPF) (Section 38.3.2) (Figure 38.5).

LHS life history stage (e.g., migration, moult, breeding) (Figure 38.6).

LPF labile perturbation factor.

Maternal Programming hypothesis proposing that the transfer of glucocorticoids from mothers to offspring is an adaptation, evolved to translate ecological and environmental conditions into permanent offspring responses (Section 38.4.2) (Figure 38.8).

Maternal-Match Hypothesis offset from the Maternal Programming Hypothesis, proposing that the fitness of the modified offspring phenotypes (through maternal programming) is context specific, and highest when the environmental conditions experienced during adulthood are similar to those experienced during development (Section 38.4.2) (Figure 38.8).

Modifying factor (also termed long-term or permanent perturbation) perturbation lasting months or years, imposing high energetic demands and resulting in a permanent disruption of lifecycles, potentially leading to populations extinction (Section 38.3.4) (Figures 38.5 and 38.6).

Permanent perturbation modifying factor.

Perturbation (also termed stressor) unpredictable and potentially noxious environmental stimulus. Perturbations can be classified as either labile (LPF; and these can be direct or indirect) or permanent (also known as modifying factors) (Section 38.3) (Figures 38.2, 38.4, and 38.5).

Phenotypic engineering experimental method consisting in altering a trait (e.g., elevating systemic hormone levels through subcutaneous implants) to explore whether and how such trait is adaptive. This method is a powerful tool in field endocrinology studies (Section 38.5.3) (Figure 38.11).

Predictive homeostasis range (corticosterone levels) intermediate levels of corticosterone allowing circadian and seasonal adjustments in response to predictable environmental changes. (Equivalent terms: baseline levels, seasonal baseline levels and regulated predictive levels) (Section 38.2.2) (Figures 38.3 and 38.4).

Reactive homeostasis range (corticosterone levels) elevated levels of corticosterone needed to reestablish homeostasis after a perturbation. Upper, facultative range of corticosterone levels required to cope with unpredictable challenges. The elevations of corticosterone levels within this range are known as the stress response, and can trigger an emergency life history stage ELHS. (Equivalent terms: acute levels, stress-regulated levels, regulated facultative levels) (Sections 38.2.2 and 38.2.3) (Figures 38.3 and 38.4).

Reactive Scope Model graphical tool for characterizing the physiological state of animals across time, in response to perturbations, and according to the levels of allostasis mediators such as circulating corticosterone. Offshoot of the Allostasis Model, presenting a different terminology for contextualizing the impact of stress in the body, a new classification of corticosterone levels (see Reactive Scope System) and introducing the concept of wear and tear (Section 38.2.3) (Figures 38.3 and 38.4).

Reactive Scope System recently proposed nomenclature describing corticosterone ranges and functional thresholds within the framework of the Reactive Scope Model. Corticosterone levels are presumed to exist in four ranges of increasing magnitude: homeostatic failure, predictive homeostasis, reactive homeostasis, and homeostatic overload (Sections 38.2.2 and 38.2.3) (Figures 38.3 and 38.4).

Reactive scope range of corticosterone levels defining the upper and lower physiological constraints of a healthy animal, according to the Reactive Scope Model. Combination of the predictive and the reactive homeostasis ranges above and below which serious pathologies arise. The amplitude of the reactive scope can be reduced through wear and tear (Section 38.2.3) (Figures 38.3 and 38.4).

Regulated facultative levels (of corticosterone) acute levels, stress regulated levels, corticosterone levels within the reactive homeostasis range.

Regulated predictive levels (of corticosterone) baseline levels, seasonal baseline levels, corticosterone levels within the predictive homeostasis range.

Seasonal baseline levels (of corticosterone) baseline levels, regulated predictive baseline levels, corticosterone levels within the predictive homeostasis range.

Stress hormones a misleading short-hand term for glucocorticoids; note that this is a misnomer, as the primary role of these hormones is the regulation of energy balance. This term should generally be avoided (Figure 38.1).

Stress hyporesponsive period temporary inability to elevate circulating glucocorticoids in response to perturbations (Section 38.4.1) (Figure 38.7).

Stress regulated levels (of corticosterone) acute levels, regulated facultative levels, corticosterone levels within the reactive homeostasis range.

Stress response facultative and short-term elevations of corticosterone levels in response to perturbations, allowing rapid physiological and behavioral changes aimed at maximizing survival (Sections 38.2.2 and 38.2.3) (Figures 38.3 and 38.4).

Stress series serial collection of blood samples at predefined intervals of time following capture, aimed at characterizing the adrenocortical response of the individual through subsequent determination of glucocorticoids levels (Section 38.5.1) (Figure 38.10) (Box 38.1)

Stress-induced corticosterone (or CORT) levels levels of corticosterone experienced after exposure to an acute stressor, including investigator handling (Box 38.1).

Stress polysemous term that depending on the context may mean: (1) the stimuli that challenges homeostasis (i.e., stressor, perturbation), (2) the emergency responses to perturbations (stress response), or (3) the chronic state of imbalance that follows overactivation of the adrenocortical axis (pathology; chronic stress). Modern field endocrinologists are making efforts to define and consolidate alternative and unequivocal terms, leading to the recent introduction of the word allostasis (Section 38.2).

Stressor perturbation.

Wear and tear the cost of maintaining corticosterone elevations during a stress response, as proposed in the Reactive Scope Model. Cost of maintaining and using the physiological systems that mediate allostasis. Wear and tear can be graphically represented as a decrease in the threshold level between the reactive homeostasis range and homeostasis overload which results in a decreased ability to cope with perturbations and increased likelihood of pathology (Section 38.2.3) (Figures 38.3 and 38.4).

Acknowledgments

The authors would like to acknowledge Dr. Tracy Marchant and Dr. Sonia Cabezas for their conversations, collaborations and support over the years, and thank Jose A. Sencianes (Casa de la Ciencia, CSIC) for the artwork and design of the revised figures.

Chapter 39

Avian welfare: fundamental concepts and scientific assessment

N.J. Beausoleil[1], D.E.F. McKeegan[2] and J.E. Martin[3]

[1]*Animal Welfare Science and Bioethics Centre, School of Veterinary Science, Massey University, Palmerston North, Manawatū, New Zealand;* [2]*Institute of Biodiversity, Animal Health and Comparative Medicine, University of Glasgow, Glasgow, Scotland;* [3]*Royal (Dick) School of Veterinary Studies and the Roslin Institute, University of Edinburgh, Edinburgh, Scotland*

39.1 Introduction

Around the world, there is increasing public, industry, and scientific interest in the welfare of nonhuman animals (European Commission, 2007; Coleman, 2018). Despite this interest, avian welfare has received relatively little attention. Notable exceptions include research on the welfare impacts of various aspects of poultry production systems and some aspects of management and veterinary care for companion and threatened wild bird species. However, our fundamental understanding of avian biology relevant to welfare assessment, even for these species and in these contexts, still lags behind that of mammals.

The lack of general attention to avian welfare may be partly because fewer people have direct experience of, or close contact with, birds, because there are fewer commercially important avian taxa, because we humans value birds less than other kinds of animals and are therefore less disposed to be empathetic toward them, or simply due to our less well-developed understanding of their biology and behavior (Arluke and Sanders, 1996; Hawkins, 2006; Olsson et al., 2012; Paul-Murphy and Hawkins, 2015). However, understanding animal welfare is important for ethical and reputational reasons and because welfare state often influences the survival, fitness, and productivity of animals (Virden and Kidd, 2009; Von Keyserlingk et al., 2009; Coleman and Hemsworth, 2014; Beausoleil et al., 2018; Coleman, 2018; Williams et al., 2019). Thus, there is a need to improve our understanding of relevant features of avian biology, and in doing so, our ability to assess and respond to potential bird welfare issues.

The purposes of this chapter are to introduce animal welfare as a subject available for scientific exploration and to illustrate how we can undertake such explorations. In the following sections, we describe animal welfare as it is currently understood and demonstrate that birds meet the prerequisites for welfare consideration: sentience and consciousness. We then explain how our current characterization of welfare influences its scientific assessment in birds. Key to this is the use of observable indicators to infer subjective mental experiences that matter to the animal. The Five Domains Model is introduced as a method for systematically exploring the negative and positive experiences that might influence a bird's welfare in a specific situation. However, before applying the Model to assess the impacts of events or conditions on bird welfare, evidence is needed to support the capacity of the taxon of interest to have the specific mental experiences proposed, e.g., pain or fear. We outline evidence that can be compiled for this purpose and illustrate the process by evaluating the capacity of domestic chickens (*Gallus gallus domesticus*) to experience negative states such as anxiety/fear and breathlessness during preslaughter stunning using carbon dioxide.

39.2 What is animal welfare?

Animal welfare is now generally considered to represent a dynamic state within the animal itself. This state reflects the various mental experiences, both positive and negative, the animal is having at a particular point in time. In other words, an animal's welfare state is a reflection of how it is experiencing its own life at that time (Fraser and Duncan, 1998; Harvey et al., 2020). Mental experiences arise due to processing of sensory information by the animal's nervous system. Sensory receptors gather information about the outside environment (e.g., visual or auditory signals about a predator or conspecific, mechanical information about substrate hardness, chemical information about the

Sturkie's Avian Physiology. https://doi.org/10.1016/B978-0-12-819770-7.00013-X

atmosphere being breathed) and about the animal's internal physical state (e.g., body water or glucose levels, tissue damage or inflammation, appropriateness of respiration) (Denton et al., 2009). Detection, processing, integration, and interpretation of this kind of sensory information occurs at many levels of the nervous system, in a way that is specific to the species, reflecting its natural ecology, and to the individual, influenced by its genetics and previous experiences (Mellor et al., 2009; Hemsworth et al., 2015).

In vertebrates, this processing and interpretation culminates in regions of the forebrain, leading to generation of mental experiences, some of which matter to the animal (Feinberg and Mallatt, 2013; Mellor, 2019). Such experiences have valence or affective quality, i.e., they are experienced as either negative or positive, and their valence influences behavioral and physiological responses in predictable ways (Mendl et al., 2009, 2010; Paul et al., 2018). Negative or unpleasant mental experiences such as thirst, hunger, pain, breathlessness, and fear often act as signals to the animal to respond in a specific way to try to alleviate or rectify the underlying problem and/or to reduce the risk of future reoccurrence (Denton et al., 2009; Elwood, 2011; Williams et al., 2019). Positive or pleasant experiences are proposed to act as rewards to ensure that the animal behaves in ways to achieve the same outcome again in the future (Fraser and Duncan, 1998; Boissy et al., 2007; Mellor, 2015). Negative experiences are detrimental to an animal's current state of welfare (although they may have survival benefits), while positive experiences can have both short- and longer-term enhancing effects.

In addition to valence, the specific quality of experience (e.g., pain vs. breathlessness vs. thirst) and its intensity and duration will determine its influence on welfare state (Banzett et al., 2008; Beausoleil, 2017). Importantly, unpleasant experiences that cannot be effectively rectified through behavioral and physiological responses, and so persist (e.g., chronic pain), will have a greater detrimental impact on welfare state than short-lived experiences (Fraser and Duncan, 1998; Dawkins, 2015). It is also important to note that the absence of negative experiences alone is not sufficient to achieve good welfare. If welfare state is considered as a point on a continuum from poor to good, preventing or mitigating negative experiences can only ever achieve, at best, a neutral state. To ensure "good" or "acceptable" welfare, animals also need to have some positive experiences, and welfare assessments should include evaluation of both (Boissy et al., 2007; Mellor, 2015; Mellor and Beausoleil, 2015).

This focus on mental experiences in the characterization of animal welfare has not always been widely accepted (Fraser, 2008; Dawkins, 2015). Historically, animal scientists aligned to one of three main orientations to understanding and assessing welfare: biological function, affective state, or naturalness/natural living (Fraser et al., 1997; Fraser, 2003; Broom, 2007; Korte et al., 2007; Hemsworth et al., 2015; Learmonth, 2019). These orientations emphasize the physical functioning of the animal, the mental or affective experiences the animal might perceive, or the degree to which the animal is able to live a life to which it is naturally adapted, respectively. Accordingly, an animal with good welfare would function well (including being productive for many domestic animals), feel well (be largely free of unpleasant experiences and have some pleasant ones), or live a life that allowed it to express its *telos* (naturally designed purpose or function) (Fraser et al., 1997; Rollin, 2013).

While each orientation reflects a key component of animal welfare, it is now generally acknowledged that an animal's biological function and mental experiences are intrinsically linked and that both must be considered in holistic assessments of welfare (Fraser et al., 1997; Hemsworth et al., 2015; Mellor, 2017). In particular, imbalance or dysfunction within the animal's physiological systems leads to the generation of some mental experiences and these can, in turn, influence biological function. For example, the mental experience of thirst arises due to detection of an imbalance in the amount of water and solutes in body fluids (e.g., dehydration) by the animal's nervous system (Denton et al., 2009). On the other hand, being unable to escape prolonged or regular threats such as rough human handling may lead to chronic fear, which has been shown to suppress immune function, growth and productivity in pigs, poultry, and dairy cows (Barnett et al., 1992; Hemsworth et al., 1994; Coleman and Hemsworth, 2014). However, it is important to note that the relationships between biological function and welfare state are complex, and proposed associations between observable indicators of function and welfare state should be carefully scrutinized (Beausoleil and Mellor, 2017; Veasey, 2017). To illustrate, while animals selected for high productivity such as fast growth or milk yield are biologically functional in that specific regard, such selection can predispose them to other physical impairments that compromise their welfare (see Section 39.5.1).

Naturalness reflects the species' evolutionary history in terms of the physical, sensory, and social environment for which the animal is adapted. Considering naturalness in the links between physical states and mental experiences *may* allow us to determine which environmental and social features are important for good biological function and for preventing unpleasant experiences and promoting positive ones (Veasey et al., 1996; Spinka, 2006; Rushen and de Passille, 2009). For example, knowledge of the normal social structure, sensory capabilities, and home range of wild species may inform the design of captive environments, group management, or cognitive enrichment activities (but consider Veasey et al., 1996; Learmonth, 2019). However, naturalness is problematic as a conceptual

approach to understanding and assessing the welfare of domestic animals, which have co-evolved with humans and in the environments they provide (Learmonth, 2019). Thus, both biological function and naturalness can be integrated into a characterization of animal welfare that focuses on the animal's mental experiences but only with careful consideration of the caveats outlined above.

39.3 Birds are sentient and their welfare should be considered

Animals capable of having at least some affective experiences are referred to as "sentient", and sentience is considered by most to be a prerequisite for attention to welfare state (Duncan, 2006; Dawkins, 2015; Mellor, 2019). Sentience requires a nervous system sophisticated enough to generate subjective experiences from sensory information, accompanied by behavioral responses indicative of the animal's emotional capabilities (Dawkins, 2006; Elwood, 2011). Sentient animals must also have the *capacity* to be conscious, in other words they must be capable of expressing and sustaining a state in which they are *aware* of their own sensations and affective experiences (Feinberg and Mallatt, 2013; Mellor, 2019). The capacity for consciousness and thus sentience can be inferred when animals exhibit neural complexity and behavioral flexibility, including the ability to direct attention to relevant stimuli, to determine appropriate responses in novel situations (problem solving) and to engage in volitional, goal-directed behavior (Mashour and Alkire, 2013; Dawkins, 2015; Weary et al., 2017; Paul et al., 2018; Pennartz et al., 2019). Finally, sentient animals exhibit different states of consciousness at different times and only experience affective states during times that they are consciously aware (Mellor, 2019). This is important to understand when considering the relevance to welfare of sensory events occurring when animals are not conscious, e.g., when sleeping, under general anesthetic or following effective stunning before slaughter.

39.3.1 Birds are sentient and different states of consciousness can be recognized

On the basis of their neural anatomy and physiology and their behavior, birds are regarded as sentient and conscious in ways relevant to welfare (e.g., Edelman et al., 2005; Butler and Cotterill, 2006; Panksepp et al., 2012; Feinberg and Mallatt, 2013; Mellor, 2019; Pennartz et al., 2019). Briefly, the avian brain and particularly the forebrain or pallium, which is involved in many higher-level cognitive functions, is now considered to be equivalent in complexity, connectivity, and function to the cerebral cortex of mammals (Butler and Cotterill, 2006; Rattenborg et al., 2009). Specifically, neural networks considered analogous or functionally homologous to mammalian networks involved in sensory integration, long-term memory, associative learning, and emotion have been identified in birds (e.g., The Avian Brain Nomenclature Consortium, 2005; Güntürkün, 2012; Marzluff et al., 2012; Shanahan et al., 2013; Clayton and Emery, 2015).

Birds also show complex and flexible behavioral responses, reflecting high-level cognitive processes such as sophisticated problem solving, long-term memory, learning, theory of mind, social reasoning, and emotion generation (reviewed by Butler and Cotterill, 2006; Mashour and Alkire, 2013; Clayton and Emery, 2015; Pennartz et al., 2019), including in domestic chickens (e.g., Nicol and Pope, 1994; Hogue et al., 1996; Gyger and Marler, 1998; Vallortigara et al., 1998; D'eath and Stone, 1999; Abeyesinghe et al., 2005; Nicol et al., 2009; Zimmerman et al., 2011; McCabe, 2019). Some of these cognitive skills rival or even exceed those demonstrated by nonhuman primates, such as the creation and application of tools by New Caledonia crows (*Corvus moneduloides*), use and comprehension of human language by African gray parrots (*Psittacus erithacus*), and self-recognition by magpies (*Pica pica*) (e.g., Pepperberg, 2007; Prior et al., 2008; von Bayern et al., 2018).

Thus, despite 300 million years of independent evolution, it appears that similar selective pressures have resulted in the development of similar neural and cognitive functions that support complex behavior and conscious awareness in mammals and birds (Butler and Cotterill, 2006; Rattenborg et al., 2009). This understanding is reflected in the animal welfare legislation of many jurisdictions, which state or imply that birds are sentient (e.g., European Council, 2010; New Zealand Government, 2015; McCulloch, 2018; Australian Capital Territory, 2019). In addition, birds, along with all other vertebrates, are noted as sentient in the proposed Universal Declaration on Animal Welfare (Anonymous, 2014) and the World Organisation for Animal Health's Global Animal Welfare Strategy, adopted by 180 member countries (2017).

As in humans and other mammals, different states of consciousness can be recognized in birds. For example, Sandercock et al. (2014) demonstrated differences in quantitative variables derived from the electroencephalogram (EEG), reflecting changes in electrical brain activity, in five states of consciousness in chickens and turkeys. Reliable changes in both EEG and behavior were detected when birds went from being fully awake to semiconscious (sedated), unconscious (general anesthesia), or irreversibly unconscious (after killing). McIlhone et al. (2018) observed similar changes in EEG variables with deepening general anesthesia. Finally, birds, like mammals demonstrate two different types of sleep [rapid eye movement (REM) and non-REM] which are distinguishable from each other and

from the state of wakefulness using EEG, electromyography, and behavior (reviewed by Rattenborg et al., 2009; Rattenborg et al., 2019). Thus, it is possible to assess the impacts of sensory events on the welfare of birds when they are in states of conscious awareness.

39.4 How can bird welfare be scientifically assessed?

Our current characterization of welfare means that assessing birds' welfare states hinges on our ability to recognize their mental experiences. However, mental experiences and thus welfare state are subjective and internal. That is, they are not directly observable or measurable and thus are not available for scientific scrutiny in the strictest (positivist) sense (Fraser, 1999; Dawkins, 2015). Rather, observable indicators of biological function and of behavior are used to cautiously *infer* the associated mental experiences a bird might be having. This approach is supported by the reciprocal interaction between biological function and affective experiences noted above and is reflected in the framework for welfare assessment presented below.

39.4.1 The Five Domains model for welfare assessment

The Five Domains model is a framework that has proven useful for guiding scientific investigations of animal welfare. It allows systematic organization of the observable evidence and requires interpretation of that evidence in terms of the animal's likely mental experiences (Mellor and Beausoleil, 2015; Mellor, 2017). Fig. 39.1 shows the general structure of the model and provides some examples of how physical/functional impacts on the animal may relate to specific negative and positive mental experiences. As shown in the figure, specific qualities of unpleasant experience might include breathlessness, pain, thirst, hunger, and fear while pleasant ones might include feelings of

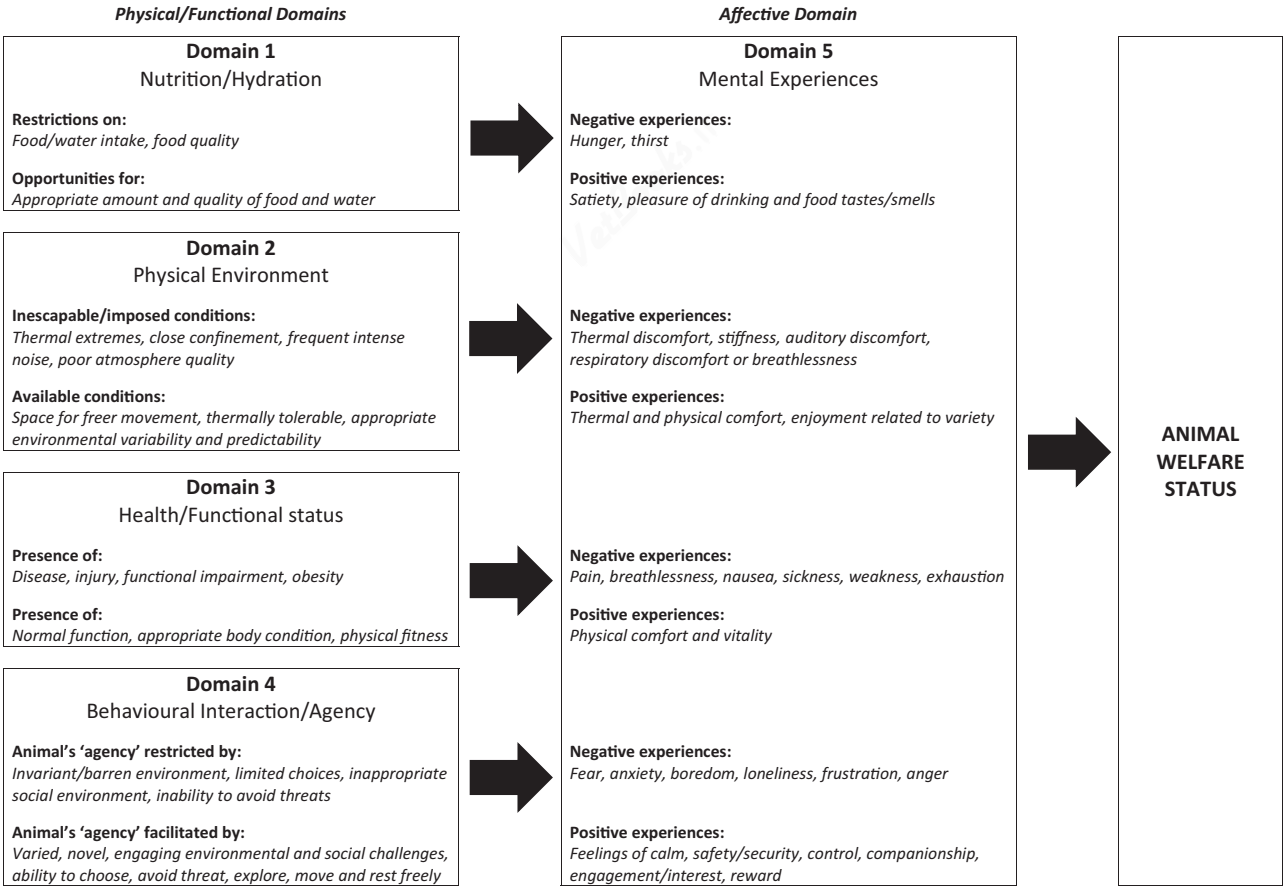

FIGURE 39.1 The Five Domains model for welfare assessment. Impacts/restrictions and opportunities in the four physical/functional domains lead to negative (unpleasant) and positive (pleasant) mental or affective experiences which are placed in Domain 5. The integrated mental/affective experiences in Domain 5 determine the welfare status of the animal. Generic examples of conditions or events that influence the animal's physical/functional state (Domains 1–4) and the associated inferred affective experiences are presented. In Domain 4, "agency" refers to animals' volitional, goal-directed behavior. Observable evidence (indicators) of physical/functional state should be collated in Domains 1–4. For more detail of the model and its application, see Mellor and Beausoleil (2015).

satiety, comfort, and companionship. Observable evidence of physical/functional states (welfare indicators) should be collated in Domains 1 to 4 and the associated mental experiences inferred in Domain 5.

Potential welfare indicators include measures of physical health and condition and behavioral, physiological and neurophysiological responses. They can be used to infer not only the occurrence but also the intensity and duration of specific affective experiences that contribute to the animal's overall welfare state. However, the onus is on the user to scientifically justify the inclusion of specific experiences for the taxon being assessed, as well as demonstrate the validity of the observed indicators considered to reflect those experiences (Beausoleil and Mellor, 2017). To ensure that the model is applied appropriately for the birds under investigation, a multidisciplinary, collaborative approach involving those with expertise in avian neuroscience, behavioral ecology, and animal welfare science is recommended (Beausoleil and Mellor, 2017; Harvey et al., 2020).

39.4.2 Hierarchy of evidence to support specific affective experiences in birds

Acknowledgment of sentience in birds means that we recognize their capacity to consciously perceive at least *some* negative and positive mental experiences that matter to them (Mellor, 2019). However, this does not mean that birds are capable of all mental experiences reported by humans, nor that we have the capacity for all of their experiences (Elwood, 2011). For example, some birds are capable of flight or of detecting polarized light or magnetic fields, things we cannot do (Freire et al., 2011; Wiltschko and Wiltschko, 2013); it seems plausible that birds might experience pleasant and unpleasant feelings associated with these kinds of sensory information that we cannot imagine (Nicol et al., 2020). In addition, the class *Aves* represents 10,000 species that are diverse in neuroanatomy, sensory physiology, behavior, and lifestyle (Martin, 2017). Thus, specific evidence is needed to support the capacity of birds, and perhaps even species of birds, for particular qualities of mental experience, to inform application of the Five Domains model for assessing the impacts of events or conditions on bird welfare.

The kinds of evidence that can be used to support the inference of a specific affective experience are: 1. Human report of experiences during exposure to similar situations or stimuli; 2. Homologous or analogous anatomical, physiological, and neural pathways and mechanisms in the taxon of interest; 3. Expression of specific protective behavioral and/or physiological responses by the animal during or after exposure; and 4. Effects of applying strategies known to circumvent or mitigate human experiences on the expression of protective responses in the taxon of interest (Dawkins, 2006; Elwood, 2011; Martin et al., 2016; Beausoleil, 2017). Note that there is also a hierarchy for the kinds of behavioral and physiological evidence that provide support for affective experiences (Dawkins, 2015; Weary et al., 2017). Following this structure, the case for birds' capacity to experience pain is outlined in Chapter 14 of this volume. While birds may not be capable of all the same experiences of humans in comparable situations, considering human experiences informs the specific affective states (and thus observed responses) that should be purposefully investigated (Steiner et al., 2019). For suspected affective experiences associated with sensory modalities humans do not have, researchers should focus on understanding the neural pathways underpinning sensory and affective processing, as well as the specific behavioral and physiological responses expressed by the animals and their mitigation.

39.5 Avian welfare research to date

While much of the research on avian neuroanatomy, sensory physiology, and high-level cognitive capabilities has been undertaken using species such as domestic pigeons, starlings, zebra finches, psittacines, and corvids (reviewed by, for example, Butler and Cotterill, 2006; Rattenborg and Martinez-Gonzalez, 2011; Shanahan et al., 2013; Güntürkün et al., 2014; Clayton and Emery, 2015; Pennartz et al., 2019), most welfare-specific research has been done on poultry, because of the very large numbers of birds commercially raised and the multiple sources of welfare compromise in these industries (see below). In addition, specific research has been done on pain and analgesia in birds kept as pets or treated in veterinary clinics (see Chapter 14, this volume), and there is increasing consideration of some aspects of welfare in free-living birds, particularly as they relate to the success of conservation activities (e.g., Sorace et al., 2001; Casper, 2009; Dickens et al., 2009; Marzluff et al., 2012; Jerem et al., 2018; Maggini et al., 2018). Because of the greater body of relevant information available, we will focus on poultry welfare here. We first briefly summarize key welfare issues relating to commercial poultry production then use one specific aspect (preslaughter stunning with carbon dioxide) to illustrate how the capacity of birds for welfare-relevant mental experiences can be scientifically evaluated.

39.5.1 Key welfare issues in commercial poultry production

Three bird species account for the majority of commercial poultry production globally: chickens (*Gallus gallus*), ducks (Pekin breed of *Anas platyrhyncos*), and turkeys (*Meleagris gallopavo*). Chickens have diverged into two types, selected specifically for meat (broilers) or egg production (layer hens). Most commercial birds are managed

indoors in closely regulated physical, thermal, atmospheric, and light environments. These factors, coupled with genetic selection for specific production traits, specialized nutrition and prevention and treatment of many infectious diseases, are tailored to maximize productivity. Some aspects of management are beneficial for welfare (e.g., supportive nutrition, disease prevention) while others present welfare risks. The selected traits, housing and management systems are generally similar for broilers, turkeys, and ducks, all of which are raised for meat, and similar welfare concerns arise for each species. Layer hens are managed differently and in more variable housing systems (e.g., caged vs. free range). Due to this, and the different physiological demands of egg production, they are predisposed to different welfare problems (reviewed by Karcher and Mench, 2018).

Broiler chickens and turkeys reach slaughter weight or conformation between five and nine weeks of age and 12 and 20 weeks, respectively (Karcher and Mench, 2018). Genetic selection for these very fast growth rates and for large breast size has numerous welfare-relevant consequences. Key problems include musculoskeletal disorders, particularly inflammatory osteoarthritis of the legs causing lameness, cardiovascular pathologies, poor thermoregulatory capacity, and poor fitness leading to limited ability to perform normal behaviors, such as walking, dust-bathing, flapping, and foraging even when opportunities exist to do so (Julian, 2005; Knowles et al., 2008; de Jong et al., 2012; Hassanzadeh et al., 2013; Norring et al., 2018; Dixon, 2020). In addition, breeding birds, which are kept into adulthood have to be severely food restricted during the rearing phase and moderately restricted during the laying phase to be reproductively competent and avoid obesity (Mench, 2002); this restriction leads to chronic hunger which is intense in the rearing phase (De Jong et al., 2002; Sandilands et al., 2006).

Layer hens are kept for much longer and are predisposed to abnormalities and fractures of the long bones and keel. This is a consequence of genetic selection for egg production, which results in osteoporosis despite adequate nutrition because calcium is preferentially deposited in eggs rather than bones (Sandilands, 2011; Wilkins et al., 2011; Tarlton et al., 2013). For both meat and egg-producing birds, welfare concerns related to housing environment and management also include respiratory and eye irritation due to poor air quality, thermal discomfort, foot problems due to poorly managed or inappropriate substrate, thwarting of strongly motivated behaviors, and the occurrence of social aggression and associated injuries and/or preventative tissue removals (i.e., beak and toe trimming in layers, turkeys, and ducks) due to limited space, high-stocking densities, and environmental barrenness (Appleby and Hughes, 1991; Rodenburg et al., 2008; de Jong et al., 2012; Widowski et al., 2016). In addition, interactions with humans, handling, and transport can induce fear and injury, especially in metabolically exhausted layer hens at the end of production (Kettlewell and Mitchell, 1994; Weeks and Nicol, 2000). Finally, the methods of bringing about unconsciousness of poultry (stunning) either prior to slaughter or during mass depopulation on farm at the end of lay or for emergency management of disease has the potential to compromise welfare before death (Steiner et al., 2019).

39.6 Case study—evaluation of the potential for chickens to experience negative states due to carbon dioxide stunning

Every year, billions of chickens are killed and some of those are first rendered unconscious by exposing them to atmospheres containing carbon dioxide (CO_2; hypercapnic atmospheres) (Nielsen et al., 2019; FAO, 2020). Here we apply the four criteria outlined above to investigate whether these birds are likely to have unpleasant experiences associated with inhaling hypercapnic gas mixtures: Human report, neural mechanisms for detection and generation of affective experiences, protective behavioral and physiological responses, and the effects of applying proposed mitigation strategies on those responses.

Normal air has less than 1% CO_2, and while CO_2 is an anesthetic gas, unconsciousness occurs only at concentrations of 15−40%, depending on the rate at which the concentration rises, the other gases in the atmosphere and the type and age of the birds (Raj et al., 1992; Gerritzen et al., 2004, 2013; Coenen et al., 2009). Inhaling CO_2 leads to higher blood CO_2 level, which strongly stimulates the rate and depth of respiration in all vertebrates (Milsom et al., 2004). Higher levels suppress neural activity, leading to loss of consciousness and death if maintained long enough (Terlouw et al., 2016). Carbon dioxide stunning is a reliable method and has welfare benefits over electrical water-bath stunning in that birds do not have to be shackled and can therefore be left in groups in their transport crates or treated in their normal housing environment with no further handling or restraint (Shields and Raj, 2010; Nielsen et al., 2019). However, breathing hypercapnic gas mixtures is known to be strongly aversive to humans and other mammals (Banzett et al., 2008). The specific unpleasant mental experiences reported by humans breathing as little as 7% CO_2 are predominantly a sense of breathlessness (air hunger) and fear/anxiety/panic, both of which intensify with rising CO_2 concentration (reviewed by Parshall et al., 2012; Améndola and Weary, 2020). In mammals, breathing CO_2 concentrations greater than about 40% also causes

painful irritation of the mucosa of the eyes, nose, and throat by activating nociceptors (Anton et al., 1991; Shusterman and Balmes, 1997). Thus, CO_2 stunning of poultry may lead to welfare impacts through at least three different unpleasant experiences: pain, air hunger, and/or anxiety.

For commercially slaughtered chickens, the most common form of CO_2 stunning involves a multiphase process, in which birds are exposed to progressively increasing concentrations of CO_2 in stages. After birds lose consciousness at around 15−30% (Raj et al., 1992; Gerritzen et al., 2004, 2013), final phases expose them to 60−80% CO_2 which is maintained until a state of nonrecovery is reached, followed by exsanguination. Although birds have CO_2-responsive nociceptors in the oral and nasal mucosa (McKeegan, 2004), most birds lose consciousness before the concentration reaches receptor activation threshold, so mucosal pain is not expected. However, on the basis of human reports and the behavioral responses of various mammals, birds might be expected to experience unpleasant breathlessness and fear before loss of consciousness if they have the capacity for sensory detection and generation of these affects.

Chickens are able to detect elevated CO_2 at concentrations much lower than those used for stunning. Unlike mammals, birds have intrapulmonary chemoreceptors that respond to small changes in inhaled CO_2, stimulating deeper, slower breathing (Milsom et al., 2004; Fedde, 2012). Other behavioral evidence also supports sensitivity to subnociceptive concentrations of CO_2 in birds. Hens spent less time feeding in a chamber containing 7.5% or 10% CO_2 than in one containing normal air (Raj and Gregory, 1991). Likewise, at 10% CO_2 and above, layer hens changed their previous behavior, began manipulations ("tasting" movements of the bill) and noticed the end of exposure (McKeegan et al., 2005, 2006).

However, detection of a hypercapnic atmosphere doesn't necessarily lead to generation of unpleasant experiences such as the breathlessness and anxiety/fear reported by humans. Since birds have a unique respiratory system (see Chapter 20 this volume), extrapolation of respiratory sensations from mammals may not be valid. For example, birds have fixed lung volume, unidirectional airflow, and higher dead space (due to air sacs), all of which may influence the adaptive value of the sensation of air hunger, which arises in mammals due to a mismatch between ventilatory drive and lung inflation (Banzett et al., 2008). Although the neurological bases of feelings of breathlessness are understood in humans and other mammals (Parshall et al., 2012; Beausoleil and Mellor, 2015), these have not been specifically explored in birds. Similarly, the neural circuitry for fear in birds is well characterized (reviewed by Papini et al., 2019) but whether it is activated by exposure to hypercapnic gases has not been investigated (Steiner et al., 2019).

Thus, the most compelling available evidence is the protective behavioral responses demonstrated by chickens exposed to hypercapnic environments. Most studies report that 30% CO_2 or higher elicits a suite of behaviors such as head shaking, mandibulation, wing flapping, and abnormal respiratory patterns, including open-bill, labored or difficult breathing with a prolonged inspiratory phase; these behaviors begin before loss of consciousness (reviewed Steiner et al., 2019). While these responses could represent unpleasant experiences ("distress"), they may be automatically generated, and their significance to welfare is difficult to interpret without additional information.

In an attempt to better access birds' affective experiences, several studies have allowed chickens to choose between remaining in a hypercapnic environment to access a food reward and withdrawing from the atmosphere but forfeiting the reward. These kinds of tests provide stronger evidence of any unpleasant experience because the animal has to cognitively compare and decide between different priorities (Weary et al., 2017). McKeegan et al. (2006) showed that broilers continued to feed in the presence of subnociceptive hypercapnic gas while hyperventilating, suggesting that respiratory disruption does not necessarily reflect an unpleasant experience in birds. Collectively, the outcomes of this and other studies suggest that atmospheres containing 10−70% CO_2 are only mildly to moderately aversive to chickens (Raj and Gregory, 1991; Gerritzen et al., 2000; Webster and Fletcher, 2004; McKeegan et al., 2006).

However, the results of some of these studies may have been confounded by the research design, e.g., requiring slaughter-weight broilers to walk up a 5 m inclined ramp to get out of the CO_2 atmosphere (Webster and Fletcher, 2004). Additionally, it has been suggested that failure to leave an area where potentially sedative or narcotic gases have been introduced may reflect the subject's physical inability to do so or reduced cognitive capacity, rather than a lack of aversion per se (Gerritzen et al., 2000; Leach et al., 2002; Wong et al., 2014). In support of this, chickens exposed to CO_2 gas mixtures exhibit sitting down in an upright posture much earlier than do birds exposed to air, which may reflect their inability to remain standing due to the anesthetic effect of the gas (Gerritzen et al., 2000). Conditioned place aversion tests may help address such limitations by asking birds to display any learned aversion after, not during, exposure to CO_2. As yet, such tests have not been undertaken.

Nor have mitigation studies been undertaken for CO_2 stunning of birds. Treating humans and rats with antianxiety drugs has demonstrated the contribution of fear/anxiety/panic to human reports of unpleasantness and animals' behavioral responses indicative of aversion (Améndola and Weary, 2020). Likewise, the effects of treatment with drugs such as inhaled furosemide, known to relieve

breathlessness in humans, on chickens' responses to CO_2 have not been explored. Overall, and despite the equivocal evidence, the general view is still that CO_2 stunning is likely to cause unpleasant experiences in poultry, although the character of those experiences is not yet clearly understood, and more specific research is needed (Steiner et al., 2019). As gaseous methods of stunning poultry are becoming more widespread (due to welfare and other advantages over electrical water-bath stunning), understanding the associated affective experiences and welfare impacts becomes all the more pressing.

39.7 General conclusions

Birds are undeniably sentient and thus capable of at least some negative and positive mental experiences that matter to them. The impacts, both negative and positive, of events and conditions on bird welfare should be systematically evaluated using a structured, evidence-based framework such as the Five Domains model. However, our current understanding of the specific affective experiences of birds is relatively limited, partly because of the strong focus of animal welfare scientists on commercial poultry species. There is a need for research to translate avian neuroscience, behavioral ecology, and cognitive sciences knowledge to better understand birds' affective experiences and welfare states, including in a wider range of avian species. This is particularly important as the effects of human activities on wild animal species is ever expanding. While productive interaction among scientific fields is growing, it is anticipated that greater cross-disciplinary discussion involving avian neuroscientists, behavioral ecologists, psychologists, and animal welfare scientists will rapidly advance our understanding of bird welfare.

PRL Prolactin
T Testosterone

40.1 Introduction

For a species to persist, reproduction is arguably the most important life history stage. In most species, reproduction is associated with the expression of some type of reproductive behavior, an orderly sequence of behavioral events that can include visual and auditory displays, copulation, nest building, oviposition, incubation, and care (including food provisioning) of young. Reproductive behavior is a crucial target of selection, and understanding its proximate bases can therefore help us address issues related to the persistence and evolution of organisms. Within vertebrates, reproductive behavior is widespread and exhibited by representatives of all classes, and it is thought to have evolved well before the emergence of birds. Indeed, similar to modern birds, nonavian maniraptoran dinosaurs probably exhibited a daily oviposition pattern, produced eggs with a complex shell microstructure, and protected their clutch (Zheng et al., 2013). Based on correlative analysis of clutch size and adult bone morphology, Varricchio et al. (2008) conclude that some Cretaceous dinosaurs exhibited paternal care and possibly had a polygamous mating system (Varricchio et al., 2008). More recently, ancestral phoenicopterids from the early Miocene are thought to have built floating nests, as do some of their extant relatives (grebes: Grellet-Tinner et al., 2012).

Given its distant origin, it is not surprising that within each vertebrate class, reproductive behavior varies enormously with respect to complexity, seasonal timing, duration, and control mechanisms. Birds have long been considered to be choice models to investigate the mechanisms that control the expression of reproductive behavior. Being endotherms, they thrive in diverse environments ranging from cold and hot deserts across a wide range of latitudes and altitudes to tropical and equatorial forests, as well as oceanic islands. Many species are, therefore, readily accessible to researchers. In addition, all aspects of avian reproductive behavior, as well as avian social systems, which range from social monogamy to polygyny and polyandry (dunnock, *Prunella modularis*: Langmore et al., 2002; Owens, 2002; spotted sandpiper, *Actitis macularius*: Rissman and Wingfield, 1984), are extremely diverse, and this diversity presents boundless opportunities for comparative work. Furthermore, many species are diurnal and colorful, and they sport a sexually dimorphic adult plumage. Their reproductive behavior often includes conspicuous visual (e.g., social displays, copulation, and parental feeding) and auditory (e.g., song) signals that are relatively easy to observe and quantify. Also of note, the expression of avian reproductive behavior is in many species seasonal and generally restricted to the time of year when environmental resources, in particular food, that are necessary for the optimal development of the offspring are most abundant and accessible. This expression is often regulated by hormones whose secretion likewise fluctuates seasonally. Not unexpectedly, therefore, birds have long been used as primary model organisms for correlative studies on hormones and reproductive behavior, and for mechanistic research aimed at identifying the hormonal and neural bases of this behavior during ontogeny and in adulthood. Finally, several species (chicken, *Gallus*

Sturkie's Avian Physiology. https://doi.org/10.1016/B978-0-12-819770-7.00052-9

domesticus; Japanese quail, *Coturnix coturnix japonica*; domesticated turkey, *Meleagris gallopavo*; ring dove, *Streptopelia risoria*; domesticated canary, *Serinus canaria*; and zebra finch, *Taeniopygia guttata*) have long been domesticated, and many aspects of their reproductive behavior and physiology have been studied extensively (see Sections 40.4.1, 40.6.2, and 40.6.5). This knowledge gained from these studies, along with ready access, presents unsurpassed opportunities for in-depth mechanistic investigations (Ball and Balthazart, 2004; Balthazart et al., 2003).

40.2 Regulation of reproductive behavior

The expression of reproductive behavior at maturity is regulated by a multitude of external factors—environmental and social—as well as internal factors, the nature and relative importance of which often vary interspecifically, between sexes, during ontogeny, as a function of adult age and experience, and according to the reproductive stage. A comprehensive review of the vast literature related to this regulation well exceeds the scope of the present chapter. Thus, we focus on a limited number of representative topics based on their potential interest to readers, progress made in the recent past, and the generality of conclusions that can be reached based on the available information. We begin with an analysis of environmental factors and then social factors with well-documented effects on the reproductive system and behavior. Age and breeding experience can profoundly impact the adult reproductive system and the expression of reproductive behavior, and so we address the respective roles of these factors. Many studies have investigated the mechanisms by which peripheral hormones and neurohormones regulate reproductive behavior. We follow those sections with an analysis of this regulation, with particular attention paid to the role of gonadotropin-releasing hormone (GnRH), gonadotropin-inhibitory hormone (GnIH), arginine vasotocin (AVT), prolactin (PRL), gonadal steroids, and neurosteroids.

Three underlying themes run through the present chapter. First, we emphasize that gonadal hormones play an overwhelming role in the control of avian reproductive behavior. Any analysis of the mechanisms that regulate this behavior must, therefore, necessarily encompass a discussion of the mechanisms that control the activity of the reproductive system itself. For this reason, we provide examples drawn not only from the behavioral literature but also from the endocrine literature. Second, when addressing the (neuro)endocrine mechanisms that regulate reproductive behavior, one needs to take into account that this regulation is frequently reciprocal. For example, gonadal steroids profoundly influence the expression of reproductive behavior, but social and perhaps chemical signals from conspecifics can markedly affect the secretion of gonadal hormones. In some cases, even an individual's own behavior causes marked endocrine changes within this individual. Third, at the individual level, most endocrine systems do not operate independently but are functionally interrelated. Illustrating this point, gonadal steroids can markedly influence the production and secretion of behaviorally active neuropeptides such as adrenocorticotropic hormone and AVT. Furthermore, during stress, elevated secretion of hypothalamo–pituitary–adrenal (HPA) axis hormones can negatively affect aspects of reproductive physiology and behavior.

40.3 Environmental factors

Many environmental factors have the potential to influence the reproductive physiology and behavior of birds. These factors include weather-related events such as droughts (Reichert et al., 2012) and storms (Astheimer et al., 1995; Bolger et al., 2005), temperature (Ardia et al., 2009), and humidity (Cynx, 2001). Understanding the effects of these factors and how they affect reproduction is of considerable importance given the potential outcome of global climate change on biological systems (Beale et al., 2006; Senapathi et al., 2011; Shine and Brown, 2008; Moller, 2013), but this understanding is complicated by several factors. For example, weather-related events such as storms are generally perceived as stressful and often have negative reproductive consequences (e.g., they delay the onset of breeding and incubation behavior), but whether this is the case can be reproductive stage dependent (Wingfield, 1984). In addition, the effects of weather- or climate-related factors on the reproductive system can be direct (temperature: Ardia et al., 2009; Visser et al., 2009) but, alternatively or in addition, be indirect and result from changes, such as in food resources (drought: Bolger et al., 2005). Here we consider the direct and indirect roles of weather and climate, as well as other important environmental factors including light and urbanization.

40.3.1 Temperature and climate change

Global temperatures have increased over the last century, a trend that is predicted to continue at an even greater rate over the coming decades (Stillman, 2019), with a concurrent increase in number and duration of extreme weather events such as storms, floods, droughts, and heat and cold waves similarly predicted (Rahmstorf and Coumou, 2011; Coumou and Robinson, 2013). There is already an abundance of evidence for changes to physiology and behavior of a multitude of organisms due to climactic changes. These long and short-term events have the potential to impact bird populations on both a sudden and dramatic scale (i.e., mass mortality events associated with extreme events), as well as more subtle changes that may be revealed across

generations, leading to birds being considered one of the most at-risk animal groups (Foden et al., 2013). To mitigate the risk of overheating in high temperatures, birds use physiological and behavioral responses including shade-seeking behaviors, resting, changes to wing posture, and panting (Fedde, 1998; Dawson, 1982; Pattinson et al., 2020). Some species can also tolerate a controlled increase in body temperature in order to reduce the temperature gradient between their body and the environment (Gerson et al., 2019). All of these mechanisms promote survival of the individual, but often at the cost of other physiological demands, including reproductive behaviors, which can be energetically expensive. For example, the little bustard (*Tetrax tetrax*), uses "snort-calling" to signal to females, a behavior which is reduced in increased temperatures (Gudka et al., 2019), and negatively impacts breeding success. More directly, in both domestic chickens (*Gallus gallus*, Karaca et al., 2002) and zebra finch (*Taeniopygia guttata*, Hurley, et al., 2018), heat stress (where temperature and intensity are manipulated to mimic a heat wave) decreases sperm concentration and viability. Most of what is known about the effects of increasing temperature on reproduction come from studies on birds already living in tropical and other warm climates, and comparatively little research has studied the effect of climate change on those adapted to more temperate climates. This is a notable oversight, as the higher latitudes are expected to warm at an increased rate (IPCC, 2014). Photoperiod and circadian rhythms control the initiation of changes to physiology and behavior in seasonal breeders (Farner, 1964; Dawson et al., 2001); however other cues, such as temperature, can regulate gonadal growth and other reproductive behaviors due to direct and indirect effects (for review, see Chmura et al., 2020). For example, a 2017 meta-analysis showed that, over the last 45 years, the length of the breeding season has changed differentially based on the birds' brooding habits, where single-brooded species have shortened their season by two days per decade and multibrooded species have prolonged their season by four days (Figure 40.1, Halupka and Halupka, 2017a). Indirectly, changing temperature patterns can affect the availability of food sources and therefore energy available for reproduction. Foraging behaviors and successes are decreased with increasing temperatures for various species (Conradie et al., 2019). Global climate change may further complicate reproductive cues, as the timing between temperature changes and photoperiod cues (a topic addressed in Section 40.3.2) will become mismatched (Walker et al., 2019).

40.3.2 Light

In most avian species studied to date, exposure to sufficiently long days (i.e., above a minimum, species-specific threshold) stimulates a cascade of physiological events, including synthesis and secretion of chicken gonadotropin-releasing hormone-I (cGnRH-I). This stimulation ultimately causes gonadal development and increases the secretion of gonadal steroids (Dawson, 1999; Dawson et al., 2001; Stevenson et al., 2013), which play a primary role in the control of reproductive behavior (see Section 40.6.4). It is notable that even species such as the opportunistic zebra finch, which has traditionally been considered to be nonphotoperiodic, respond to very long days by activating their reproductive system (Bentley et al., 2000b). Due to its effects on the hypothalamo−pituitary−gonadal (HPG) axis, photostimulation in many cases exert effects that are indirect and mediated by elevated circulating concentrations of gonadal hormones. Limited evidence, however, suggests in some conditions that photoperiod influences avian reproductive behavior independent of its effects of the HPG axis. For example, castrated, androgen-treated ring doves exposed to long photoperiods exhibit higher levels of nest-building activity than short-photoperiod-exposed birds (McDonald and Liley, 1978). The mechanism mediating this effect remains unclear and may be related to changes in body condition. Indeed, birds exposed to long days have more time to feed and gain energy daily than short-day-exposed birds, and they may consequently be able to devote more resources to energy-consuming activities such as those associated with breeding (Perfito et al., 2008). Stimulatory effects of artificial urban lights on the timing of the dawn chorus of songbirds, as well as on their laying dates and male pairing success (Kempenaers et al., 2010; Longcore, 2010), may likewise result from extension of the daily feeding time and access to more food resources. Exposure to artificial light at night, mimicking urban light pollution, advanced gonadal development in male European blackbirds (*Turdus merula*) (Dominoni et al., 2013), and great tits (*Parus major*) (Dominoni et al., 2018). In free-ranging birds, separating behavioral effects of photoperiod that are mediated by changes in energy intake from those that are secondary to elevated HPG hormone secretion has proved challenging, and additional work on this subject is clearly warranted.

40.3.3 Food resources

Resource availability has long been thought to exert a critical influence on the timing of reproduction, including the expression of reproductive behavior, with parents generally raising young when food is seasonally most abundant. This view is supported by correlative and manipulative studies. For example, crossbills (*Loxia* spp.) feed primarily on conifer seeds, the abundance of which varies greatly and often unpredictably in time and space (Benkman, 1992). In these birds, food availability (along with day length and social factors) plays a determining

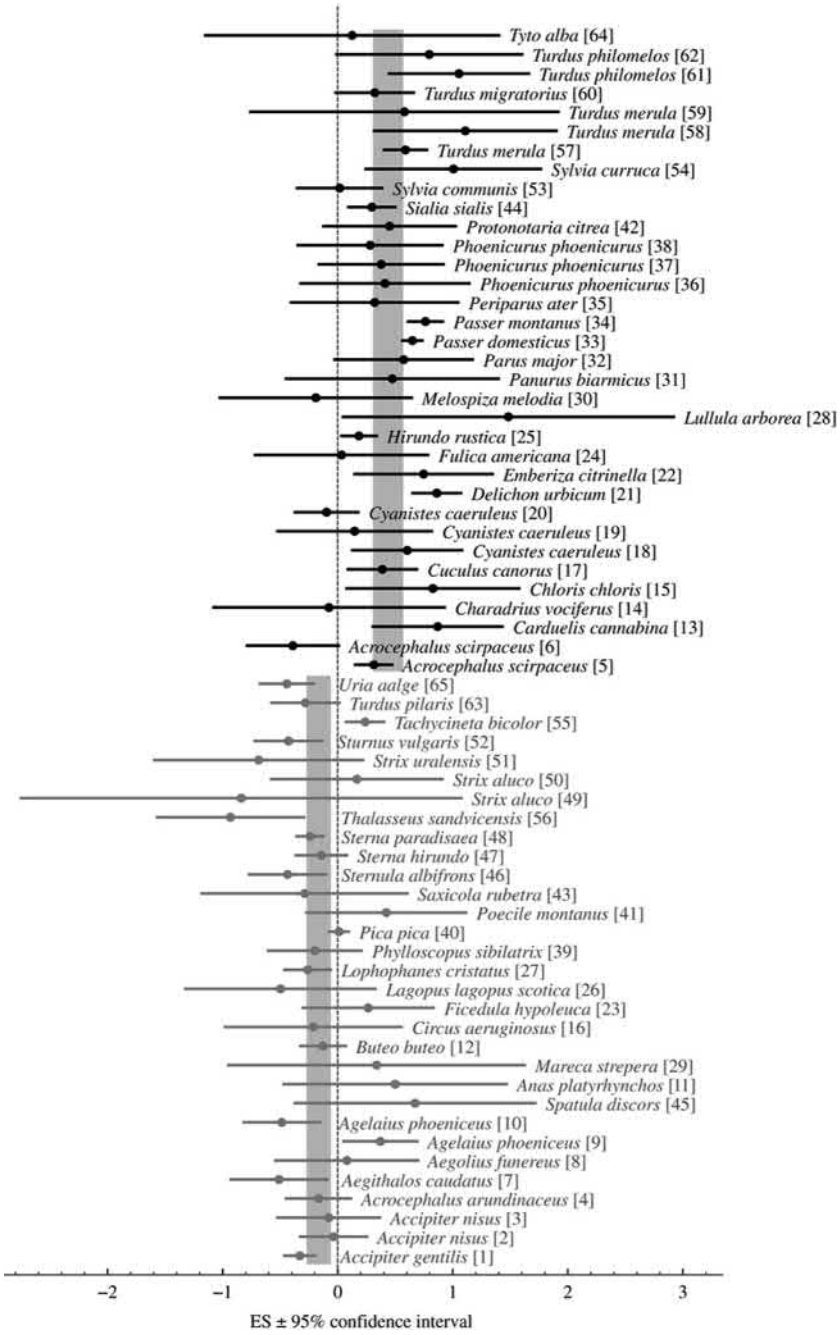

FIGURE 40.1 The rate of change of breeding season length for 65 studies of 34 multibrooded (black) and 31 single-brooded (gray) species. Numbers in brackets refer to population IDs in Haulpka and Halupka (2017a). *Reprinted from Haulpka and Halupka (2017b) with permission.*

role in the timing of reproduction (Benkman, 1990; Hahn, 1995; Deviche and Sharp, 2001). Another illustration is provided by research on blue tits (*Cyanistes caeruleus*). Blue tits preferentially feed their young noctuid lepidopteran caterpillars, but will also feed them less preferred tortricid lepidopteran caterpillars, which are smaller but easier to obtain and have a different phenology than noctuids. In this species, an adjustment of the timing of reproduction that is associated with an increased proportion of noctuids fed to young results in heavier nestlings (Garcia-Navas and Sanz, 2011).

Food resource manipulations—supplementation or restriction—are commonly used to investigate the role of these resources. With some exceptions (Harrison et al., 2010), food supplementation generally promotes the activity of the reproductive system as assessed by gonadal development, plasma levels of reproductive hormones, laying date, and expression of reproductive behavior

(Hahn, 1995; Brommer et al., 2004; Schoech et al., 2004; Watts and Hahn, 2012). It is noted that these effects are, however, susceptible to modulation by various factors, including photoperiod and social interactions (Hahn, 1995) and predation pressure (Zanette et al., 2003). In addition, the interpretation of the findings from food manipulation studies needs to consider that short-term reproductive effects of food supplementation may differ from long-term effects. For example, food supplementation to song sparrow (*Melospiza melodia*) parents has transgenerational behavioral effects, causing these parents to produce more offspring than control parents. However, this apparent advantage is mitigated by the fact that food-supplemented parents produce smaller eggs and nestlings than control birds and that their male offspring have a smaller song repertoire—and are thus presumably less fit—than the offspring of control parents (Zanette et al., 2009, Figure 40.2).

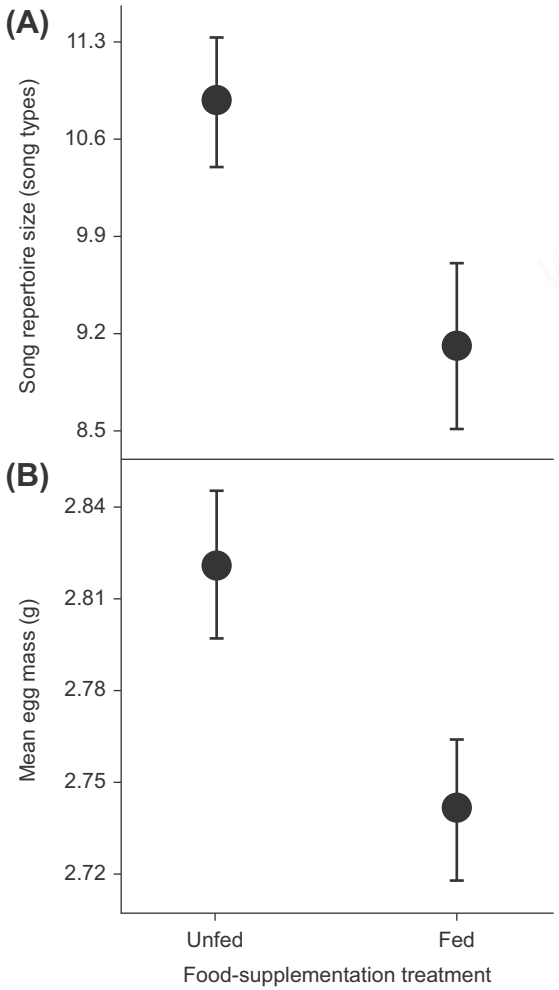

FIGURE 40.2 Food supplementation to song sparrow parents decreases (A) the song repertoire size of their sons ($P = .030$) and (B) the mean egg mass ($P = .017$). *Reprinted from Zanette et al. (2009) with permission.*

Food restriction generally results in effects in the opposite direction compared to those of food supplementation (Bauchinger et al., 2009). In the hen, this manipulation leads to lower plasma luteinizing hormone (LH) and gonadal steroids, as well as decreased mass of reproductive organs, and these changes are reversed in response to refeeding (Richard-Yris et al., 1987). Endocrine effects of food restriction in hens are reproductive stage specific, however, with plasma follicle-stimulating hormone being lower in food-restricted than *ad libitum*—fed birds prior to sexual maturity, but not in egg-laying birds (Bruggeman et al., 1998). Similar to the situation in females, food restriction in males leads to reproductive deficits such as reduced sperm quality and semen volume (Cerolini et al., 1995). In the male zebra finch, no testicular development occurs following transfer from short to long day length in food-restricted males, but this transfer stimulates testicular recrudescence in *ad libitum*—fed birds (Perfito et al., 2008). In this opportunistic breeder, food availability, therefore, apparently plays a more important role than day length in the control of HPG axis activity.

40.3.4 Case study: urbanization

The diversity of environmental factors to which birds can respond and of the effects of these factors (e.g., migration: Tryjanowski et al., 2013; reproduction: Partecke and Gwinner, 2007; Davies et al., 2013; community structure: Gagne and Fahrig, 2011; Schlesinger et al., 2008; parasite infection: Sitko and Zalesny, 2012) is well illustrated by research on the effects of urbanization. Urbanization is associated with massive and in most cases largely irreversible environmental changes, including an increase in ambient noise, temperature heat island effect: Zhang et al., 2010b, and nocturnal illumination, and differences in plant community composition and phenology (Mimet et al., 2009) that can in turn drive alterations in the food resources that are available to herbivores and carnivores. These changes, acting separately and/or cumulatively, and directly and/or indirectly, have the potential to profoundly affect the reproductive physiology and behavior of urban birds. The net consequences of urbanization on fitness remain, however, debated and poorly understood. On the one hand, urban birds frequently have an advanced reproductive phenology compared to corresponding nonurban birds (Davies et al., 2013; Davies et al., 2015; Dominoni et al., 2013), and this advancement has the potential to increase their reproductive output and fitness by increasing the duration of the annual breeding period. On the other hand, urban birds are exposed to physical factors that can be perceived as stressful and that adversely affect physiological and behavioral processes. One such factor is anthropogenic noise (noise pollution). Correlative evidence strongly suggests that noise pollution has a detrimental

influence on breeding success and individual fitness (eastern bluebird, *Sialia sialis*: Kight et al., 2012; house sparrow, *Passer domesticus*: Schroeder et al., 2012). This conclusion is supported by experimental studies. For example, greater sage grouse (*Centrocercus urophasianus*) that are experimentally exposed to chronic noise show elevated excretion of glucocorticoid metabolites, suggesting enhanced stress levels, and decreased lek attendance (Blickley et al., 2012). The reproductive effects of noise pollution are, however, often species specific and can be complex. Illustrating this, exposure to elevated ambient noise level does not substantially affect plasma corticosterone (CORT) or reproductive behavior in the Australian black swan (*Cygnus atratus*) (Payne et al., 2012). In addition, by disrupting predator–prey interactions, ambient noise can in some situations in fact *increase* breeding success (Francis et al., 2009). A few studies have examined the relationships in birds between urbanization and the acute stress response (increased plasma glucocorticoids in response to capture and restraint: Fokidis et al., 2009; Partecke et al., 2006). Urban European blackbirds (*Turdus merula*) show a lower response to acute stress than forest conspecifics (Partecke et al., 2006). For the most part, however, the physiological (including endocrine) bases of differences between urban and corresponding nonurban birds remain poorly understood, and this research topic is ripe for new correlative and manipulative investigations.

40.4 Social factors

Studies over many years, using a variety of experimental models and carried out in field and laboratory settings, consistently demonstrate that social interactions between conspecifics can influence all aspects of their reproductive behavior. Research on this subject also shows that an individual's own behavior can influence its physiology, including the production and secretion of behaviorally active hormones and neurochemicals, and this influence can in turn lead to behavioral modifications. The modulation of reproductive behavior by social factors is often complex, and with a few exceptions (e.g., the ring dove; see Section 40.4.1) the proximate underlying mechanisms—including the sensory modalities involved and the pathways that underlie sensory information processing—remain poorly understood. This topic provides rich opportunities for new and exciting research.

40.4.1 Effects of males on conspecific females

Intraspecific social interactions can profoundly affect the behavior and physiology of individuals of the opposite sex. In the female Japanese quail, plasma CORT increases as a result of mating (Rutkowska et al., 2011). This increase is not seen in females that interact with a male without opportunity for mating, but it is observed in females that interact socially with other females. Thus, direct social interactions rather than the act of mating per se apparently elevate plasma CORT in these birds. The role of social interactions is shown also by work on Gouldian finches (*Erythrura gouldiae*), in which females that are experimentally paired with a nonpreferred, poor-quality male have chronically higher plasma CORT than females paired with a preferred male (Griffith et al., 2011, Figure 40.3). Across species, lower stress levels in females that are paired with attractive mates may contribute to these females investing more in reproduction, as measured by egg size and food-provisioning behavior (Horvathova et al., 2012). In another type of investigation, exposure of females to conspecific song was found to induce behavioral and neural effects. For example, in several species, this exposure enhances female sexual responsiveness (song sparrow: Searcy and Marler, 1981; Pasteau et al., 2012; brown-headed cowbird, *Molothrus ater*: Freed-Brown and White, 2009) and activity level (European starling, *Sturnus vulgaris*: Riters and Teague, 2003). Exposing females to male songs also has physiological consequences that may influence fitness, as shown in canaries by the fact that females exposed to attractive male song repertoires deposit more testosterone (T) in their eggs than females exposed to unattractive male song repertoires (Gil et al., 2004).

The role of social interactions on the female reproductive system is further exemplified by work on captive willow tits (*Poecile montanus*), in which ovarian development is advanced in females paired with a male compared to females held in isolation (Silverin and Westin, 1995).

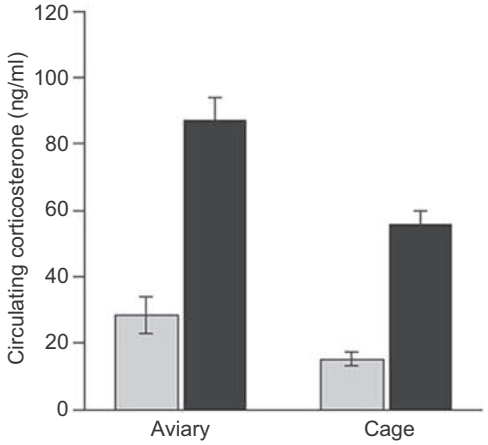

FIGURE 40.3 Baseline plasma corticosterone (CORT) during the egg-laying period in female Gouldian finches paired either with a genetically compatible (gray bars) or with a genetically incompatible (black bars) conspecific male. During breeding, birds were held either in a group aviary (aviary) or in cages containing one pair of birds (cage). Irrespective of the setting, females paired with an incompatible male have higher plasma CORT than females paired with a compatible male. *Reprinted from Griffith et al. (2011) with permission.*

This study did not isolate the factors that promote ovarian development, but other studies have addressed this question and demonstrate an important role for acoustic signals. For example, in song sparrows and domesticated canaries, exposure to conspecific song stimulates follicular development (Bentley et al., 2000a). The neuroendocrine mechanism mediating this stimulation is explored in the white-throated sparrow (*Zonotrichia albicollis*). In this species, male song rapidly (within 1 h) increases the secretion of LH and the expression of the immediate early gene, early growth response-1, in the mediobasal hypothalamus, but not in GnRH-producing neurons, suggesting behaviorally induced secretion of the peptide (Maney et al., 2007).

The most detailed investigations on the neural pathways that mediate reproductive effects of conspecific vocalizations in females have been conducted in the ring dove, a domesticated species that has long been used as an excellent model to unravel interactions between hormones and reproductive behavior (Lehrman, 1964; Lehrman and Friedman, 1969; McDonald and Liley, 1978; White, 1975). In the female ring dove, visual and auditory (but not physical) contact with a male stimulates the expression of courtship vocalizations (nest-coos) and ovarian development, and this effect is more pronounced after exposure to intact than castrated males (e.g., Lott et al., 1967). Females whose hypoglossal nerves (which innervate the vocal organ or syrinx) are sectioned show a reduction in their expression of nest-coos and, concurrently, in male courtship–induced ovarian development (Cohen and Cheng, 1979), leading to the remarkable hypothesis that a female's vocal behavior promotes her own ovarian development. The selectivity of this activation is demonstrated by the observation that plasma LH increases more in female doves that are exposed to female than male nest-coos (Cheng, 2008; Cheng et al., 1998). As neuronal track-tracing studies demonstrate, the self-stimulation of ovarian development involves the relay of auditory information to the midbrain nucleus intercollicularis (ICo). This brain region in turn communicates with the anterior hypothalamus, where some neurons themselves respond to auditory stimulation, through enkephalinergic projections (Cheng and Zuo, 1994). When stimulated, some hypothalamic neurons increase their secretion of GnRH, and this increase is in turn responsible for elevated gonadotropin secretion and ovarian development.

40.4.2 Effects of females on conspecific males

The above studies conclusively show effects of males on the reproductive system of conspecific females, but there is also strong experimental evidence that females can in some cases influence the reproductive system of conspecific males. In the domesticated Japanese quail, the reproductive maturation rate of photostimulated males that are held with females is faster than in isolated males; paired males also have higher plasma LH and T than isolated males (Delville et al., 1984). In experimental aviaries, the presence of a female increased singing and plasma T of male European starlings (*Sturnus vulgaris;* Pinxten et al., 2003). Parallel findings are reported in free-ranging birds: treatment of free-ranging female song sparrows with estradiol at the beginning of the breeding season increases their sexual behavior, and this increase correlates with elevated plasma T and territorial behavior in males residing in the same area (Wingfield and Monk, 1994). Similarly, estradiol administration to free-ranging female pied flycatchers (*Ficedula hypoleuca*) in breeding condition stimulates the aggressive behavior of their mates (Silverin, 1991). It must, however, be pointed out that the presence of females does not necessarily have stimulatory effects on the male reproductive system, and so great care must be exercised when trying to generalize findings across species. Illustrating this, in captive male willow tits exposed to long photoperiods, testicular maturation is *delayed* and birds regress their testes *earlier* when kept in the presence of a female than when in isolation (Silverin and Westin, 1995). It also needs to be stressed that experiments using estrogen-treated versus control females or comparing paired versus isolated males to study the role of social factors do not, by themselves, inform about the specific factors (e.g., visual and auditory) to which males respond behaviorally and physiologically. Even though most birds have a relatively poor sense of olfaction relative to many other vertebrates, olfaction may play a role to regulate the behavioral response of males to conspecific females. Supporting this conclusion, the courtship behavior of male chickens is apparently influenced by olfactory signals emanating from the female uropygial gland, a structure that has long been considered to be a potential source of pheromones (Zhang et al., 2010a; Hirao et al., 2009). Consistent with these findings, spotless starlings (*Sturnus unicolor*) can recognize the sex of conspecific individuals based on chemical olfactory cues that may be released by the uropygial gland (Amo et al., 2012). The crested auklet (*Aethis cristatella*) also exhibits an attraction to a feather-derived odor, which is heightened during the breeding season and is implicated in courtship displays (Hagelin et al., 2003). Interestingly, many species of vertebrate can detect differences in major histocompatibility complex (MHC) characteristics through olfactory means, allowing for mate selection to enhance genetic heterozygosity (Penn, 2002; Tregenza and Wedell, 2000). This MHC choice has been observed in several species of birds (Bonneaud et al., 2006; Juola and Dearborn, 2012; Strandh et al., 2012), and although the mechanism is unclear, there is evidence that odor can correlate with MHC make up in birds (Leclaire et al., 2012), highlighting a hypothesis for further study.

40.4.3 Effects of males on conspecific males

A great deal of research has investigated the effect of male behavior on the reproductive physiology and behavior of conspecific males, with particular attention given to the role of visual and auditory stimuli. Long-term (several weeks) studies find stimulating effects of hearing conspecific song on the HPG axis. For example, in the male rufous-winged sparrow (*Peucaea carpalis*), plasma LH is higher and testes develop faster in response to photostimulation for several weeks when birds are exposed daily to conspecific song than in control males not hearing this song (Small et al., 2008, Figure 40.4). Social stimulation can also induce short-term effects on the reproductive endocrine system. These effects are often assessed experimentally by presenting males with prerecorded conspecific vocalizations combined with a decoy bird (Balthazart et al., 2009; Wingfield, 1994b; Silverin et al., 2004). This situation, generally referred to as simulated territorial intrusion (STI), often provokes a strong aggressive response on the part of the challenged male (Wingfield, 1994a), and this response is in some cases associated with a rapid (within minutes) increase in plasma T (Wingfield and Hahn, 1994). T can exert rapid (within minutes to hours) physiological (Sachs and Leipheimer, 1988) and behavioral (Wright et al., 2009) effects, and it can enhance attention to novel conspecifics and other relevant stimuli (Archer, 1977). According to the Challenge Hypothesis (Wingfield et al., 1987; Wingfield and Goldsmith, 1990), elevated plasma T in response to social challenge may, therefore, function to enhance the persistence of a challenged individual's behavioral response even after the end of the challenge (Oyegbile and Marler, 2005; Wingfield, 1994b; Lynn et al., 2005). It should be pointed out that a social challenge of the above-described type often either fails to detectably increase (Addis et al., 2010; Deviche et al., 2012) or even decreases plasma androgens (Landys et al., 2007; for a review, see Goymann, 2009). This variability suggests a modulation of the response to STI by other factors. Indeed, it has been proposed that this response is contingent upon the mating system (Wingfield and Goldsmith, 1990; single vs. multiple broodedness: Landys et al., 2007), the contribution of males to incubation (Hirschenhauser et al., 2003), and the duration of the breeding season and the breeding state (Goymann, 2009).

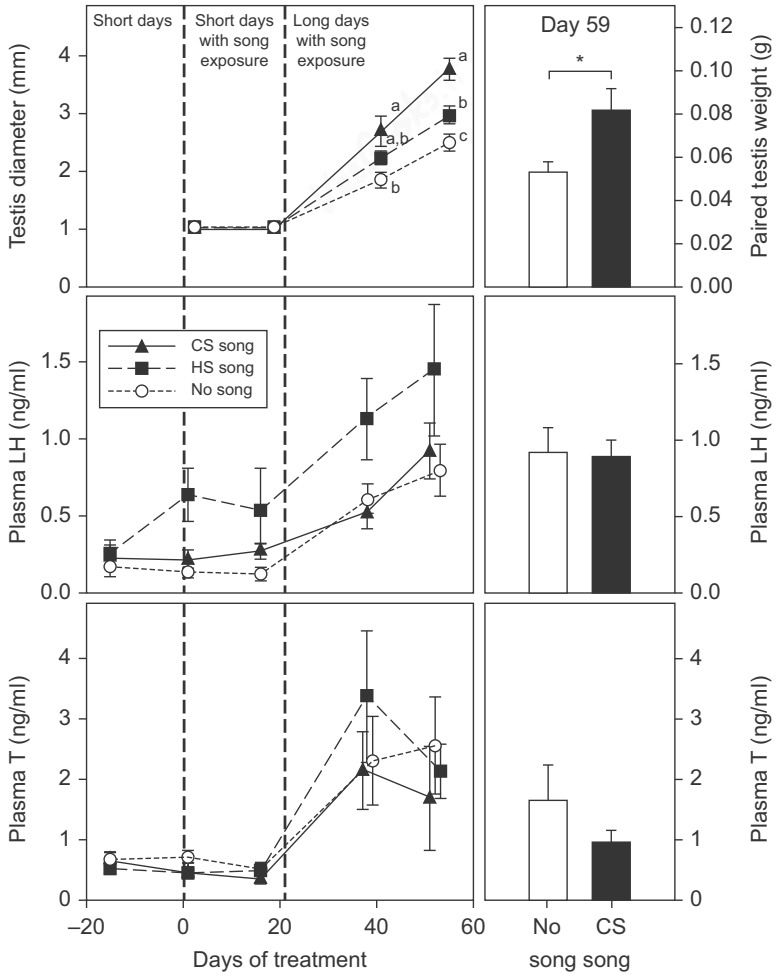

FIGURE 40.4 Left panels: Testis diameter (top left) and plasma luteinizing hormone (LH) and testosterone (T) in captive adult male rufous-winged sparrows exposed daily to conspecific song (CS Song), to heterospecific song (HS Song), or to no song (No Song). Birds were exposed to short days followed with exposure to a stimulating long photoperiod. On the same sampling day, different letters indicate significant differences between corresponding groups. Right panels: Testis mass and plasma LH and T measured at the time of euthanasia in the same birds as shown on the left panels. *Reprinted from Small et al. (2008) with permission.*

40.4.4 Effects of females on conspecific females

Though comparatively less studied than male–male interactions, female–female conspecific interactions occur in similar situations to that of males. Female birds express a variety of competitive traits that can provide a reproductive advantage including ornamentation, vocalization, and aggression. In an experimental model using the ring dove (*Streptopelia risoria*), devocalized females showed decreased follicular development, and, conversely, upon hearing other female coos, follicular growth increased (Cheng, 1986). Studies of this nature are limited, however, and most of the literature focus on female aggression. The advantages of aggressive or dominant behavior may include acquisition of breeding sites, maintenance of monogamy (Guo et al., 2020), and overall higher reproductive success. In the dark-eyed junco (*Junco hyemalis*), dominant females are more likely to breed and have a greater reproductive success (Jawor et al., 2006; Cain and Ketterson, 2012). The tree swallow (*Tachycineta bicolor*) requires a cavity for nesting, but does not make their own (Winkler et al., 2011); therefore females must compete for nesting sites. The more aggressive females out-compete those that are less aggressive (Rosvall, 2008), a behavior which may be partially mediated by T (Rosvall, 2013). The female–female aggressive behavior may come at a cost, however, as it can increase the risk of oxidative stress and injury (Silva et al., 2018), as well as place demands on time and energy at the expense of maternal care behaviors (Cain and Rosvall, 2014).

40.5 Age and experience

Ample evidence exists in birds that breeding performance is age-related (Forslund and Part, 1995). For example, the reproductive output of stitchbirds (*Notiomystis cincta*) increases during the first years of life and then declines as birds become senescent (Low et al., 2007). As discussed by Forslund and Part (1995), age-related differences in breeding performance may result from many nonexclusive factors that include age per se but also breeding experience, foraging success, and reproductive effort. Disentangling the respective contribution of these factors has been a major impetus of numerous studies. Research on free-ranging birds clearly indicates in some species that breeding experience gained during previous breeding attempts influences the reproductive output positively and independently of age. Using sophisticated statistical approaches, these studies show that breeding experience per se increases the probability of breeding and/or the reproductive output in birds belonging to various families (greater flamingo, *Phoenicopterus roseus*: Pradel et al., 2012; black-legged kittiwake, *Rissa tridactyla*: Desprez et al., 2011; snail kite, *Rostrhamus sociabilis*: Reichert et al., 2012). The interplay of age and experience is illustrated by research on free-ranging lance-tailed manakins (*Chiroxiphia lanceolata*; DuVal, 2012). In this species, males begin to breed when they reach high (alpha) social status and at an age that varies individually. The reproductive success of these males increases as a function of age and breeding experience. However, as birds get older, senescence negatively affects their breeding success, but this effect is compensated by the positive influence of social experience. Manipulative studies likewise support the idea of age-independent effects of breeding experience. For example, inexperienced male ring doves display less courtship behavior than age-matched experienced males (Cheng et al., 1986). This difference is specific to this behavior, as indicated by the observation that the two groups of males show similar levels of agonistic behavior. In another study, Cichon (2003) compared the reproductive output of inexperienced and experienced female collared flycatchers (*Ficedula albicollis*) (Figure 40.5). These two groups of birds had similar breeding success, but broods from experienced females were heavier and larger than those of inexperienced females, suggesting a positive effect of experience on fitness.

An insight into the mechanisms by which experience proximately influences reproductive behavior is provided by research on Japanese quail (Cornil and Ball, 2010). In this species, the probability of copulation is higher in sexually experienced than naïve males. However, visual (without physical) contact with a female (vs. a male or no bird) also enhances the occurrence of subsequent precopulatory behavior (latency to mate), indicating that male sexual performance is stimulated by sensory cues from females without actual sexual encounter taking place. Importantly, this study used castrated, T-treated birds, and behavioral effects of social experience were, therefore, not related to plasma T. Similarly, behavioral effects of social experience in the male ring dove (Cheng et al., 1986) do not result from differences in plasma T between naïve and experienced males. That the influence of a bird's social experience on its behavior can be modulated by sensory cues provided by another bird is demonstrated by other type of work (Michel, 1976). In the ring dove, birds with previous nest-building breeding experience are more likely to initiate incubation in response to progesterone treatment than inexperienced birds. However, the propensity of a bird to enter the nest area and stand on the nest also depends on the breeding experience of its mate.

40.6 Endocrine and neuroendocrine regulation of reproductive behavior

Based on the observation of changes in aggressive and mating behavior resulting from castration or castration

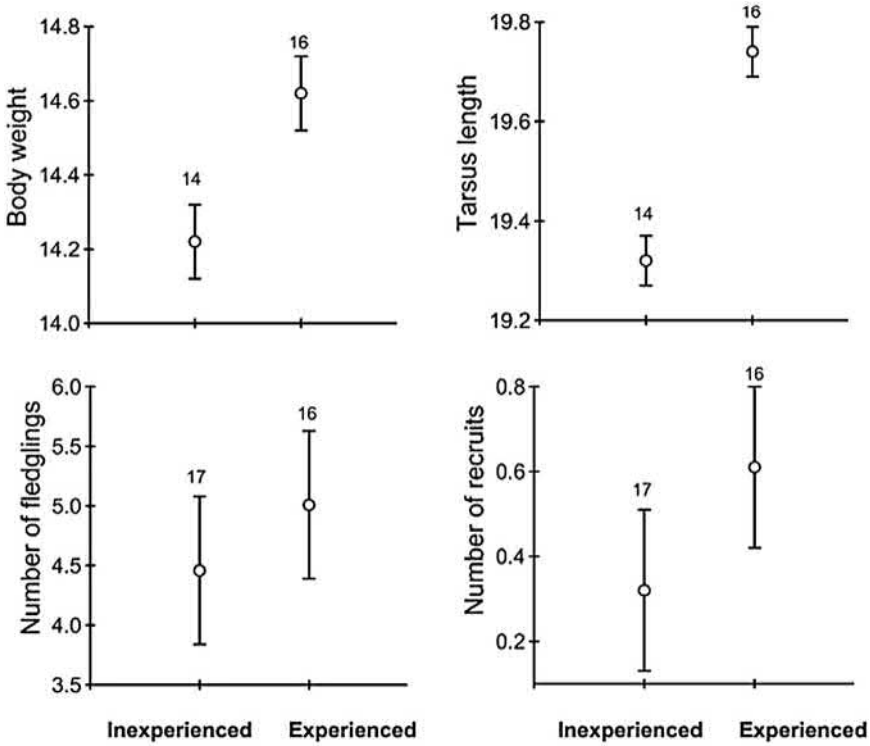

FIGURE 40.5 Breeding performance of two-year-old female collared flycatchers with (experienced) or without (inexperienced) previous breeding experience. Nestlings produced by inexperienced females were lighter (body mass on day 12 after hatching: $P = .006$) and smaller (tarsus length: $P < .001$) than those produced by experienced females, but there was no difference in the number of fledglings produced or subsequently recruited. Numbers above symbols refer to the number of nests studied. *Reprinted from Cichon (2003) with permission.*

followed with testis reinsertion into the abdominal cavity of roosters, Berthold was among the first to postulate that the reproductive behavior of birds is influenced by internally produced substances (Quiring, 1944). Since then, this behavior has been shown to be regulated by a great variety of hormones and neuropeptides. This section presents an overview of the influence of the best-studied endocrine and neuroendocrine factors on specific aspects of reproductive behavior. However, the reader should be aware that other factors that are not discussed here due to space limitations play an influential role as well. These factors include opioid peptides and corticotropin-releasing hormone, which can inhibit copulation solicitation in females (Maney and Wingfield, 1998) and sexual behavior (opioids: Kotegawa et al., 1997), and catecholamines (Barclay et al., 1992; Rauceo et al., 2008).

40.6.1 Gonadal steroids

Gonadal steroids (androgens, estrogens, and progestagens) have been the subject of most attention by far in terms of endocrine regulation of avian reproductive behavior. Their action mechanisms and behavioral effects are summarized in several reviews (Ball and Balthazart, 2010; Balthazart et al., 2010; Fusani, 2008), and the reader is referred to these publications for detailed information on this subject. Traditionally, steroid function is examined from the perspective of long-term changes to concentrations in the blood stream. Many studies on this topic are correlative and take advantage of the fact that most birds are photoperiodic (see Section 40.3.1). In these species, day length plays a critical role in the regulation of seasonal cycles, including gonadal development and the secretion of gonadal hormones, this secretion being dramatically higher during (compared to outside of) the breeding season. The seasonality of the reproductive system activity offers excellent opportunities to relate cyclic (neuro)endocrine changes (e.g., in plasma steroid concentrations) (Osorno et al., 2010; Landys et al., 2010) and the brain expression of steroid-metabolizing enzymes (Soma et al., 2003) or steroid receptors (Fraley et al., 2010), with the occurrence of reproductive behavior. Numerous studies on the behavioral role of gonadal steroids have also been manipulative. Commonly used approaches in these studies include gonadectomy (El Halawani et al., 1986; Hagelin, 2001), peripheral or central administration of hormones (Seredynski et al., 2013; Hunt and Wingfield, 2004; Komisaruk, 1967; also see Sections 40.6.4 and 40.6.6), and treatment with pharmacological agents. Some such agents serve as specific agonists or antagonists for steroid hormone receptors (Delville and Balthazart, 1987), whereas others affect the production or metabolism of steroid hormones (Belle et al., 2005; Schlinger and Callard, 1990). Investigations on the centrally mediated effects of gonadal steroids also take

advantage of the coupling of hormonal manipulations with localized brain lesions (Bailhache et al., 1993; Del Negro et al., 1998) or electrophysiological approaches (Meitzen et al., 2007).

Gonadal steroids influence aspects of reproductive behavior at all life stages, including during sexual differentiation (Adkins-Regan, 2009; Banerjee et al., 2012) and in adulthood, when they impact courtship (Fusani, 2008), singing (see Section 40.6.6), sexual receptivity, copulation, incubation, and parental behavior (O'Neal et al., 2008; Van Roo, 2004). Gonadal steroids also play important roles in the regulation of life history stages outside of the reproductive period, such as during preparation for migration (Tonra et al., 2011). They additionally influence metabolic processes and body condition (Deviche, 1992; Buchanan et al., 2001; Jaccoby et al., 1995) and immunity (Deviche and Cortez, 2005; Selvaraj and Pitchappan, 1985), although the pathways (direct vs. indirect and mediated, e.g., by glucocorticoids) involved in this influence remain poorly understood (Buttemer et al., 2008; Owen-Ashley et al., 2004). We discussed relationships between gonadal steroids and aspects of social behavior in Section 40.4. The remainder of this section further exemplifies the importance of gonadal steroids in the control of reproductive behavior, in particular, their relationships with the AVT system (see Section 40.6.4) and their critical influence on brain regions that are responsible for song production in oscine passerines (see Section 40.6.6).

40.6.2 Neurosteroids

It has become clear in the past few decades that the vertebrate (including avian) brain is capable of neurosteroidogenesis, either from de novo synthesis from cholesterol or from precursors from the periphery (Schlinger and Remage-Healey, 2012; Ubuka et al., 2009). Steroids produced in the brain can have highly localized paracrine functions, which allows for fine-tuning of its function, without effects on the general responses of physiology and behavior that are seen when steroids are in circulation (Cornil and de Bournonville, 2018; Wingfield, 2017; Wingfield et al., 2018). In bids, it has been shown that the brain expresses enzymes that are involved in the synthesis of steroids, including pregnenolone, progesterone, T, and estradiol, and this expression is region and developmental stage specific (London et al., 2006). The roles of these enzymes and their products in songbirds are well illustrated by research on brain aromatase, the enzyme that converts androgens to estrogens. Aromatase in the songbird brain is widely distributed and present, among others, in areas that are involved in the control of song production (e.g., the medial border of the HVC and robust nucleus of the arcopallium (RA); see Section 40.6.6) and auditory information processing (e.g., the caudal medial nidopallium (NCM); Schlinger and Balthazart, 2012). Physiological and behavioral studies reveal that rapid changes in the brain production of estrogen result in behavioral changes. For example, local pharmacological inhibition of estrogen production within the left NCM of male zebra finches rapidly disrupts their ability to preferentially respond behaviorally to their own song versus conspecific song (Remage-Healey et al., 2010, Figure 40.6). Reciprocally, a bird's own behavior, as well as relevant external stimuli, can rapidly modify the brain production of estrogen. Indeed, in the male zebra finch forebrain, the expression of aromatase rapidly increases in response to the act of singing (but not to hearing song; Remage-Healey et al., 2009), and the forebrain concentration of estradiol rapidly increases during social interactions with females (Remage-Healey et al., 2008). In the male white-crowned sparrow (*Zonotrichia leucophrys*), a social challenge (STI) rapidly decreases the local concentration of estrogen in several brain regions (Charlier et al., 2011). Rapid, steroid hormone—mediated, and centrally mediated changes in behavior suggest that these hormones act via nonclassic (i.e., nongenomic) mechanisms (discussed further in this section). This proposition is supported by the fact that steroids can bind to cell membrane receptors and induce rapid nongenomic cellular effects (Heimovics et al., 2012).

The Japanese quail has proved to be a particularly profitable experimental model in which to investigate the rapid behavioral effects of neurosteroids and in particularly neuroestrogens. As anatomical and functional studies demonstrate, the quail preoptic area (POA) plays a critical role in the regulation of male sexual behavior (Balthazart et al., 1992; for reviews, see Balthazart et al., 2006; Panzica et al., 1996). This brain region is sexually dimorphic (it is larger in males than females, which do not show masculine

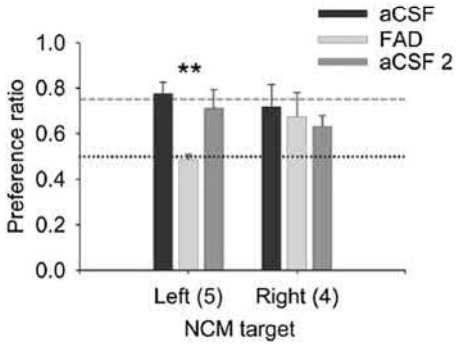

FIGURE 40.6 Influence of the aromatase inhibitor fadrozole (FAD) administered by in vivo retrodialysis into the auditory region caudal medial nidopallium (NCM) of the male zebra finch brain on behavioral preference for the bird's own song versus conspecific song. Control vehicle injections consisted of artificial cerebrospinal fluid. Song preference was abolished by FAD administration into the left but not right NCM. *Reprinted from Remage-Healey et al. (2010) with permission.*

sexual behavior) and is a target region for sex steroids: it contains androgen and estrogen receptors, and its volume decreases after castration and is restored following T treatment (Seredynski et al., 2011). The POA contains aromatase, and estrogen in the quail plays a critical role in the control of sexual behavior (Balthazart et al., 2009). Brain aromatase and, therefore, the local production of estrogens in the POA are regulated not only by slow-acting steroid-mediated genomic mechanisms that involve changes in transcription (Voigt et al., 2011) but also by nongenomic mechanisms that can rapidly (within minutes) enhance the local availability of estrogen (Balthazart et al., 2004). This stimulation can in turn stimulate a short-term increase in expression of some aspects of sexual behavior (Cornil et al., 2006a,b; Seredynski et al., 2011), particularly sexual motivation, but not copulatory behavior (Seredynski et al., 2013, 2015). Collectively, research on Japanese quail and the studies described here on songbirds firmly establish neurosteroids as important modulators of reproductive behavior (Schlinger and Remage-Healey, 2012).

40.6.3 Gonadotropin-releasing and gonadotropin-inhibitory hormones

GnRH in vertebrates plays an essential stimulatory role in the regulation of anterior pituitary gland gonadotropins. In mammals, GnRH also acts as a neurotransmitter and/or in a paracrine fashion to modulate sexual behavior, an effect that is presumably mediated by central GnRH receptors (Hsueh and Schaeffer, 1985). Limited evidence supports the view that GnRH has centrally mediated behavioral actions also in birds. Some of the original work on this subject was conducted in ring doves, in which synthetic GnRH administration stimulates courtship behavior, and this effect is apparently not mediated by LH or progesterone (Cheng, 1977). The brain of many vertebrates expresses at least two forms of GnRH: GnRH-I (cGnRH-I), which is released into the median eminence and stimulates the pituitary gland, and GnRH-II, which is normally not released into the median eminence but into extrahypothalamic brain regions. Central injection of GnRH-II to female white-crowned sparrows rapidly increases their expression of courtship behavior in response to hearing conspecific male song, and this effect is specific to GnRH-II, as it is not induced by cGnRH-I administration (Maney et al., 1997b). Thus, consistent with the situation in mammals (Hsueh and Schaeffer, 1985), GnRH in birds may act centrally to influence reproductive behavior. It should also be pointed out that, at least in some avian species, the brain contains a non-neuronal source of GnRH. This conclusion is drawn from studies on ring doves, in which the medial habenula contains immune (mast) cells that synthesize GnRH as well as other neurochemicals (Wilhelm, 2011). The activity of these cells is regulated by the endocrine (gonadal steroid) environment, and their number increases within hours in response to courtship (Zhuang et al., 1993), suggesting that their secretory products and in particular GnRH are involved in the control of reproductive behavior.

The discovery of GnIH, a neuropeptide with inhibitory effects on gonadotropin secretion and with fibers extending to a large number of brain areas (Tsutsui et al., 2000; Ukena et al., 2003), has prompted considerable research into its endocrine and behavioral functions. GnIH has been found in a multitude of avian species, including quail, chicken, sparrows, zebra finches, and starlings (for review, see Tsutsui et al., 2015). GnIH in birds is primarily localized in the paraventricular nucleus, with projections to the median eminence (Bentley et al., 2003). Centrally mediated roles for GnIH are suggested by the widespread brain distribution of immunostained GnIH fibers (Ubuka et al., 2008). In the female white-crowned sparrow, central treatment with GnIH inhibits courtship behavior (Bentley et al., 2006), thereby exerting effects that are opposite of those induced by GnRH-II treatment (Maney et al., 1997b; and discussed in this chapter). This behavioral inhibition may result from negative effects on GnRH function because midbrain regions where GnRH-II is produced contain GnIH fibers, and in the European starling, cGnRH-I- and GnRH-II–producing neurons express GnIH receptor mRNA (Bentley et al., 2008). Recent work using RNA interference of the GnIH gene in the Japanese quail provides further support for a centrally mediated behavioral role of this neuropeptide. Here, brain injection of small interfering RNA (siRNA) against GnIH precursor mRNA (GnIH siRNA) stimulated sexual behavior, and this stimulation was blocked by GnIH treatment (Ubuka et al., 2013). An emergent conclusion from studies on the behavioral role of GnIH is that it may function as an important inhibitory modulator of social interactions, including reproductive behavior (Calisi et al., 2011). In particular, GnIH administration increased the neurosynthesis of estrogen in male Japanese quail, and concurrently decreased aggressiveness, an effect which is likely mediated by GnIH effects on aromatase (Ubuka et al., 2014).

40.6.4 Arginine vasotocin

A peptide whose behavioral role in birds has received considerable attention is AVT, the avian homolog of vasopressin. Given peripherally to zebra finches, AVT decreases courtship behavior, and this decrease is attenuated by T administration (Harding and Rowe, 2003). Zebra finches are opportunistic breeders whose reproduction is induced by water availability. AVT plays a major role in the control of water balance (Sharma et al., 2009). Thus, it is postulated in these finches that drought conditions stimulate AVT secretion and the peptide in turn inhibits the reproductive system, including T secretion, thereby

preventing reproduction during periods of unfavorable environmental conditions. Contrasting with its suppressive action after peripheral administration, AVT exerts centrally mediated stimulatory behavioral effects, as shown by studies reporting that brain injection of the neuropeptide stimulates singing (Voorhuis et al., 1991a; de Kloet et al., 1993; Maney et al., 1997a). AVT is synthesized in several brain regions, including the paraventricular and supraoptic nuclei and the nucleus of the stria terminalis (Panzica et al., 1999b), and AVT-immunostained fibers extend to a large number of brain areas, some of which are involved in the control of vocal behavior (the RA and mesencephalic nucleus ICo: Kiss et al., 1987; Panzica et al., 1999b; Voorhuis and de Kloet, 1992). Binding sites for AVT in the avian brain are similarly widespread (Leung et al., 2009, 2011), and regions containing these sites are innervated by AVT fibers and terminals (Voorhuis et al., 1988b). Collectively, the neuroanatomical distribution of AVT and its receptors suggests that the peptide is involved in the control of multiple functions, including sexual behavior and GnRH secretion (Panzica et al., 2001).

As shown by a number of investigations, the central AVT system and the behavioral effects of the neuropeptide are steroid hormone sensitive. This conclusion is supported by work on canaries showing a sex difference in brain AVT immunostaining (Voorhuis et al., 1988a) and showing, in males of this species, that seasonal changes in AVT immunostaining parallel changes in plasma T (Voorhuis et al., 1991b). Manipulative studies, including gonadectomy and hormone replacement experiments, confirm an important, region-specific stimulatory role for gonadal steroids in the brain expression of AVT (Kimura et al., 1999; Plumari et al., 2004; Viglietti-Panzica et al., 1994) and AVT mRNA (Panzica et al., 1999a). In castrated male Japanese quail, the effects of T administration on the brain expression of AVT are mimicked by treatment with estradiol but not the nonaromatizable T metabolite 5α-dihydrotestosterone (5α-DHT) (Viglietti-Panzica et al., 2001). Effects of T on brain AVT in this species may, therefore, require aromatization of this steroid. Similarly, when given to female quail, estradiol but not 5α-DHT mimics the stimulatory influence of T on the brain expression of AVT mRNA (Aste et al., 2013, Figure 40.6).

It should be noted that while estradiol influences the central AVT system, there is also evidence that AVT may modulate the brain production of estrogen. Indeed, in the Japanese quail, aromatase-containing cells in brain regions that control reproductive behavior (e.g., the medial POA; see Section 40.6.2) apparently receive AVT innervation (Balthazart et al., 1997). Acute stress in quail rapidly (within minutes) upregulates their medial POA aromatase activity (Dickens et al., 2011), and there are indications that AVT contributes to mediating this effect (Dickens et al., 2013). AVT may accordingly be an important component of the neural system that controls rapid stress-induced changes in reproductive behavior, as AVT is involved in both the central and peripheral stress response (Kuenzel et al., 2020). New research is clearly warranted to confirm this hypothesis and elucidate the precise nature of this behavioral regulation.

40.6.5 Prolactin

The secretion of PRL in birds is under complex regulation by environmental and physical factors. The main environmental factor that controls PRL secretion in many species is day length, with long days stimulating this secretion (Dawson et al., 2001; Sharp et al., 1998). Plasma PRL in these species is accordingly elevated in spring and summer (i.e., during the breeding period) (Gahali et al., 2001; Sharp et al., 1998), and then declines. Elevated plasma PRL toward the end of the breeding period is believed to contribute to, but not be responsible for, the seasonal gonadal regression that signals the end of the reproductive season (Dawson et al., 2001). On a shorter term basis, the secretion of PRL is influenced by factors associated with incubation. For example, the introduction of an artificial egg into the nest of yellow-eyed penguins (*Megadyptes antipodes*), before birds normally start laying, stimulates PRL secretion in females (but has the opposite effect in males; Massaro et al., 2007). Inversely, plasma PRL rapidly decreases in captive female common eiders (*Somateria mollissima*) that are deprived of their eggs (Criscuolo et al., 2002). And in the chicken hen, a precocial species, physical contact with chicks stimulates brooding behavior and precipitates a decrease in plasma PRL, suggesting a role for the hormone in the transition from incubation to brooding (Richard-Yris et al., 1998). Consistent with this conclusion, plasma PRL in this species is high during incubation and then rapidly decreases after hatching (Kuwayama et al., 1992). In the altricial canary, however, plasma PRL remains elevated in females after hatching and decreases gradually during rearing of the young (Goldsmith et al., 1981). In over 25 species of birds, PRL shows some relationship with paternal care, with elevated levels associated with the transition from sexual to paternal activities such as incubation and male feeding behavior (Schradin and Anzenberger, 1999). However, this is not the case for all species. In male canaries, which do not incubate or feed young, plasma PRL increases only slightly during the parental phase of the reproductive cycle (Goldsmith et al., 1981). Regardless of the direction of the association, together these studies support the hypothesis that PRL is involved in the control of parental behavior. It should be noted in some species (Adélie penguin, *Pygoscelis adeliae*; and emperor penguin, *Aptenodytes forsteri*) that the increase in plasma PRL that occurs during reproduction is apparently controlled endogenously rather than by day

length or tactile stimulation (Lormee et al., 1999; Vleck et al., 2000). Sustained plasma PRL in the absence of tactile input in these species is thought to be necessary for breeding birds to maintain parental behavior despite the fact that they are absent from their nest for prolonged periods while foraging at sea.

The ring dove has proved to be a particularly informative model to study the involvement of PRL in the control of parental behavior. In contrast to the situation in many species, PRL secretion in doves does not change seasonally and is not photoperiod regulated, and these birds can breed year-round (Lea et al., 1986a). A role for nest-associated stimuli in the control of PRL secretion in this species is indicated by the observation that plasma PRL increases during incubation, but nest deprivation causes a rapid decline in hormone level (Lea et al., 1986b). Furthermore, injections of PRL enhance the persistence of incubation behavior (Janik and Buntin, 1985) and stimulate food provisioning to squabs (Buntin et al., 1991). Stimulatory effects on parental behavior (including feeding squabs) are also observed after intracerebroventricular administration of the hormone at doses that do not stimulate PRL-sensitive peripheral tissues such as the crop sac, indicating that these effects are mediated centrally (Buntin et al., 1991, Figure 40.8). Consistent with this proposition, the ring dove brain contains PRL-binding sites (Buntin and Ruzycki, 1987), and chemical lesion of the POA produces a deficit in parental behavior in response to PRL administration (Slawski and Buntin, 1995). Centrally acting PRL may be of peripheral (pituitary gland) origin. However, the dove brain contains PRL-immunopositive cells and fibers that project to several hypothalamic regions (Ramesh et al., 2000). Thus, in this species, centrally produced PRL binding to local receptors, perhaps in addition to PRL reaching the brain through systemic circulation, may activate parental behavior.

All living beings are, at times, faced with stress in the form of unpredictable stimuli, leading to the activation of the HPA axis and secretion of CORT. This elevation of CORT can, in turn, negatively influence reproductive and

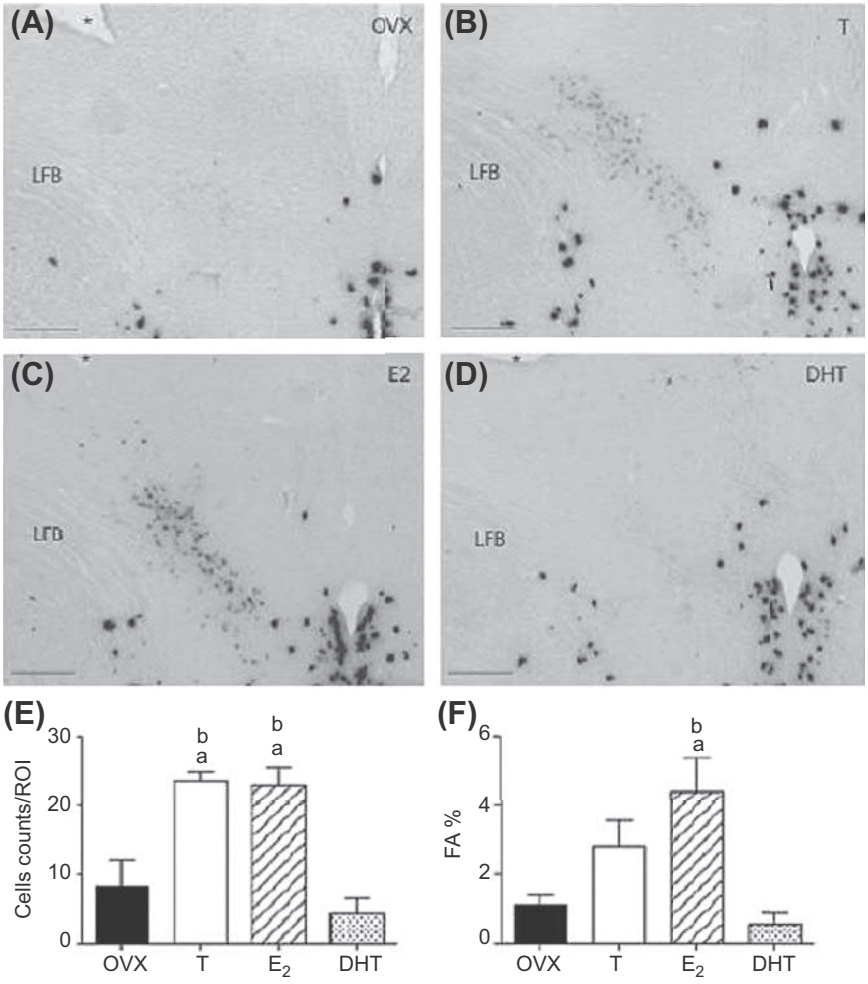

FIGURE 40.7 Regulation of arginine vasotocin (AVT) mRNA expression by gonadal steroids in the female Japanese quail brain. (A–D): Photomicrographs showing the distribution of AVT mRNA-expressing neurons in the caudomedial part of the bed nucleus of the stria terminalis after ovariectomy and one systemic injection of vehicle solution (OVX), testosterone (T), estradiol (E2), or 5α-dihydrotestosterone (5α-DHT). (E): Number of AVT mRNA-containing cells in the region of interest (ROI). This number is increased by T or E2, but not 5α-DHT, treatment. (F): Fractional area (FA) covered by mRNA hybridization signal in the same region. The FA is increased only after E2 administration. *Reprinted from Aste et al. (2013) with permission.*

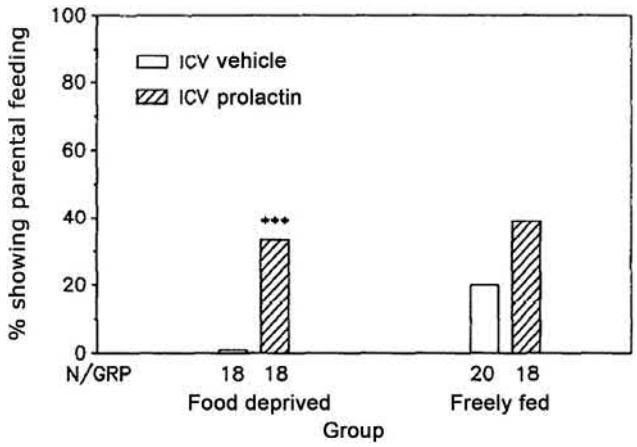

FIGURE 40.8 Stimulation of parental feeding behavior in nonbreeding ring doves by daily intracerebroventricular injection of prolactin or vehicle solution. Birds were either fed ad libitum or food deprived for 16 h before behavioral testing. N/GRP refers to the number of birds in each experimental group. *** Denotes a significant difference with the vehicle-treated group. *Reprinted from Buntin et al. (1991) with permission.*

parental behavior (Wingfield et al., 1998). Exposure to stressful conditions also often depresses plasma PRL (Angelier et al., 2013). These observations have led researchers to ask whether CORT and PRL normally exert opposite actions on parental behavior, and whether stress-related changes in plasma CORT and PRL are mechanistically related. These questions have been studied extensively in some seabirds. Correlative evidence is provided by work on black-legged kittiwakes (Chastel et al., 2005). In this species, acute stress decreases PRL more in failed breeders than in breeding birds, suggesting that maintaining sufficiently high-plasma PRL during stress may result in birds continuing to breed rather than abandoning their nest. Supporting this proposition, plasma PRL in Adélie penguins is low in birds that abandon their nest compared to birds that do not do so (Spee et al., 2010). However, pharmacological blockade of PRL secretion in this species does not cause nest desertion Thierry et al. (2013), suggesting the involvement of additional factors. One such factor may be CORT because male penguins that abandon their nest have high-plasma CORT (Spee et al., 2010), and CORT administration leads to nest desertion (Kleven et al., 2009). Thus, nest abandonment in this species may require high-plasma CORT combined with low-plasma PRL. In a more general sense, the above studies suggest in breeding birds that during periods of stress the parental decision to continue to breed can be at the expense of their own condition and survival, and this decision is critically influenced by baseline (prestress) and stress-induced plasma CORT and PRL (Angelier et al., 2009). The extent to which the PRL (decrease) and CORT (increase) stress responses are mechanistically related, however, remains largely conjectural (Angelier et al., 2013).

40.6.6 Case study: the oscine vocal control system

Acoustic signaling in some species is mediated by nonvocal signals such as those produced by wings (e.g., manakins: Schlinger et al., 2008) and tail feathers (e.g., some hummingbirds: Clark and Feo, 2008), but in many species, this signaling is mediated primarily by vocalizations. The neural circuit that controls the perception and expression of vocal behavior in passerines has been the object of enormous attention. This circuit provides an exquisite model in which to investigate how hormones regulate reproductive behavior, the central mechanisms that mediate this regulation, and the reciprocal interactions between behavior and the (neuro)endocrine system. The control of vocal perception and output has been particularly well studied in oscine passerines. Many oscines produce complex, learned vocalizations (songs), the learning and production of which are controlled by a network of discrete and interconnected brain regions called the vocal control system (Nottebohm et al., 1976, 1982, Figure 40.7). Many suboscine passerines also produce complex songs, but in contrast to oscines, vocalizations in these species are generally thought to be innate rather than learned (but see Saranathan et al., 2007), and suboscine song control regions are correspondingly absent or rudimentary (Liu et al., 2013). In oscines, song control regions are typically larger in males than females in species in which males do most of the singing (Tobari et al., 2005; Tramontin et al., 1998), and this morphological difference is associated with cytoarchitectural (Del Negro and Edeline, 2002; Nealen, 2005), biochemical (Charlier et al., 2003; Riters and Ball, 2002; Sakaguchi et al., 2000), and physiological (Adret and Margoliash, 2002; Del Negro and Edeline, 2001) differences between sexes. The exact role of song control regions in females that do not normally sing remains incompletely understood. Some of these regions serve an auditory as well as motor function (Figure 40.9), and in females they may, therefore, regulate vocal behavior perception rather than output (Hamilton et al., 1997).

A remarkable feature of the adult oscine vocal control system is its neuroplasticity. In seasonal breeders, the size of song control regions such as the HVC and RA changes seasonally. These regions are larger during the breeding season, when birds are exposed to long photoperiods, gonads are developed and release large amounts of steroid hormones, and birds sing at a high frequency, than outside this season (Meitzen and Thompson, 2008; Nottebohm, 1981; Smith et al., 1997). The basis of these changes has been researched in particular detail for the HVC, a telencephalic region that plays a major role in song production. Seasonal changes in HVC volume are associated with cytoarchitectural changes, including neuron number, density, and life span (Bowers et al., 2011; Meitzen and Thompson, 2008; Nottebohm et al., 1994). Some vocal

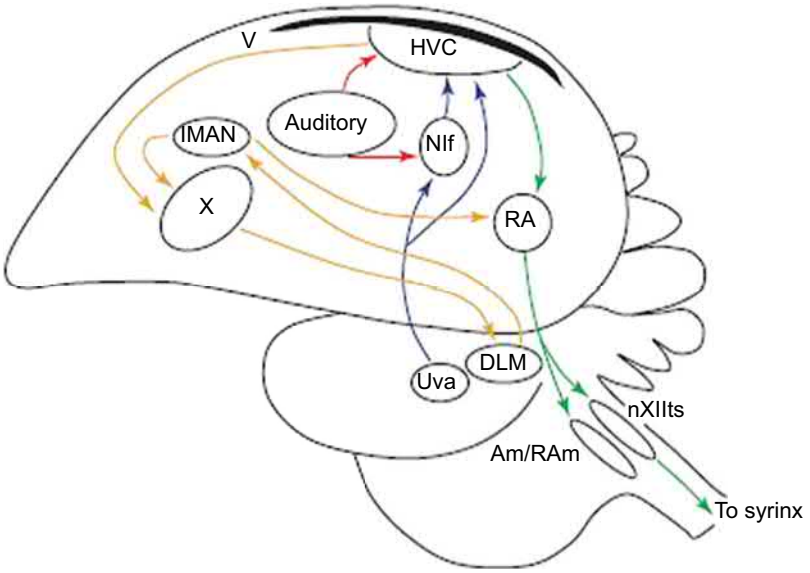

FIGURE 40.9 Projections of the major regions of the oscine brain vocal control system. The system consists of a motor pathway (green) that controls vocal output and includes projections from the HVC (correct full name; not an abbreviation) to the robust nucleus of the arcopallium (RA). A second pathway (orange) is essential for song learning and perception, and includes the medial portion of dorsolateral thalamus, the lateral magnocellular nucleus of the anterior neostriatum, area X, HVC, and RA. *Reprinted from Brenowitz and Beecher (2005) with permission.*

control regions including the HVC contain sex steroid receptors (Fraley et al., 2010; Gahr et al., 1987, 1993; Nordeen et al., 1987) whose density is regulated seasonally (Fusani et al., 2000; Soma et al., 1999), suggesting locally mediated roles for these hormones. Consistent with this view, considerable evidence indicates that gonadal steroids play many-faceted roles in the control of the vocal control system's plasticity in adulthood (Bottjer et al., 1986; Ball et al., 2003). These roles include regulation of the size of song control regions (Thompson et al., 2007; Tramontin et al., 2003), newborn neuron migration into the HVC, and the density and survival of existing neurons (Hall and MacDougall-Shackleton, 2012). Considerable attention has been devoted to the cellular and molecular mechanisms of action of steroids in song control regions (Thompson et al., 2012), and these studies have identified an important role for brain-derived neurotrophic factor (BDNF). In concert with T, BDNF is thought to promote the proliferation and survival of HVC neurons (Brenowitz, 2013; Alvarez-Borda et al., 2004; Rasika et al., 1999) and also to contribute to seasonal plasticity in the RA (Wissman and Brenowitz, 2009; Li et al., 2000). Furthermore, in the vocal control system, the expression of numerous genes that are involved with diverse functions such as neurogenesis, apoptosis, and axonal growth changes seasonally (Thompson et al., 2012). A major challenge in the future is to identify the role of these genes' products and to determine whether and how steroids regulate the activity of these genes. Adding to this complexity, factors such as photoperiod (Dloniak and Deviche, 2001; Gulledge and Deviche, 1998) and social factors (Boseret et al., 2006) influence the size and cytoarchitectural characteristics of song control regions, and this influence is in some situations independent of gonadal steroids. Finally, while this chapter's discussion makes it clear that song control regions play an important role in the expression of vocal behavior, some of these regions are also influenced by sensory (acoustic) stimulation. For example, T administration to female canaries increases their HVC volume, but this increase is attenuated after deafening (i.e., in the absence of auditory stimulation) (Bottjer et al., 1986). The mechanism mediating this difference is not fully understood, and it may involve a role for the auditory stimulus-regulated production of neurosteroids (see Section 40.6.2), in particular estradiol (Hall and MacDougall-Shackleton, 2012; Remage-Healey et al., 2012; Soma et al., 2004).

Chapter 41

Growth

Colin G. Scanes, Nima K. Emami and Sami Dridi
Center of Excellence for Poultry Science, University of Arkansas, Fayetteville, AR, United States

Abbreviations

ACTH Adrenocorticotropic hormone
ADG Average daily gain
BMP Bone morphogenic protein
CORT Corticosterone
EGF Epidermal growth factor
EGFR Epidermal growth factor receptor
F:G Feed to gain
GH Growth hormone
IGF Insulin-like growth factor
IGFBP Insulin-like growth factor binding protein
mTOR Mechanistic (or mammalian) target of rapamycin
NFκB Nuclear factor kappa B
Pit-1 Pituitary -specific positive transcription factor 1 also known as POU domain, class 1, transcription factor 1
TGF Transforming growth factor
TNF-α Tumor necrosis factor-α

41.1 Introduction

41.1.1 Overview

This chapter will review the current knowledge of the biology of growth in birds focusing on posthatch growth. Growth is a complex process involving tissue-specific gene expression, paracrine, autocrine, and intracrine controls, the endocrine regulatory systems, and other contributing factors including nutrition and environment. Particular attention will be placed on hormonal regulation of growth and development.

Discussion will consider growth of wild birds and poultry species. Where there is either little information on one grouping or disparate information, this will be noted. It is recognized that there is selection pressure in wild birds including the ancestors of poultry including the following:

- Optimal adult mass and organ weights for the niche and to withstand the rigors of flight and migration,
- Optimal size for flight and in preparation for egg production,
- Maximal utilization of nutrients, and
- Maximal growth rate during the period of parental care and after to increase chances for survival.

There is intensive selection by breeding companies for poultry species with the following traits being among the most important:

- Growth rate
- Feed to gain ratio (F:G) or feed efficiency
- Increased proportion of marketed meat (skeletal muscle).

41.1.2 Growth curves

Growth in poultry and wild birds can be described by a sigmoidal growth curve (Figure 41.1). This is irrespective of whether the metric for growth is body weight, skeletal length parameter, or organ weight.

41.1.2.1 Logistic equation

The growth rate can be estimated by the following logistic equation:

$$W_t = A/(1 + \exp[-k(t - t_0])$$

where W_t is the weight at time t,
t_o is the initial time,
A is the asymptote or plateau, and
k is the growth rate constant (Ricklefs, 1979). The growth rate is maximal at half A (Ricklefs, 1979). However, the early hatched chick exhibits the maximal posthatch percentage growth rate, and this will subsequently decline.

41.1.2.2 Gompertz model

An alternative and frequently used mathematical expression for growth is the Gompertz model (see below).

Sturkie's Avian Physiology. https://doi.org/10.1016/B978-0-12-819770-7.00019-0

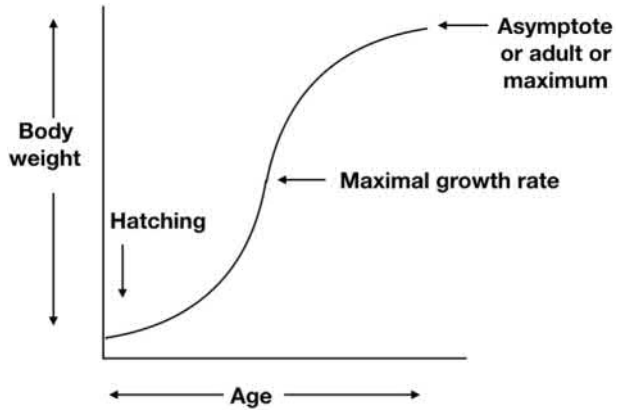

FIGURE 41.1 A generalized growth curve in birds. The sigmoidal S-shaped curve describes the accelerating growth rate in young birds (late embryonic/early post hatch) to a maximal growth rate following by decelerating growth and finally the end of growth.

Gompertz's growth model

$$W_t = A \cdot e^{-be^{-kt}}$$

where W_t is the weight at time t,
t_o is the initial time,
A is the asymptote or plateau,
B is a constant
e is the mathematical constant, and
k is the growth rate constant.

Examples of growth rate constants for three similarly sized birds are shown in Table 41.1. Growth rates were approximately fourfold greater in the altricial starling compared to the precocial Japanese quail.

An alternative approach to growth rate is average daily gain (ADG). This is equivalent to delta body weight. An example of the changes in ADG in chickens is shown in Figure 41.2.

41.1.3 Growth of different organs

In wild birds, relative organ weights exhibit marked shifts during growth with the relative organ weight for pectoralis skeletal muscle increasing ~10-fold in starlings, terns, and Japanese quail (Table 41.1). In contrast, the relative weight of the heart is consistent between young chicks and adult birds (Table 41.1). Body composition changes during growth with increases in the proportion of solids and lipids (Table 41.1). Similarly, in poultry, there is disproportional growth of organs (Table 41.2).

41.2 Evolutionary perspectives of avian growth

Growth is continuous, rapid, and without interruption in Neornithine avian species (all extant birds). In contrast, growth in preavian theropods was intermittent (Chinsamy and Elzanowski, 2001). One of the characteristics of birds is their fast growth rate.

Tables 41.3 and 41.4 compare growth rates in vertebrate taxa. Altricial land birds exhibit faster growth rates than precocial birds (Case, 1978). Modern birds (Neornithes) exhibit high growth rates and markedly greater growth rates than nonavian dinosaurs (Erickson and Tumanova, 2001; Werner and Griebeler, 2014). In contrast, based on fossil evidence from the Upper Jurassic Epoch (~150 million years ago), the growth rate of the primitive bird, *Archaeopteryx*, was slow (see Figure 41.3) (Erickson et al., 2009) and similar to that of nonavian dinosaurs (Werner and Griebeler, 2014). There appears to have been parallel evolution of high growth rates in mammals and modern birds (Neornithes).

41.3 Altricial versus precocial birds

Growth rates are markedly greater in altricial than precocial birds (Case, 1978) (Table 41.3.). This is explicable by the diversion of energy and other nutrients for development in precocial birds and altricial species requiring considerably more parental care. Interestingly, there appears to be acceleration of the posthatch development of the profile of circulating concentrations of growth hormone (GH) and insulin like growth factor (IGF) 1 in altricial species. Peaks in plasma concentrations of both GH and IGF1 during posthatch growth occur earlier in altricial (European starlings) than precocial birds (Japanese quail) (Schew et al., 1996).

41.4 Sexual dimorphism in growth

41.4.1 Overview

There is sexual dimorphism in adult body weight in birds and, hence, in growth rate. This is according to Angel and colleagues (2015); they employed the following as an index of size dimorphism:

$$\text{Size dimorphism index(SDI)} = \left[\frac{\text{Mean male}}{\text{Mean female}} - 1\right] \times 100$$

where males are larger than females, the SDI is positive, and when females are larger than males, the SDI is negative.

TABLE 41.1 Growths rates in three avian species.

	Starling (*Sturnus vulgaris*) Altricial	Common tern (*Sterna hirundo*) Semialtricial	Japanese quail (*Coturnix japonica*) Precocial
Body weight in g			
Newly hatched chick	5.23	13.5	6.5
Adult	79	110	113
Age at maximal growth rate in days	6.4	7.9	28.9
Growth rate k	0.405	0.267	0.106
Body composition			
% solid			
Chick	13.2	21.3	24.1
Adult	35.6	40.1	35.8
% lipid			
Chick	1.6	1.9	6.4
Adult	4.4	6.0	9.0
Organ weights at % of body weight			
Heart			
Chick	1.0	1.3	1.5
Adult	1.4	1.6	1.3
Liver			
Chick	3.9	4.8	2.6
Adult	5.3	6.3	3.9
Pectoralis			
Chick	2.4	1.3	1.7
Adult	20.2	16.3	19.4

Data from or calculated from Ricklefs (1979).

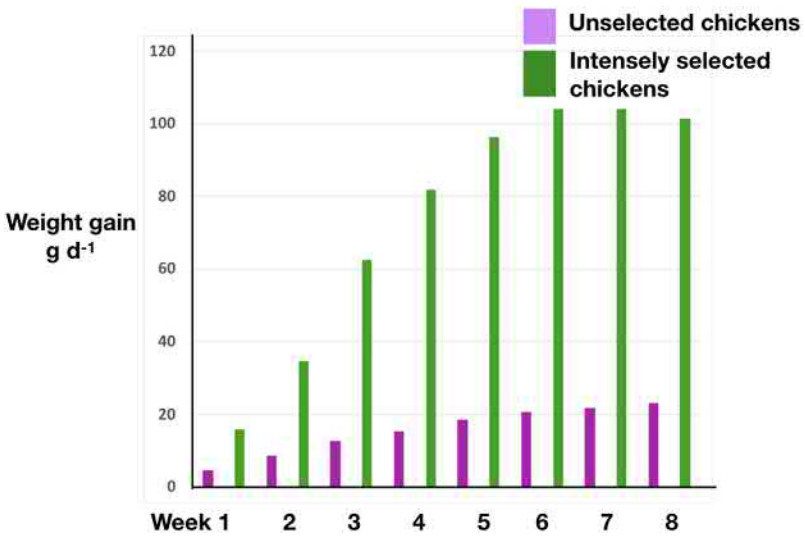

FIGURE 41.2 Changes in growth rate expressed as average daily gain in unselected meat-type chickens and highly genetically selected broiler chickens. *Data from Zuidhof et al. (2014).*

TABLE 41.2 Effect of intensive genetic selection of relative organ weights in 6-weeks-old chickens.

Genetic stock	Relative weights as %		
	Breast muscle e.g., pectoralis	Heart	Abdominal fat pad
Females			
Unselected meat-type chickens	11.9 + 0.44	0.556 + 0.030	0.50 + 0.10
Highly selected 2001 broiler chickens	20.5 + 0.44	0.484 + 0.030	1.50 + 0.10
Males			
Unselected meat-type chickens	11.2 + 0.44	0.591 + 0.030	0.75 + 0.10
Highly selected 2001 broiler chickens	19.5 + 0.44	0.535 + 0.030	1.29 + 0.10

Data shown as mean + SEM from Havenstein et al. (2003a).

TABLE 41.3 Comparison of growth rates in extant altricial with extant precocial land birds and *Archaeopteryx* and extant reptiles.

	Growth rates g/day
Extant altricial land birds	28.6
Extant precocial land birds	5.7
Archaeopteryx	1.9
Extant reptiles	0.46

Data from Case (1978).

TABLE 41.4 Differences in growth characteristics (regressions of $\log_{10}$ maximal growth rate per day versus $\log_{10}$ body weight at maximal body weight) between modern birds and other vertebrate groups.

Vertebrate taxa	Intercept [95% confidence limits]
Modern birds	
Altricial birds	−0.61 [−0.50 to −0.72]
Precocial birds	−0.83 [−0.61 to −1.05]
Eutherian mammals	−1.05 [−0.88 to −1.23]
Nonavian dinosaurs	−1.95 [−1.43 to −2.46]
Reptiles	−2.14 [−1.64 to −2.65]
Fish	−2.80 [−2.34 to −3.26]

Adapted from Werner and Griebeler (2014).

41.4.2 Sexual dimorphism in domesticated birds

There is some sexual dimorphism in growth rate in chickens, turkeys (Table 41.5), Muscovy ducks, and domestic ducks (Figure 41.4.) with size dimorphism indices (SDIs) of, respectively, 30%, 16%, 47%, and 6.5% (Tai and Rouvier, 1998; Werner and Griebeler, 2014). Interspecies hybrids between Muscovy ducks and domestic ducks exhibit either SDIs similar to those in Muscovy ducks (offspring of female Muscovy ducks and male domestic ducks) or domestic ducks (offspring of male Muscovy ducks and female domestic ducks) (Figure 41.4). The growth rate of males of interspecies hybrid males between Muscovy ducks and domestic ducks is between those in Muscovy ducks and domestic ducks. This is consistent with dosing of growth-related genes on the WW chromosomes or codominant genes. Similarly, in male offspring of male Muscovy ducks and female domestic ducks, growth rates are below that of either Muscovy ducks or domestic ducks

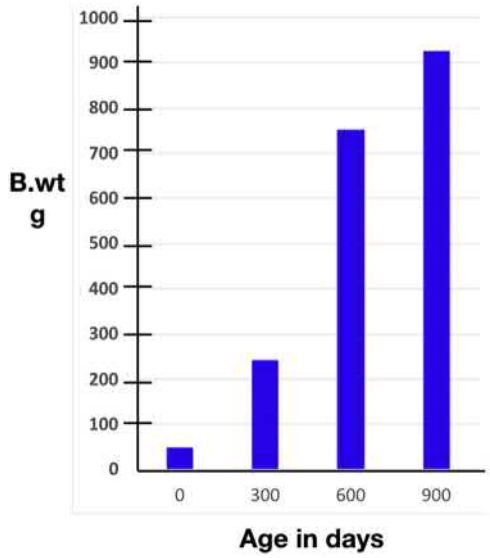

FIGURE 41.3 Slow growth of an early bird, *Archaeopteryx*. *Adapted from data in Erickson et al. (2009).*

In contrast, in female offspring of female Muscovy ducks and male domestic ducks, growth rates are below that of either Muscovy ducks or domestic ducks. This is consistent with low growth rate of this hybrid being due to the Z chromosome for the domestic duck.

Concomitant with sexual dimorphism in Muscovy ducks (Figure 41.4), there is analogous and marked sexual dimorphism in circulating concentrations of IGF1 in (Baéza et al., 2001). There was no sexual dimorphism in body weights (at either hatching or at 6 weeks posthatching) in ZW females subjected to sex reversal *in ovo* following administration of an aromatase inhibitor compared to ZZ males (Mohammadrezaei et al., 2014). In addition, there were marked increases in the growth rate of ZW genetic females subjected to sex reversal following IGF1 administration *in ovo* (Mohammadrezaei et al., 2014).

41.4.3 Sexual dimorphism in wild birds

Table 41.6 provides examples of avian species where the male is larger, the female is larger, and where there is little difference. Similarly, among seabirds, there are species where the male is larger and others where the female is larger (Fairbairn and Shine, 1993). In contrast, in 26 passeriform species, the male is larger than the female (Mills, 2008).

41.5 Growth hormone

41.5.1 Overview

GH is one of a series of hormones that influence growth rate. GH acts by binding to the growth hormone receptor (GHR). This is followed by dimerization of two GHR molecules and activation of JAK2 and ultimately synthesis and release of IGF1 (see Figure 41.5); IGF1 mediating the effects of GH on growth (Figure 41.5).

41.5.2 Chemistry and evolution of GH

There is marked conservatism in GH in nonpasserine birds (see Figure 41.6). This conservatism argues for the importance of GH in birds. Passerine birds exhibit an unusual feature with duplication of the GH gene (Yuri et al., 2008; Arai and Iigo, 2010). Along with the gene duplication of GH in passeriform birds, there is 10-fold acceleration in the rates of amino acid substitution, particularly in GH-B (Yuri et al., 2008) (see Figure 41.6). This may be due to relaxed selection pressure.

41.5.3 GH and growth

Growth of chickens was reduced by about 40% in hypophysectomized chickens (King, 1969; King and Scanes, 1986) (see Figure 41.7). Hypophysectomy not only removes GH but also depresses thyroid activity due to the absence of thyrotropin. Replacement therapy with GH improves growth rate (see Figure 41.7). In dw chickens, growth is depressed reflecting the decreases in circulating concentrations of triiodothyronine (T_3) and IGF1 (Tixier-Boichard et al., 1992) (see Figure 41.7). About 60% of growth is independent of pituitary hormones and 70% is independent of GH.

TABLE 41.5 Sexual dimorphism in growth rate in poultry science.

Species and age	Weight in kg		SDI	References
	Female	Male		
Chickens (8 weeks old)				
Nonselected	0.76	1.01	32.9%	Havenstein et al. (2003b)
Selected	3.49	4.40	26.1%	Havenstein et al. (2003b)
Turkeys (12 weeks old)				
Intensive production	5.94	6.92	16.1%	Sogut et al. (2016)
Free range	3.76	4.04	16.4%	Sogut et al. (2016)

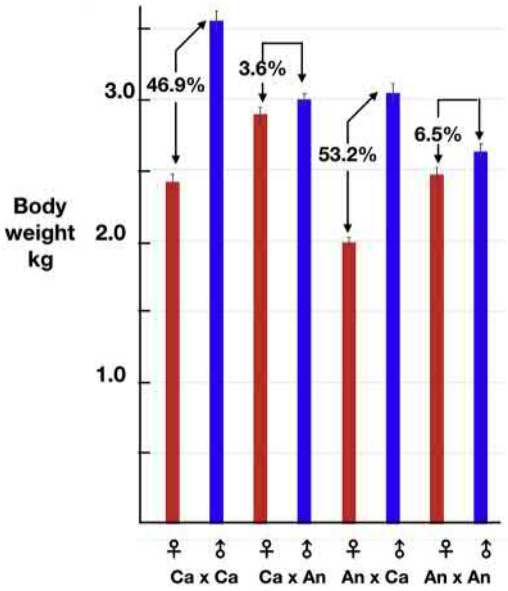

FIGURE 41.4 Sexual dimorphism in body weight at 10 weeks old in Muscovy and domestic ducks and intergeneric hybrids. [Ca - *Cairina moschata* (Muscovy ducks); An - *Anas platyrhynchos* (domestic duck and mallard)]. *Data from Tai and Rouvier (1998).*

In hypophysectomized turkeys, growth is depressed, but GH replacement has no discernible effect on growth rate of young turkeys (Proudman et al., 1994). Young rapidly growing broiler chickens (7 weeks of age) do not respond to exogenous GH (Burke et al., 1987), while older chickens appear to be GH responsive (VasilatosYounken et al., 1988), presumably due to greater abundance of the hepatic GHR (Burnside and Cogburn, 1992). There is a strong synergism between exogenous GH and dietary T_3 in reducing body fat deposition in young broiler chickens (Cogburn, 1991). In 8-week-old female chickens, pulsatile, but not continuous, GH infusion stimulated growth (Vasilatos-Younken et al., 1988), while in 12-week-old male chickens, continuous administration of GH increases growth rate (Scanes et al., 1990).

41.5.4 GH receptors

There is evidence that GHR is downregulated by GH; hepatic GH binding in chickens being increased following hypophysectomy and return to control levels with GH

TABLE 41.6 Examples of sexual dimorphism of adult body weight of birds.

injections (Vanderpooten et al., 1991a). Moreover, high hepatic GH binding declines as plasma concentrations of GH rise late in embryonic development and are increased in adults that have low circulating concentrations of GH (chicken: Vanderpooten et al., 1991b).

41.5.5 Sex-linked dwarf chickens as a model for growth hormone action

The sex-linked dwarf chicken (gene symbol, dw) (Hutt, 1959; Guillaume, 1976) is an interesting model for understanding the role of GH in growth and development as dw chickens have a defect in the GHR (Burnside et al., 1991; Huang et al., 1993). Obviously, the dw chickens exhibit both reduced growth and adult size (Hutt, 1959; Guillaume, 1976; Tixier-Boichard et al., 1992). There is some, albeit very low, GH-binding activity in the liver of dw chickens (Leung et al., 1987; Vanderpooten et al., 1991b).

As might be expected, dw chickens have shifts in circulating concentrations of hormones, plasma levels of GH and thyroxine (T_4) being elevated, while those of T_3 and IGF1 levels are depressed (Scanes et al., 1983; Huybrechts et al., 1985). The depression in circulating concentrations of IGF1 would be anticipated due to the impairment of GH action. Another consequence of the GHR lesion is that metabolism of T_4 to the active thyroid hormone, T_3, is impaired (Scanes et al., 1983; Kuhn et al., 1990). This is consistent with deiodination being regulated by GH (Kuhn et al., 1987; Darras et al., 1990). The hypothyroid state of dw chickens contributes to lowered basal metabolism (Guillaume, 1976). Continuous treatment of dw chicks with both T_3 and IGF1 partially restores growth rate (see Figure 41.7) (Tixier-Boichard et al., 1992).

41.6 Insulin-like growth factors

41.6.1 Overview

As in mammals, birds have two IGFs (IGF1 and IGF2) that exert insulin-like effects on metabolism and are important regulators of cellular differentiation, proliferation, and growth of tissue. The liver is the major source of IGFs (e.g., Giachetto et al., 2004). There is also expression of both IGF1 and 2 in multiple tissues. For instance, there is marked expression of IGF1, IGF2, and IGF1 receptor (IGF1R) by both proliferative and hypertrophic chondrocytes (Leach et al., 2007) in the epiphyseal cartilage (Lu et al., 2010).

41.6.2 Chemistry and evolution of IGF1 and IGF2

IGF1 consists of a sequence of 70 amino acids. IGF1 has an identical structure across avian species, while there was a single substitution in IGF2 (see Figures 41.8 and 41.9). This remarkable conservatism argues for the very high selective value of IGF1 and IGF2. Similarly, there are very few differences (~3) between sequences of IGF1 across the eutherian mammals (Rotwein, 2017).

41.6.3 IGFs and growth

There is strong evidence that IGF1, and probably IGF2, plays a role in growth. Circulating concentrations of IGF1 are decreased in growth depressed young chickens whether hypophysectomized or dwarf (Huybrecht et al., 1985) (Tixier-Boichard et al., 1992). Administration of IGF1, together with T_3, partially restored growth in dw chickens to those in nondw birds (Tixier-Boichard et al., 1992) (Figure 41.7). Administration of IGF1 *in ovo* increased

body weights in male chickens at either hatching or at 6 weeks posthatching, thus increasing the SDI (Mohammadrezaei et al., 2014).

41.6.4 IGF1 and muscle and adipose growth

IGF1 stimulates growth of skeletal muscle There is increased proliferation of muscle satellite cells in the presence of IGF1 or IGF2 in vitro (chicken: Duclos et al., 1991). Moreover, IGF1 stimulates the proliferation of myoblast cells (Yu et al., 2015). Infusion of IGF1 increased the fractional rate protein synthesis in pectoralis muscle of fasted but not fed young chickens; fasting having depressed the fractional rate protein synthesis (Kita et al., 2002a). Moreover, a single injection of IGF1 induced an increase in the fractional rate of muscle protein synthesis (Conlon and Kita, 2002).

IGF1 also influences growth of adipose tissue with IGF1 or IGF2 stimulating proliferation of preadipocyte but

inhibiting differentiation (chicken: Butterwith and Gilroy, 1991; Butterwith and Goddard, 1991).

41.6.5 IGF receptors

IGF1Rs are tyrosine kinases as are insulin receptors. Both IGF1 and IGF2 bind to the IGF1R in birds (chicken: Duclos et al., 1991). The structure of avian IGF1R has been deduced in the chicken (*Gallus gallus*) (Genbank accession NM_205032). The actions of IGF1 are mediated by the PI3K/Akt signalling pathway based on effects on myoblast cells (Yu et al., 2015).

41.6.6 Nutrition and IGF1

Adverse nutritional status depresses the IGF1 system. For instance, fasting is followed by decreases in circulating concentrations of IGF1 and hepatic IGF1 expression (young chickens: Kita et al., 1998; Kita et al., 2002b). Similarly, feed-restricted chickens have reduced plasma concentrations of IGF1 and IGF2 (Leili et al., 1997). Moreover, chickens fed a very low protein diet have reduced plasma concentrations of IGF1 and IGF2 (Lauterio and Scanes, 1987; Leili, and Scanes, 1998; Kita et al., 2002b). In contrast, fasted young chickens were reported to

have elevated plasma concentrations of IGF2 (McMurtry, 1998) (Figure 41.10).

41.6.7 IGF1 and IGF2 in wild birds

The selective value of IGF1 and IGF2 is supported by the unexpectedly high identity between the sequences of IGF1 or IGF2 across avian species (Figures 41.8 and 41.9). There is evidence that IGF1 plays an important role in growth and/or adult size. Plasma concentrations of IGF1 are positively associated with body weight/body size in adult passerine birds (Lodjak et al., 2018). Plasma concentrations of IGF1 were associated with tail length and UV coloration in plumage in a songbird, male-bearded reedling (*Panurus biarmicus*). There are also short-term effects on circulating concentrations of IGF1. For instance, handling stress depressed plasma concentrations of IGF1 in the bearded reedling (Tóth et al., 2018). Based on studies in European starlings (*Sturnus vulgaris*) and Japanese quail (*Coturnix japonica*), wild birds exhibit the same pattern of circulating concentrations of IGF1 as poultry with a posthatch peak and a subsequently decline (Schew et al., 1996). Nutritional restriction depressed plasma concentrations of IGF1 in European starlings and Japanese quail (Schew et al., 1996).

There is further evidence that IGF1 plays a role in muscle development in wild birds. Muscle IGF1 expression is increased following flight captive European starlings (*S. vulgaris*) and in white-throated sparrows (*Zonotrichia albicollis*) exposed to a long photoperiod that would induce migratory behavior (Price et al., 2011).

41.6.8 Insulin-like growth factor–binding proteins

41.6.8.1 Overview

Both IGF1 and IGF2 circulate bound to carrier proteins known as the IGF-binding proteins (IGFBPs). Multiple tissues express IGFBPs. For instance, the proliferative and hypertrophic chondrocytes in the epiphyseal cartilage express IGFBP2, IGFBP3, IGFBP5, and IGFBP7 (Leach et al., 2007; Lu et al., 2010). Binding of IGF1 or IGF2 to IGFBPs can either increase or decrease the biological activities of the growth factors (Butterworth, 1997). Multiple IGFBPs have been reported in chickens with the sequences deduced

- IGFBP-1 Genbank Accession NM_001001294.1

- IGFBP-4 - NM_204353.1
- IGFBP-5 - XM_422069.6
- IGFBP-7 - XM_420577.6.

41.6.8.2 Nutrition and IGFBPs

Nutritional status influences IGFBPs. There are marked changes in the expression of IGFBP2 with nutritional status in young chickens. Expression of IGFBP2 is increased in the liver and gizzard of fasted birds but decreased in the brain (Kita et al., 2002b). In contrast, hepatic expression of IGFBP2 is depressed in chicks fed a fat-free diet or an extremely low protein diet (Kita et al., 2002b). Refeeding reverses the effect of fasting in the liver and gizzard (Kita et al., 2002b). Moreover, expression of IGFBP2 and IGFBP3 is increased in the liver but not brain of fasted chickens (Fujita et al., 2018).

41.6.9 Insulin-like growth factor 2–binding proteins

There are also binding proteins that bind IGF2 mRNA. Examples include the following: IGF2I mRNA–binding protein 1 binds single-stranded RNA (Chen et al., 2019). Chickens on a high fat diet exhibit increased the weights of abdominal fat pad due to adipocytes hypertrophy together with increased expression of IGF2BP in liver and adipose tissue (Chen et al., 2019). Moreover, transfection of avian cells with IGF2BP increased expression of fatty acid metabolism (Chen et al., 2019). Another IGF2 RNA–binding protein is IGF2BP3. This translational activator of IGF2 is GH dependent; expression of IGFBP3 is being depressed in skeletal muscle of dw chickens (Lin et al., 2017).

41.7 Thyroid hormones (hypothalamo–pituitary–thyroid axis)

41.7.1 Overview

The physiology of thyroid hormones is considered elsewhere (Chapter 31); however, the role of thyroid hormones in regulation of growth and development is discussed here. In birds and mammals, the predominant iodothyronine secreted by the thyroid glands is T_4, a prohormone which is converted to the active form T_3 or catabolized to metabolically inactive reverse T_3.

41.7.2 Thyroid hormones and growth

In birds, the thyroid hormones are required for normal growth (Figure 41.10), since thyroidectomy results in a reduction in growth rate in young chickens (Raheja and Snedecor, 1970; King and King, 1973, 1976; Moore et al., 1984) or in the chick embryo (McNabb et al., 1984). In young chickens, the decrease in growth results in reductions in skeletal and bone masses (King and King, 1973, 1976; Moore et al., 1984). These effects of thyroidectomy can be overcome partially by T_3 or T_4 replacement therapy (King and King, 1973). Similarly, growth can be stimulated by T_3 or T_4 administration in hypophysectomized chicks (King, 1969; Scanes et al., 1986) and in sex-linked dw chickens, which are T_3 deficient (Scanes et al., 1983; Marsh et al., 1984; Leung et al., 1984). The stimulatory effect of thyroid hormones in growing chicks can be mediated either by increases in the circulating concentrations of IGF1 and/or by direct effects of T_3 on the growing tissues. There is, indeed, evidence that T_3 can stimulate the growth of chick embryo cartilage in vitro (Burch and Lebovitz, 1982; Burch and Van Wyk, 1987).

While T_3 is required for the full manifestation of growth, dietary T_3 depresses growth rate when continuously administered to growing chickens (May, 1980; Decuypere et al., 1987). This could be due to the inhibitory effects of T_3 on GH release in chickens.

Not only do thyroid hormones appear to be required for growth in the avian embryo but also they influence differentiation and the acquisition of full functioning by embryonic organs prior to hatching (see Chapter 15 for details). Effects of T3 in the late-stage embryo are not surprising in view of the increases in circulating concentrations observed before hatching (McNabb and Hughes, 1983). However, the reduction in growth rate in chick embryos receiving goitrogen treatment is perhaps surprising since circulating T_3 concentrations are low, although T_4 levels are high at mid-stage (days 9–11) (McNabb et al., 1984). There could be significant monodeiodination of T_4 to T_3 in the peripheral tissues or high levels of T_4 could exert effects by binding to the avian thyroid hormone receptor. The latter is unlikely based on the chicken hepatic nuclear binding studies (Bellabarba and Lehoux, 1981). Further evidence that the thyroid hormones are exerting a role in the middle of development of chick embryos comes from the reports of high levels of thyroid hormone receptor in the brain and liver (Bellabarba and Lehoux, 1981; Bellabarba et al., 1983). The thyroid hormone receptors are considered elsewhere in this volume (Chapter 15).

41.7.3 Thyroid hormones and wild birds

Circulating concentrations of the active thyroid hormone, T_3, are related to basal metabolic rate (Welcker et al., 2013).

41.8 Sex steroid hormones

41.8.1 Overview

In many mammals, growth can be stimulated by androgens and/or estrogens. These effects are exerted either directly at the tissue level or mediated by the hypothalamo–pituitary axis. In either case, estrogen acts via binding to nuclear receptors, while androgens can evoke their effect via either the nuclear androgen receptor or the estrogen receptor following aromatization to estrogen.

Sex steroids have been observed to influence growth but with remarkably large differences between species in the magnitude and even direction of the effects in avian species.

41.8.2 Sex steroids and poultry

In the chicken, the marked sexual dimorphism in growth rate does not appear to be related to either androgens or estrogens. The administration of androgens (either aromatizable (e.g., testosterone or 19-nortestosterone) or nonaromatizable (e.g., 5α-dihydrotestosterone)), at physiological concentrations, to male, female, or castrated male chicks does not stimulate growth (Fennell and Scanes, 1992a). Instead, skeletal growth, particularly of the long bones, is considerably reduced (Fennell and Scanes, 1992a). In contrast, in the domestic turkey, administration of androgens is followed by considerable increases in growth (Fennell and Scanes, 1992b). In view of the ability of either aromatizable or nonaromatizable androgens to enhance growth of the turkey,

it is probable that the effect is mediated by androgen receptors in the muscle and bone.

41.8.3 Sex steroids and wild birds

Androgens have been reported to exert either positive or negative effects on growth of wild birds. This comes predominantly from studies in which androgens were administered into eggs or comparing endogenous androgen concentrations. For instance, posthatching growth is increased after testosterone administration into the egg of male great tits (*Parus major*) (Tschirren, 2015) and canaries (*Serinus canaria*). Conversely, *in ovo* administration of androgens depressed posthatching growth of nestling American kestrels (Sockman et al., 2008) and male canaries (*S. canaria*) (Müller et al., 2008). However, a stimulatory effect of in *ovo* testosterone was reported (Schwabl, 1996). In addition, administration of testosterone to canary chicks was followed by elevated rates of growth and skeletal growth (Schwabl, 1996).

The response, posthatching growth, to androgens in eggs exhibits sexual dimorphism in birds. For instance, there was a positive relationship between egg concentrations of androgens in male barn swallows (*Hirundo rustica*) but a negative relationship in females (Saino et al., 2006). Posthatching growth is increased after *in ovo* administration in male but not female great tits (*P. major*) (Tschirren, 2015).

41.9 Adrenocorticotropin and glucocorticoids (hypothalamo–pituitary–adrenocortical axis)

41.9.1 Overview

The hypothalamo–pituitary–adrenocortical axis plays a critical role in the response to stress. The pituitary hormone, adrenocorticotropic hormone (ACTH), stimulates the release of glucocorticoids from the adrenocortical cells. It is assumed corticosterone (CORT) is the major glucocorticoids in birds. Tables P and Q summarize effects of glucocorticoids in wild birds and poultry species. Much of the research on effects of ACTH or glucocorticoids on growth in birds is on chickens. There are potentially differences between chickens and wild birds due to the effect of domestication and genetic selection and that chickens exhibit precocial development, while many wild birds are altricial. It should be noted that studies predominantly employ exogenous CORT or the synthetic glucocorticoid, dexamethasone.

41.9.2 Are glucocorticoids required for development and growth?

Activation of the hypothalamic pituitary adrenocortical axis, with increased circulating concentrations of ACTH and CORT during embryonic development, induces key features of development. For instance, the glucocorticoid, dexamethasone, stimulates secretion of phosphatidylcholine (surfactant) from type II lung cells of embryonic chickens (Sullivan and Orgeig, 2001). Moreover, pituitary grafts *in ovo* or glucocorticoids in vitro induce increased UDP glucuronyltransferase activity in the embryonic liver (Wishart and Dutton, 1974; Burchell et al., 1983). Similarly, dexamethasone induces steroid hydroxylation in the liver (Kimmett et al., 1996). In addition, *in ovo* administration of CORT induces development of somatotrophs (Dean et al., 1999).

Glucocorticoids play important roles in the control of metabolism (see Chapter 17). It is reasonable to infer that maximal growth rates require normal metabolism and, hence, adequate circulating concentrations of glucocorticoids. There is little evidence that insufficient levels of glucocorticoids adversely affect growth in birds. For instance, administration of CORT to hypophysectomized chicks failed to stimulate growth (King and Scanes, 1986).

41.9.3 Glucocorticoid depression of growth

Exogenous glucocorticoids depress or even completely suppress growth in young chickens (see Table 41.7 for examples of studies in which glucocorticoids depressed growth) and chick embryos (see Table 41.8 for examples of studies in which glucocorticoids depressed growth in avian embryos). There is evidence that the genetics and/or growth rate of chickens can influence their responsiveness to glucocorticoids. CORT exerts a greater growth suppressing effect in heavy fast-growing meat type than layer (white Leghorn) chickens (Siegel et al., 1989). Administration of CORT into the yolk of Japanese quail (*C. japonica*) was accompanied by decreased posthatching growth in males but not females (Hayward et al., 2006).

Treatment of growing chickens with CORT increases abdominal fat weight (Buyse et al., 1987; Siegel et al., 1989; Taouis et al., 1993). Similarly, injection of glucocorticoids into growing Japanese quail reduces fat-free body weight (Bray, 1993), while in adults, CORT depresses nitrogen detention and increases nitrogen excretion (De La Cruz et al., 1981). It may well be that glucocorticoids released during stress exert an inhibitory effect on growth but further research in needed particularly determining their effects on posthatching growth of altricial species. Interestingly, CORT administration depressed growth even in hypophysectomized chicks (King and Scanes, 1986). Similarly, CORT exerts a transient suppression of bone growth; for instance, preventing increases in tarsus length (canaries: Müller et al., 2009).

The inhibitory effects of glucocorticoids on muscle growth (Dong et al., 2007) are mediated at least in part by mechanistic target of rapamycin (Wang et al., 2015). Moreover, there is evidence that glucocorticoids increase muscle protein degradation (Klasing et al., 1987). In

addition, there is cross-talk between the adrenocortical axis and the GH–IGF1 axis and growth factors. Dexamethasone depresses expression of IGF1 and IGF1R together with that of MYOD (myoblast determination protein 1), MSTN (myostatin) and MYF5 (Myogenic factor 5) in the *M. biceps femoris* (Song et al., 2011). In addition, effects of CORT may be mediated in part by shifts in the intestinal microbiome (Noguera et al., 2018).

41.10 Insulin

While insulin plays a major role in the control of metabolism (see Chapter 34), there is evidence from older studies that insulin is also involved in the control of growth of at least early avian embryos. Growth of chicken embryos, between days 2 and 5 of development, is increased by administration of low doses of insulin (De Pablo et al., 1985a; Girbau et al., 1987). Conversely, chick embryos treated with antisera to insulin either die or show marked growth retardation (De Pablo et al., 1985b). These reports coupled with the definitive observations of the presence of insulin in early chick embryos argue that insulin is involved in the control of early chick embryo development. Insulin can compete for binding to type-I IGF receptors, albeit to a less extent than IGF1. Thus, the effects of insulin on chicken embryo growth are probably mediated by insulin receptors because insulin is more potent than IGF in stimulating embryo growth (Girbau et al., 1987), and there is evidence from binding studies for specific insulin receptors in chick embryos (Bassas et al., 1987). Moreover, the administration of antisera against the insulin receptor to chick embryos results in reduced growth (body weight, DNA, RNA, and protein) (Girbau et al., 1988). However, the effects of insulin on muscle differentiation are probably mediated via type-I IGF receptors as antisera against the insulin receptor failed to influence embryo creatine–kinase MB isozyme (Girbau et al., 1988).

41.11 Growth factors

41.11.1 Overview

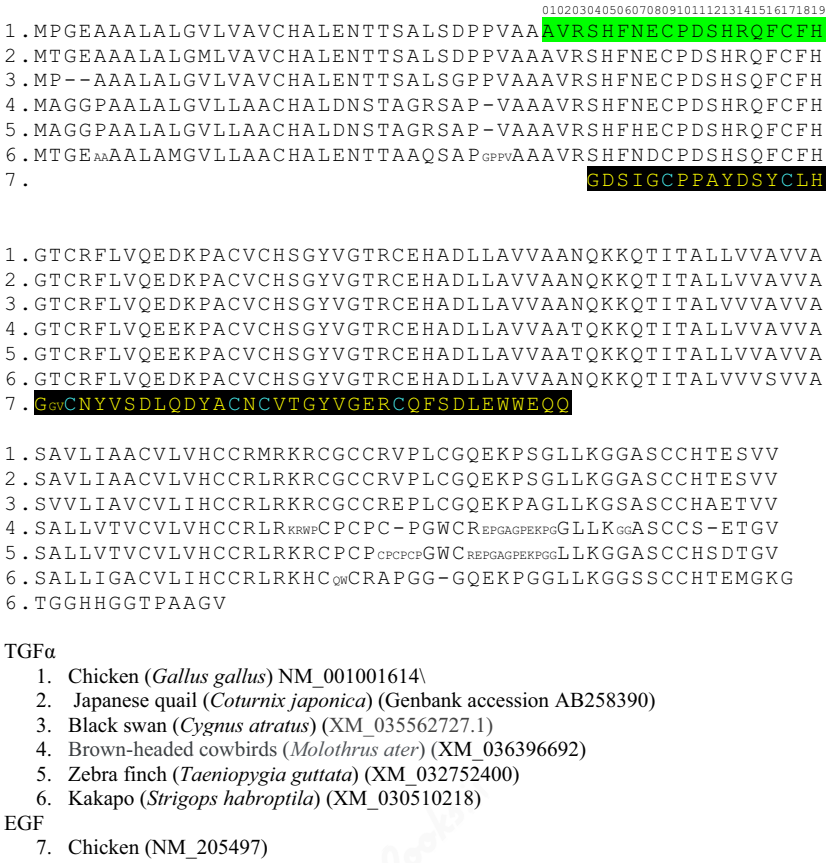
In addition to IGF1 and IGF2, multiple growth factors have been identified. These act by stimulating (or inhibiting) cell proliferation and/or differentiation. Large numbers of genes, involved in regulation of embryogenesis and development, have been studied in the chicken. During early embryogenesis, left/right asymmetry and anterior/posterior and dorsal/ventral axes are formed. Later in development, structures like the limbs and other major structures are formed. For instance, fibroblast growth factors (FGFs) and transforming growth factor β (TGF-β) play an important role in the development of the jaw (Woronowicz et al., 2018). While FGF signalling inhibits primitive hematopoeisis (Nakazawa et al., 2006).

The identification of tissue growth factors and their actions in birds will be briefly considered below.

41.12 Epidermal growth factor and transforming growth factor-α

41.12.1 Chemistry of EGF and TGF-α

The sequence of chicken EGF can be extrapolated based on the sequence of chicken preproEGF together with the



TGFα

1. Chicken (*Gallus gallus*) NM_001001614\
2. Japanese quail (*Coturnix japonica*) (Genbank accession AB258390)
3. Black swan (*Cygnus atratus*) (XM_035562727.1)
4. Brown-headed cowbirds (*Molothrus ater*) (XM_036396692)
5. Zebra finch (*Taeniopygia guttata*) (XM_032752400)
6. Kakapo (*Strigops habroptila*) (XM_030510218)

EGF

FIGURE 41.11 Comparison of the structures of avian TGF-α and the homologies shown TGF-α and EGF (alignments based on Marquardt et al., 1983). The amino acid sequence for avian EGF is based on the deduced structure of prepro-EGF and comparison to human EGF (Savage et al., 1972).

homology to human EGF. The sequence of chicken EGF can be extrapolated transforming growth factor-α (TGF-α) (Figure 41.11). EGF is a polypeptide with 53 amino acid residues with marked homologies with avian TGF-α (Figure 41.11).

41.12.2 EGFR receptor

Epidermal growth factor receptor (EGFR) (erbB1) is a type 1 tyrosine kinase. Other members of the family are erbB2, erbB3, and erbB4. Binding of EGF or TGF-α to the EGFR facilitates receptor dimerization and thereby activation.

41.12.3 Actions of EGF and TGF-α

In birds, EGF stimulates the proliferation of heart mesenchymal cells; this effect is potentiated by IGF1 (Balk et al., 1984). Either TGF-α or EGF can stimulate proliferation of adipocyte precursor cells but inhibit their differentiation (chicken: Butterwith et al., 1992).

41.13 Transforming growth factor-β

Functionally and structurally, avian TGF-βs are homodimers. These are formed with the concave aspect of monomer one binds to the convex aspect of monomer two. As would be expected, TGF-β 1, TGF-β 2, and TGF-β 3 are members of the TGF-β superfamily. Other members of the TGF-β superfamily include the following:

- Bone morphogenic proteins (BMPs)
- Müllerian inhibitory substance
- Activin
- Inhibin
- Growth and differentiation factors (GDF) e.g., GDF8 - myostatin (Hinck, 2012). Binding of TGF-β to its receptor activates R-Smads 2 and 3 (Hinck, 2012).

41.13.1 Structure of avian TGF-βs

The three TGF-βs are TGF-β1, TGF-β2, and TGF-β3. These have been characterized in chickens in birds (see

TABLE 41.9 Examples of TGF-α and TGF-β in birds together with related growth factors.

Growth factor	Gene	Species	GenBank accession number
EGF	EGF	Chicken/jungle fowl (*Gallus gallus*)	NM_205497
TGF-α	TGFA	Chicken/jungle fowl (*Gallus gallus*)[a]	AY605246

BMP4	BMP4	Great Tit (*Parus major*)	XM_015629595

[a]*Partial sequence only.*

Table 41.9). TGF-β isoforms show 75−80% homology to each other in their amino acid sequence. Moreover, the TGF-β isoforms have the same overall structure as homodimers of 114-amino acid residue−containing subunits.

There is widespread expression of TGF-β in chick embryos with TGF-β1 expressed in some mesodermal and ectodermal cells, TGF-β2 in the precardiac mesoderm, in the optic vesicles, notochord, and neural tube floor plate and TGF-β3 in the lateral embryonic and extraembryonic mesoderm including the blood islands and myocardium (Cooley et al., 2014). TGF-β isoforms are known to be produced by many cell types.

41.13.2 Physiology of avian TGF-βs

TGF-β2 is expressed by muscle satellite cells (chicken: Kocamis et al., 2001), while preadipocytes express TGF-β2, TGF-β3, and TGF-β 4 (Burt et al., 1992). TGF-β1 increases preadipocyte proliferation (chicken: Butterwith and Goddard, 1991). TGF-β bind to type II transmembrane receptor serine/threonine kinase, TGF-βR2, and two type I receptors, TGF-βR1, forming a tetra-heteromeric receptor complex.

41.13.3 Myostatin

41.13.3.1 Myostatin poultry

MSTN plays an important role in muscle growth. MSTN is expressed by muscle satellite cells (chicken: Kocamis et al., 2001).

41.13.3.2 Myostatin in wild birds

There is limited information on MSTN in wild birds. However, multiple spice variation of MSTN has been identified in white-throated sparrows (*Z. albicollis*) and European starlings (*S. vulgaris*) (Price et al., 2011). Expression of MSTN is increased in white-throated sparrows (*Z. albicollis*) in which migratory behavior is induced by exposure to a long daylength (Price et al., 2011).

41.14 Bone morphogenetic protein

41.14.1 Overview

BMPs 1−4 are homodimers (Reynolds et al., 2000). The sequences of BMP1−4 have been reported in multiple birds

(see Table 41.9 for examples). Signal transduction for BMPs following receptor binding includes SMAD transcription factors.

41.14.2 Bone morphogenetic protein 1 and tolloid

BMP1 and tolloid play a role in the production of the matrix in skeletal development. BMP1 is an approximately 700 amino acid−containing protein. Two BMP1 like proteins are similar, respectively, BMP1 and a larger form, tolloid (Reynolds et al., 2000). The N terminal of the BMP1 is homologous with zinc metalloproteinases (Reynolds et al., 2000). Both BMP1 and tolloid are expressed by osteoblasts, for instance, in embryonic chick calvarial osteoblasts together with embryonic chondrocytes (Reynolds et al., 2000).

41.14.3 Bone morphogenetic protein 2

Based on studies comparing intestinal development in chicken and zebra finches, BMP2 plays an important role in the development of the intestine (Nerurkar et al., 2017).

41.14.4 Bone morphogenetic protein 3

BMP3 plays an important role in the limb development. BMP3 does not follow classic TGF-β−like signaling system (Gamer et al., 2008).

41.14.5 Bone morphogenetic protein 4

BMP4 is involved in the development and growth of adipose tissue in birds. There is high expression of BMP4 in abdominal, mesentery, and subcutaneous adipose tissue with moderate expression in the liver and spleen (7-week-old chickens: Cheng et al., 2016). Serum concentrations of BMP4 are markedly lower in chickens selected for fat content than lean birds (7-week-old chickens: Cheng et al., 2016).

41.15 Fibroblast growth factors

41.15.1 Overview

FGFs are found throughout metazoa (Itoh et al., 2015). FGFs are classified as follows:

- Intracrine
- Paracrine (requiring heparin sulfate as a cofactor)
- Endocrine

In most vertebrates, there are three endocrine FGFs: respectively, FGF19, FGF21, and FGF23. In birds, FGF21 is not found (Itoh et al., 2015).

41.15.2 Endocrine FGFs, FGF receptors, and signal transduction

Binding of the endocrine FGFs to FGF receptors 1−4 requires the presence of the coreceptor factors, α-Klotho or β-Klotho (Itoh et al., 2015).

41.15.3 Fibroblast growth factors 19

The structure of FGF23 has been deduced from cDNA from multiple avian species including the following:

- Chicken (*G. gallus*) NM_204674
- Swan goose (*Anser cygnoides*) XM_013189044.1
- Chuck-will's-widow (*Antrostomus carolinensis*) XM_010171990
- Burrowing owl (*Athene cunicularia*) XM_026850698

41.15.4 FGF23

41.15.4.1 Overview

The structure of avian FGF23 has been deduced from cDNA from multiple birds including the following:

- Chicken (*G. gallus*) M95707.1
- Budgerigar (*Melopsittacus undulatus*) XM_005147966.2
- Great Tit (*P. major*) XM_015626966

FGF23 is produced by bone with expression and presumably release influenced by phosphate status (adult female chicken: Ren et al.). Bone calvaria from hens on a phosphate restricted diet have reduced expression of FGF23 (adult female chicken: Ren et al.).

41.15.4.2 FGF23 actions

FGF23 is one of the hormones controlling mineral and bone metabolism, inhibiting phosphate reabsorption and consequently increasing phosphate excretion. Hens immunized against a FGF23 peptide exhibited a decrease in phosphate excretion together with shifts in circulating concentrations of 1, 25 dihydroxy vitamin D (increased) and parathyroid hormone (reduced) (Ren et al., 2017c).

Maternal antibodies against FGF23 influence the physiology of the progeny. Chicks from eggs produced by laying hens immunized against a FGF23 peptide and subjected to a low-phosphate diet had increases in the following: plasma concentrations of phosphate, bone mineralization, and growth rate (Ren et al., 2017a, b). In contrast, young chickens fed a low-phosphate diet exhibit reduced bone growth and mineralization but without effect on circulating concentrations of FGF23 (Horvat-Gordon et al., 2019).

41.15.5 Other FGFs

Examples of paracrine FGFs are FGF1 (acidic FGF) and FGF2 (basic FGF).

41.15.6 FGF receptors

There are four FGFRs in birds each having tyrosine kinase activity. There is expression of FGFR1, FGFR2, FGFR3, and FGFR4 together with Klotho in the small intestine, bone calvaria, liver, and kidneys (adult female chicken: Ren et al.). Moreover, there is decreased expression of FGFR1 and FGFR4 in the kidney of laying hens on a phosphate-restricted diet (Ren et al.).

41.16 Neurotrophins

Neurotrophin family includes the following: nerve growth factor (NGF), brain-derived neurotrophic factor, and neurotrophin-3 (Kullander et al., 1997). The structure of avian NGF has been deduced in the following:

- Chicken (*G. gallus*) (NM_001293108)
- Zebra finch (*Taeniopygia guttata*) (DQ377326)

NGF plays a role in early development of the chick embryo regulating axial rotation (Manca et al., 2012) and in song control (e.g., Kim and Arnold, 2006).

41.17 Cytokines

41.17.1 Cytokines

Cytokines can be members of either the growth factor or GH gene families and/or exert there effects their effect by receptors in the same families to those receptors to growth factors or GH. Moreover, their signal transduction mechanism can identical. An example of a cytokine is discussed briefly below. Cytokines are considered in detail elsewhere is the volume (chapter).

41.17.2 Tumor necrosis factor-α (TNF-α)

The structure of tumor necrosis factor-α (TNF-α) has been deduced in multiple avian species including in ostrich, brown kiwi, mallard, chickens, turkeys, rock pigeon, house finches, white-crowned sparrows, crows, and great tits (Rohde et al., 2018). The delay in characterizing avian TNF-α is due to the gene being with a high GC region. TNF-α acts via classical nuclear factor kappa B pathway (Rohde et al., 2018).

41.18 Genetics and growth

There is considerable evidence that the genetics of poultry influence their growth rate. For instance, single nucleotide polymorphism (SNP) analysis has revealed associations between growth (body weight gain) in poultry and the following hormones, binding proteins, receptors, and signal transducers in the hypothalamic–pituitary–GH–IGF1 axis.

- Pit-1 gene (Jin et al., 2018)
- GH (Anh et al., 2015)
- IGF1 (Anh et al., 2015; Hosnedlova et al., 2020)
- IGFBP1 (Ou et al., 2009)
- IGFBP2 (Hosnedlova et al., 2020)
- IGFBP3 (Ou et al., 2009)
- STAT5B (Ou et al., 2009; Zhao et al., 2012);

for breast muscle weight with the following:

- GHSR (Demeure et al., 2013);

for abdominal fat pad with the following:

- GH (Zhang et al., 2007); and

for feed to gain ratio with the following:

- GHSR
- IGF1R (Jin et al., 2014).

Moreover, SNPs have been associated with growth with candidate genes that are part of the insulin and T_3 signal mechanisms (chicken: Abdalhag et al., 2015). SNPs associated with growth have also been identified with Myf5 (chicken: Tang et al., 2014) and TGF-β2 (Hosnedlova et al., 2020).

41.19 Nutrition and growth

Maximal growth requires optimal nutrition. Growth can be in the form of skeletal, fat, or muscle accretion, and the effect of nutrition on growth is confounded with other factors such as environmental (extrinsic) and physiological (intrinsic, exp., and GIT development) factors. Diets should be balanced for all the nutrients, including amino acids, minerals, carbohydrates, fatty acids, and fiber, and excess or deficit of a nutrient could lead to retarded growth. According to Liebig's law of the minimum (Liebig's barrel), growth is dictated by the scarcest nutrient (limiting factor) which is especially pertinent to the level of amino acids in the diet (Cant et al., 2003). For commercial poultry, nutritional requirements of meat and egg-type poultry are well identified and based on the production goal (highest body weight, lowest F:G, highest egg number, or egg mass). Recommendations are available for each type and breed (Cobb, Aviagen, and NRC nutrient recommendations). The effect of physiological stage (age) should also be considered regarding nutrition and growth. As an example, the GIT and its microbiome is underdeveloped in young poultry (Lesson and Summers, 2001; Kers et al., 2018), and thus is not capable of fully digesting fats and

fibers at young age (less than 3 weeks), which stipulates that during this period carbohydrates will be a better energy source for maximal growth. In addition, environmental factors such as temperature affect feed intake and growth (Rajaei-Sharifabadi et al., 2017); therefore, nutrient requirements of poultry for maximum growth differ based on the environmental conditions and poultry need a denser diet to compensate for lower feed intake during heat stress (Saeed et al., 2019). Nutrition could affect circulating IGF1 and 2 and hepatic mRNA levels, thus affecting growth in chickens (Beccavin et al., 2001; Giachetto et al., 2003). Nutritional restriction (energy or protein) leads to reductions in circulating concentrations of both IGF1 and T_3 with increased GH secretion due removal of negative feedback (Scanes et al., 2009). There are reports showing diets deficient in amino acids decrease plasma levels of IGF1 and IGF2 (Carew et al., 2003, 2005).

41.20 Environment and growth

41.20.1 Light and growth

There are reports that the wavelength of light influences the growth of broiler chickens being greater when the birds were raised under 440 and 560 nm light (respectively, blue and green light) compared to either 650 nm (red light) or white light (Rozenboim et al., 2013). Light spectrum influences the hypothalamo−pituitary−GH−IGF1 axis. There was greater expression of GHR in muscle satellite cells from birds raised under green and blue light than red or white light (Halevy et al., 1998; Rozenboim et al., 2013). Moreover, there were more satellite cells per muscle raised under green than red or white light (Halevy et al., 1998).

Moreover, embryonic growth, and particularly weights of the pectoralis, was enhanced under green light than darkness (Halevy et al., 2006; Rozenboim et al., 2013).

Chapter 42

Circadian rhythms

Vincent M. Cassone[1] and Vinod Kumar[2]
[1]Department of Biology, University of Kentucky, Lexington, KY, United States; [2]Department of Zoology, University of Delhi, Delhi, India

Biological circadian rhythms and the clocks that control them are fundamental properties of all freely living organisms studied in any detail. These are expressed by organisms ranging from cyanobacteria to humans with highly conserved formal properties. Among animals, the molecular details of biological clocks are highly conserved as well. The conserved nature of these rhythms and clocks likely derives from the fact that they are all adaptations to a single selective pressure—the daily change from night to day and the abiotic and biotic rhythms that accompany it. Biological clock function is particularly apparent in birds, partly due to the fact that they share with us a diurnal lifestyle, but also because time of day and time of year as we will see in the next chapter pervades all aspects of avian physiology.

42.1 Environmental cycles

42.1.1 Light cycles

Although we all know that the cycle of day to night derives from the rotation of the Earth on its axis approximately every 24 h, we experience this process through the apparent rise of the sun on the eastern horizon (dawn), its traverse across the sky, its setting in the west (dusk), and subsequent night. The most salient feature of the *solar day* is the dramatic change in visible and invisible light intensity, polarization, and wavelength spectra. Daylight intensity can be measured in a variety of radiometric and photometric ways, extending beyond the scope of this chapter. One can gather the scale of daily change in *lux* (*lx*), the International System of Units (SI) measure of *illuminance*, or the intensity of white light as perceived by the human eye. These values range from 120,000 lx in the brightest sunlight to 400 lx at dusk or dawn on a clear day to 0.0001 lx under overcast, moonless night sky. This vast range in intensity may go unperceived consciously, because our and birds' visual systems adapt to changes in intensity. However, as we shall see below, changes in absolute intensity and timing of illumination are detected and processed by the circadian clock. In addition to intensity, the wavelength of ambient light changes due to diffraction of shorter wavelengths at dawn and dusk, resulting in the perception of reddish hues at sunrise and sunset.

42.1.2 Temperature

Due to the daily changes in solar illumination, the atmosphere and surface of the Earth undergo daily changes in temperature that generally rise as the day progresses but vary dramatically due to latitude, season, and local conditions such as urban growth, proximity to bodies of water, desertification, and variations in land use (Geerts, 2002). The daily temperature range (DTR) is highly variable at different latitudes. For example, at the Equator, the DTR is 8°C in the summer and 9°C in the winter. In contrast, at 40° latitude in North America, the DTR in summer is 18°C in the summer and only 10°C in the winter. Proximity of oceans also ameliorates DTRs. For example, in July in Australia, the DTR increases from 6°C on the coast to 17°C 150 km inland. These changes are clearly important for natural ecosystems as well as agricultural activity, perhaps as important as the mean temperature itself. There is increasing evidence that, in addition to the gradual increase in mean global temperatures, the DTRs have changed as well, decreasing the daily range 0.4°C from 1950 to 1993.

42.1.3 Other physical cycles

Other physical characteristics vary over the day as a derivative of the diurnal solar cycle. These include daily changes in barometric pressure, characteristics of the magnetic field, and, in many locations, precipitation. Pressure variations derive from the thermal energy arising from the heating of the upper atmosphere that moves in a westward wave at the speed of the Earth's rotation (Hardy et al., 1998). These variations depend upon latitude, altitude, and season. Aspects of the Earth's magnetic field also vary in intensity and inclination depending on the time of day, as the solar wind emanating from the sun interacts with the magnetosphere on a regular 24 h cycle.

42.1.4 Rhythms in the biotic environment

Since daily cycles in many aspects of the physical, abiotic environment are so pervasive, it should not be surprising that nearly all free-living organisms have evolved adaptations to the changing environment. Thus, in addition to daily changes in abiotic factors, birds' biotic environment is also changing on a daily basis. The presence of food, competitors, predators, parasites, and potential mates may be present at one time of day and absent in another (Bradshaw and Holzapfel, 2010). Hence, birds, like nearly all organisms on Earth, have evolved an internal biological clock that synchronizes patterns of many aspects of behavior, physiology, biochemistry, and molecular biology to external time (Pittendrigh, 1993) and coordinate internal processes to temporally maximize efficient processes within (Navarra and Nelson, 2007).

42.2 Circadian rhythms

42.2.1 Formal properties

The internal biological clock shares fundamental formal properties among most living organisms through the expression of endogenously generated circadian (*circa* = *approximately*; *dian* = *a day*) oscillations that entrain to local time through the process of *entrainment.* Rhythmic processes cannot be identified as *circadian* unless they are experimentally observed to persist when the organism in question is placed in constant environmental conditions of either constant darkness (DD) or constant dim light (dimLL) (Constant high light, LL, may have other effects, frequently abolishing circadian rhythms altogether and/or damaging photoreceptive elements in the system; Aschoff, 1979).

To study circadian rhythms in behavior or physiology, birds are isolated in light-tight, temperature-controlled chambers in which light: dark cycles (LD) can be programmed to period, T, of an LD cycle. It is important to acclimate the birds to the chambers by maintaining them in LD for several days before commencing with research. Food and water must also be available within the cage, since the repeated disturbance of feeding and changing water can affect the data. Behavior is continuously monitored using a remote sensing device, such as microswitches mounted on perches, infrared beams, telemeters, or other sensors, so that the birds are not disturbed by visual inspection. Under these constant conditions, birds will repeatedly express patterns of behavior, physiology, or biochemical processes with an endogenous period, τ, of close to but rarely exactly 24 h (Figure 42.1). These endogenously driven rhythms must then be *entrained* to the relevant environmental cycle, typically the LD cycle of day and night, such that the internal phase, ϕ_i, of the organism's clock corresponds appropriately to the external phase, ϕ_e, of the LD cycle. Thus, a diurnal bird's locomotor activity pattern entrains to the LD cycle so that activity onset ϕ_i corresponds approximately to dawn ϕ_e, maintaining a stable phase relationship, ψ_{ie}. Conversely, a nocturnal bird's ψ_{ie} would be approximately 12 h later than that of a diurnal bird.

42.2.2 Stability and lability of circadian rhythms

In DD, the circadian τ of diurnal birds is generally longer than 24 h, while τ in owls and nightjars tends to be shorter than 24 h (Aschoff, 1979). However, there is quite a bit of

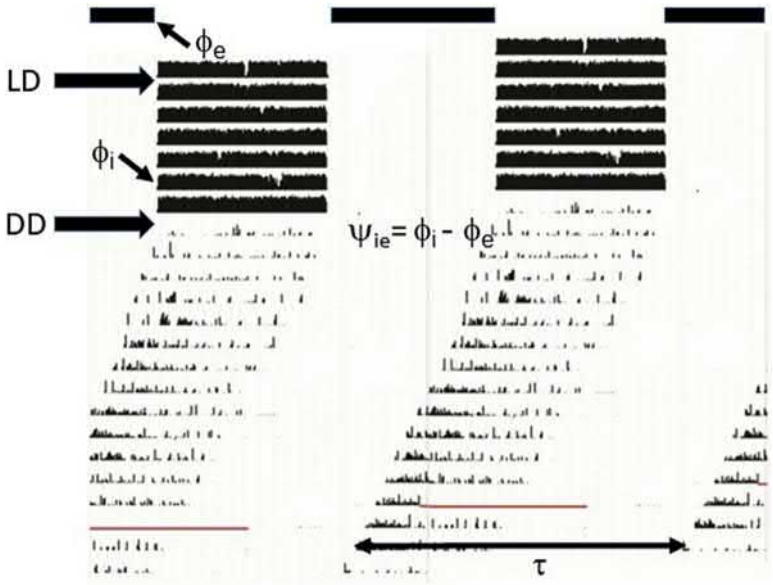

FIGURE 42.1 Actogram of locomotor activity from a single zebra finch, *Taeniopygia guttata.* The top bars indicate the times during which lights are off (black) versus on (white). These are plotted in a 48-h timespan in order to "double-plot" the data. The time of lights on, ϕ_e, indicated by the arrow, is a phase reference determined by the investigator. The internal phase, ϕ_i, is determined to be the activity onset. The relationship between ϕ_i and ϕ_e is called ψ_{ie}. This relationship may change depending on the time of year and physiological condition of the bird. The internal period, τ, is indicated here as the average interval between activity onsets.

inter- and intraspecific variability in τ and even consistent changes within an individual. For example, many house sparrows, *Passer domesticus*, will express a τ of less than 24 h upon transfer from an LD cycle to DD (see Figure 42.1). However, birds' τ gradually lengthens over several days to weeks, depending on the individual, eventually stabilizing with a τ of approximately 25 h. This is a phenomenon known as "Eskin's knee" as the actogram, described by Dr. Arnold Eskin in late 1970s (cf Menaker et al., 1978), appears bent as a knee. Once stabilized, the τ remains stable until environmental factors change.

The major environmental factor affecting τ in birds is ambient light. If diurnal birds are experimentally maintained in dim LL rather than DD, birds' τ will shorten, and as illuminance is increased, τ decreases until at constant illuminances of approximately 50−100 lx circadian patterns of locomotor activity are lost (Aschoff 1979); birds are arrhythmic. Nocturnal birds such as owls and nightjars are more highly variable than are diurnal birds. On average, however, their τs lengthen (increase) with increasing illuminance. Other environmental factors have not been studied in as much detail as has light, although birds' circadian patterns appear to be relatively insensitive to altered constant temperatures, as circadian patterns in all organisms tend to be temperature compensated with a Q_{10} of 0.8−1.1 (Pittendrigh, 1993).

42.2.3 Entrainment

A biological clock with a τ that is different from 24 h would not be a particularly useful clock if it could not confer a sense of internal time relative to external, sidereal time, or the time it takes the Earth to rotate relative to the vernal equinox, the solar day. Thus, organisms sense environmental cues called Zeitgebers (German for "time givers"), interpret them, and then adjust their internal time to external time through the process of *entrainment.* The formal properties of entrainment vary, depending on the Zeitgeber and on the process being measured.

Photic entrainment: The major Zeitgeber for nearly all organisms is the daily change in light intensity, and light affects circadian rhythms in birds profoundly. *Photic entrainment* in birds comes in two flavors: (1) *Nonparametric entrainment* entails the process by which the internal clock is differentially sensitive to the Zeitgeber depending on the time of day rather than the amount (the *parameter*) of the Zeitgeber present (Aschoff and Pohl, 1978). This process is similar to other organisms in that their circadian system is relatively insensitive to light during the subjective day. If a house sparrow is free-running in DD and she is illuminated for 15−30 min during her subjectively diurnal activity (subjective day), no or little effect on her ϕ_i will occur. However, if she is illuminated in the beginning of her *subjective night*, when she is inactive, light will change her ϕ_I ($\Delta\phi$) by delaying her activity onset ($-\Delta\phi$). If she is illuminated during the late subjective night, her subsequent activity onset will be advanced ($+\Delta\phi$). Through this process, birds' ϕ_I is maintained in a ψ_{ie} with external time (ϕ_e). This relationship between the timing of the light pulse and the amplitude and direction of the $\Delta\phi$ is referred to as the *phase response curve* (PRC), whose amplitude varies among species. (2) In diurnal birds, however, since they are active during times of great illumination, *parametric entrainment* can also contribute to the maintenance of an advantageous ψ_{ie}. Since diurnal birds tend to express a τ greater than 24 h and illumination shortens τ, illumination of increasing intensity (a *parameter*) during the day under natural conditions decreases the amplitude of $\Delta\phi$ required to maintain a stable ψ_{ie}. This is an underappreciated process that may even be relevant to human circadian organization (Roenneberg et al., 2010).

Circadian rhythms of many organisms can be entrained to LD cycles whose periods (T) do not necessarily equal 24 h within limits (Pittendrigh, 1993; Daan, 2000), including birds (Aschoff and Pohl, 1978; Zivkovic et al., 1999). T-cycles ranging in period from 22 (11 h light; 11 h dark) to 28 (14 h light; 14 h dark) can typically entrain circadian patterns of activity and other physiological functions. However, as the period of the T-cycle further strays from 24 h, the circadian system becomes less able to entrain to the T-cycle. This is largely due to the species-specific amplitude of the PRC. The T-cycles to which organisms are no longer capable of entraining are their *limits of entrainment* (Aschoff and Pohl, 1978).

It is interesting to note that birds may be unique among extant vertebrates in that they must necessarily deposit a large portion of calcium carbonate on the exterior of their eggs in order to produce the hard shell required for efficient incubation (Chapter 28). During the process of ovulation and oviposition, eggs must reside within the shell gland for a finite amount of time in order to produce a shell hard enough to withstand the pressures of incubation. In chickens, *Gallus domestica*, this period is approximately 26 h, even if the bird is entrained to a 24-h T-cycle (Fraps, 1955; Morris, 1973). Thus, as hens lay eggs in a 24-h T-cycle, the timing of oviposition drifts later and later during the day until the dark phase, at which point hens typically do not lay. This results in a 10−15 h delay in egg production (Morris, 1973). In Japanese quail, *Coturnix japonica*, the mechanism for this rhythm is only partially dependent on the circadian system itself (Underwood et al., 1997; Zivkovic et al., 1999), since removal of the eyes, which are critical for circadian rhythms in quail (see below), does not affect the oviposition rhythm (Zivkovic et al., 1999; 2000). Rather, it is more likely the result of a relaxation oscillator in the shell gland itself.

Knowledge of this oviposition cycle has been known for some time, even before the tenets of circadian organization were formulated (Byerly and Moore, 1941).

Nonphotic entrainment: Several nonphotic factors entrain birds' circadian clocks. Homoeothermic animals such as the vast majority of birds do not synchronize to daily patterns of ambient temperature, although tissue cultures from avian tissues entrain to cycles of high and low temperature (Barrett and Takahashi, 1995; Csernus et al., 2005). Further, ambient temperature can affect the rate by which birds entrain to novel light cycles (Rensing and Ruoff, 2002).

The presentation of food at a particular time of day can synchronize locomotor rhythms in many species of birds, and the data have suggested that birds, as in mammals, possess both light-entrainable oscillators and experimentally separable food-entrainable oscillators underlying food-seeking behavior. House sparrows maintained in dimLL entrain both locomotor and feeding patterns to the period of the feeding cycle, such that locomotor behavior occurs prior to the time of day at which food is presented (Hau and Gwinner, 1992). In domestic pigeons, *Columba livia,* presentation of food every 23.5 h to birds on a 24 h LD cycle results in an uncoupling of food-associated anticipatory changes in body temperature (Tb) and O_2 consumption with activity associated with LD (Rashotte and Stephan, 1996). Similarly, Svalbard ptarmigan, *Lagopus mutus hyperboreus*, and Indian weaver birds', *Ploceus philipinus*, food entrainment is coupled to birds' entrainment to the light cycle, suggesting in both species the food-entrainable oscillator is coupled to the light-entrainable pacemaker (Reierth and Stokkan, 1998; Rani et al., 2009).

Although birds are well known for their capacity to synchronize vocalization and other social cues (Benichov et al., 2016), there is a very little evidence for social cues influencing circadian patterns in birds. Daily presentation of taped sounds recorded from an aviary entrains circadian locomotor rhythms of house sparrows maintained in dimLL (Menaker and Eskin, 1966). These data suggest that birdsong and/or calls may influence the circadian clock. This may be a fruitful area for future research.

42.2.4 Masking

Photic masking: While light cycles are the major Zeitgeber involved in entraining avian circadian rhythms, light per se may not always affect the endogenous clock. Under some circumstances, exposure to light may alter the behavioral output of the clock as opposed to the clock itself. This is referred to as *masking* (Aschoff and von Goetz, 1989). As an example, Aschoff and von Goetz (1989) maintained canaries (*Serinus canaria*) in LD cycles of low intensity light. They then subjected birds to 1 h dim light pulses during the D phase and dark pulses during the dim light phase. Birds increased activity during the light pulses (positive masking), and decreased their activity during the dark pulses (negative masking). However, no long-term effect on circadian ϕ of these interventions could be discerned. The pulses did not affect the clock itself, just its output.

Artificial Light at Night: The difference between entrainment and masking may seem arcane, but the growing interest in the impacts of urban lighting and/or light pollution on avian behavior and health may require understanding of these differences. It is widely understood that artificial light is a worldwide human-caused alteration of our environment (Falchi et al., 2016), and that radiance and extent of artificial light at night (ALAN) continues to increase (Kyba et al., 2017). Since light has profound effects on avian circadian systems, many researchers have asked whether ALAN affects daily and circadian patterns of behavior. Using radio-telemetric analyses, Dominoni et al. (2013a) found that urban European blackbirds (*Turdus merula*) were more active earlier during the day than forest dwelling blackbirds. They also showed that urban blackbirds expressed lower levels of the pineal hormone melatonin (see below) than did rural birds (Dominoni et al., 2013b). Similarly, Amichai and Kronfeld-Schor (2019) found that common swifts (*Apus apus*) outfitted with acoustic loggers exhibited increased nocturnal activity under the bright lights of Jerusalem's western wall. However, it is important to point out that, although the authors indicated the data pointed to an effect on the circadian clock, laboratory analyses would be required to establish this notion.

Laboratory studies of ALAN on birds generally corroborate the idea that ALAN affects the daily distribution of behavior and can have profound effects on avian health. Zebra finches (*Taeniopygia guttata*) exposed to dim light during the night exhibit increased nocturnal locomotor behavior (Batra et al., 2019; Moaraf et al., 2020). Similarly, great tits (*Parus major*) exposed to different wavelengths of light during the night were more active during the night, with white light being more efficacious than was red or green light (Ouyang et al., 2018). There is some indication that ALAN has other deleterious effects on these birds, since great tits and house sparrows (*P. domesticus*) exposed to ALAN are also more susceptible to malaria and West Nile virus, respectively (Ouyang et al., 2018; Kernbach et al. 2018, 2020). However, it is not clear if the effects of ALAN on daily distribution of activity and disease states are causally related or just correlative.

Having said this, it's also important to point out that the effects of ALAN may not necessarily reflect an effect on the circadian clock. For example, Spoelstra et al. (2018) exposed great tits to ALAN, which advanced the ϕ of locomotor activity as in previous studies. However, to determine whether the ALAN also advanced the ϕ_i, the

authors transferred the birds into DD and revealed that the ϕ_i was not affected by the ALAN (Figure 42.2). Their activity onsets were fixed to the onset of the light cycle and not the activity onset in ALAN. Thus, these birds, at least, exhibited masking in ALAN. Of course, this does not diminish the importance and impact of ALAN on avian physiology (Schoech et al., 2013).

42.3 Photoreceptors

Since light is the major Zeitgeber involved in circadian entrainment to LD, masking, and an environmental factor that strongly influences τ under constant environmental conditions, the pathways by which light influences clocks and their outputs provide profound clues to the mechanisms underlying biological clocks. Intuitively, we might think that these photoreceptive processes are the exclusive domain of retinal photoreceptors, but this would be the furthest from the truth. While the retinae participate in photic entrainment and/or parametric responses to light, they are minor participants.

42.3.1 Encephalic photoreceptors

In addition to photoreceptors in the lateral eyes shared by all vertebrate classes, it has been known for some time that nonmammalian vertebrates express functional photopigments within the brain that are critical for entrainment of both circadian rhythms and circannual cycles (Okano and Fukada 2000). Early studies by Benoit in the 1930s showed that domestic ducks, *Anas platyrhynchos*, which had been blinded (enucleated) continued to exhibit reproductive responses to changing photoperiod (cf. Benoit and Assenmacher 1954). Work by Menaker and colleagues in the 1960s and 70s in passerine birds clearly showed that the eyes are not necessary for circadian entrainment (Menaker, 1968; Menaker and Underwood, 1976). In a classic series of experiments, Menaker's group demonstrated that enucleated house sparrows could entrain to a series of LD cycles of dimmer and dimmer illuminances, showing definitively that the eyes were not necessary for circadian entrainment. Under very dim LD cycles, birds no longer entrained and free-ran with a circadian period. They showed that the photoreceptors responsible for entrainment reside within the head by simply plucking feathers on the scalp, increasing the amount of light able to penetrate the cranium, and entrainment was reinstated. They then blocked entrainment by injecting India ink beneath the scalp (Menaker and Underwood, 1976).

Subsequent research has now identified at least four distinct structures within the brain that are functionally photoreceptive, containing several opsin-based photopigments and photoisomerases (Nakane and Yoshimura, 2010; Peirson et al., 2009; Bailey and Cassone, 2004) (Figure 42.3). These include the pineal gland, which expresses a pineal-specific opsin, pinopsin (Bailey et al., 2003;

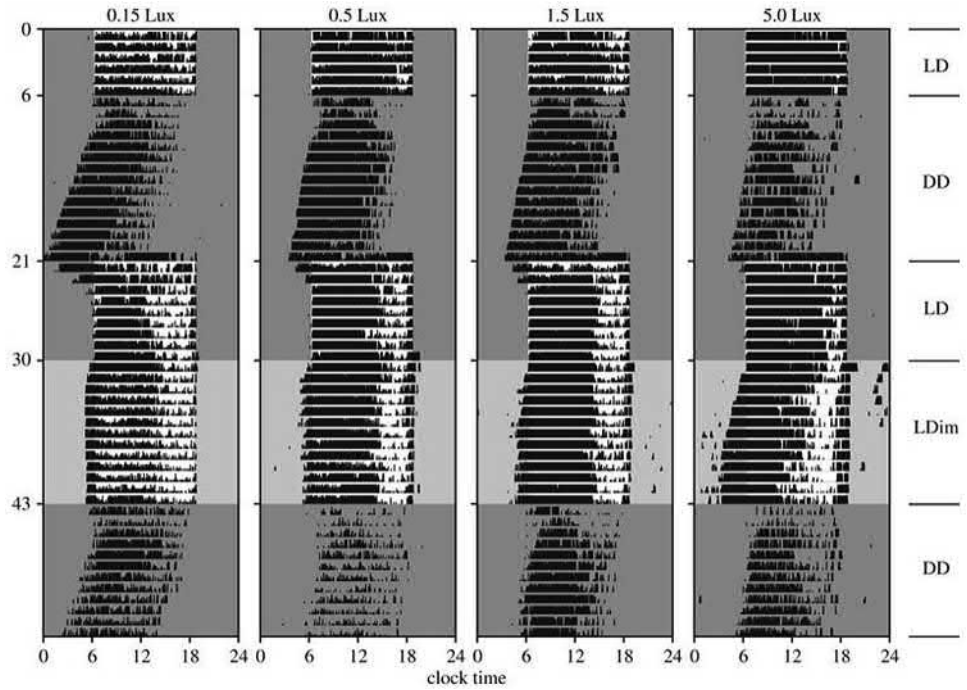

FIGURE 42.2 Example actograms of four great tits that were exposed to ALAN of different intensities from days 31–43 of these records. Note that activity onset was advanced during the ALAN, but, when birds were placed in constant darkness (DD), onsets reverted to the time of lights on (ϕ_e) demonstrated that ALAN did not entrain birds' clocks. This is an example of masking. *From Spoelstra et al. (2018).*

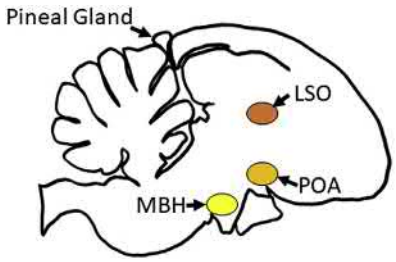

FIGURE 42.3 Schematic representation of a sagittal view of an avian brain. The general locations of extraocular photoreceptors are delineated in the pineal gland, the lateral septal organ (LSO), preoptic area (POA), and mediobasal hypothalamus (MBH).

Okano et al., 1994; Max et al., 1995), as well as melanopsin (OPN4) (Bailey and Cassone, 2005; Bailey et al., 2003; Chaurasia et al., 2005) and iodopsin (OPN1) (Masuda et al., 1994; Natesan et al., 2002) and whose photoreceptive function will be discussed further below. In addition, neurons within the preoptic area express VA (vertebrate ancient) opsin (Halford et al., 2009; Davies et al., 2010, 2012), and project to the tuberal hypothalamus, while the tuberal hypothalamus itself expresses a plethora of photoreceptive cells that appear to be divergent among avian species. In Japanese quail, *C. japonica*, CSF-contacting neurons in the mediobasal hypothalamus express both OPN4 and neuropsin (OPN5) (Nakane et al., 2010). In house sparrows, neurons within the arcuate nucleus express rhodopsin (OPN2) itself, in addition to OPN4 and OPN5 (Wang and Wingfield, 2011). Finally, the lateral septal organ expresses rhodopsin-like immunoreactivity (Wada et al., 1998). It is not clear whether each of these photoreceptive organs and/or their photopigments subserves mutually exclusive physiological processes or whether these overlap in their functions.

In addition to opsin-based photopigments, birds express flavin-based cryptochromes (Bailey et al., 2005; Chaurasia et al., 2005; Kubo et al., 2006). While cryptochrome is the major photopigment responsible for photoentrainment in *Drosophila* (Emery et al., 1998), the multiple cryptochromes expressed by vertebrates have not been established as photoresponsive molecules. Interestingly, cryptochromes have been implicated in the remarkable capacity of birds to detect and navigate by changes in the Earth's magnetic field (Wiltscko and Wilschko, 2019), and this capacity is dependent on photic conditions, such that exposure to short wavelengths of light (373−424 nm) sensitizes cryptochromes residing in cone photoreceptors to changes in magnetic inclination (Günther et al., 2018; Nießner et al., 2018). Bioinformatic (Bailey et al., 2005), chemical, and structural (Zoltowski et al., 2019) analyses of avian cryptochromes also point to a photoreceptive capacity for these proteins. However, they have as yet not been directly linked to entrainment of circadian clocks.

42.3.2 Pineal gland

The avian pineal gland emerges from the epithalamus of the diencephalon and extends to the dorsal surface of the brain, where it resides nestled between the two cerebral hemispheres and the cerebellum (Figure 42.3). There, the gland's narrow stalk extends to the skull itself, enlarges in its distal aspects, and attaches to the dura mater. There is considerable variability in pineal structure among birds (Quay, 1965; Menaker and Oksche, 1974). For example, nocturnal owls, shearwaters, and petrels exhibit only a vestigial or rudimentary pineal complex (Quay, 1965), while diurnal birds express well-developed pineal glands of differing overt anatomy. According to Menaker and Oksche (1974), avian pineal glands can be categorized as (1) saccular (passerine birds), (2) tubulofollicular (columbiform and anseriform birds), and (3) lobular (galliform birds). At the cellular level, pineal glands comprise at least four classes of cell types. The photoreceptor-like pinealocytes express outer segments reminiscent of retinal photoreceptors of a sensory ciliated type with a characteristic 7:0 microtubule configuration, although these are reduced in size and frequently coiled (Oksche et al., 1972; Menaker and Oksche 1974). These cells, as stated above, express several opsin-based photopigments, flavin-based cryptochromes, and phototransduction signaling molecules (Masuda et al., 1994; Bailey et al., 2003; Bailey and Cassone, 2004), clearly indicating that pinealocytes are directly photosensitive. This will be discussed further below. In addition, pineal glands contain "interstitial cells" that include ependymal and astrocytic neuroglia as well as leukocytes and leukoblasts (Oksche et al., 1972), and, in some species, neurons that project to the epithalamic habenular complex (Sato and Ebisawa, 1988). Finally, the pineal gland is vascularized and contains endothelial capillary cells (Oksche et al., 1972).

42.3.3 Retina

It is axiomatic that the retinae are photoreceptive, but their role as photoreceptors in avian circadian entrainment is less clear. In mammals, which do not possess extraocular photoreceptors (cf. Doyle and Menaker, 2007), circadian entrainment is predominantly mediated by intrinsically photoreceptive retinal ganglion cells, expressing melanopsin (OPN4; cf. Panda, 2007). These cells project directly to circadian pacemakers in the hypothalamic suprachiasmatic nuclei (SCN). In birds, as stated above, the eyes are not necessary for circadian entrainment to LD cycles, since enucleated house sparrows and several other species entrain to LD cycles. However, that is not to say that the eyes are not involved. Multiple layers of the retinae of domestic chicks, *Gallus gallus domesticus*,

express OPN4, including retinal ganglion cells (Bailey and Cassone, 2005; Chaurasia et al., 2005), similar to the situation in mammals.

Employing a retinal degenerate chick model developed by Semple-Rowland (Semple-Rowland and Cheng, 1999; Guido et al., 2010), Guido and colleagues have shown that the chicks possessing only inner retinal photoreceptors are capable of entraining feeding rhythms to an LD cycle (Valdez et al. 2009, 2013). When encephalic photoreceptors are covered with a blackened hood, the chicks expressed a free-running rhythm with a 24.5 h τ. When the birds were enucleated, hooded birds free-ran, but illumination of the skull reestablished entrainment. The picture that emerges is that multiple photoreceptors in the brain, the pineal gland, and the retina redundantly contribute to photic entrainment in birds (Doyle and Menaker, 2007; Guido et al., 2010; Rios et al., 2019).

42.4 Pacemakers

As we will see below, the capacity to express circadian rhythms is widely distributed among tissues and cells in multicellular organisms (Bell-Pedersen et al., 2005). However, certain tissues have been designated "pacemakers" because of their capacity for sustained circadian rhythmicity and their importance for *circadian organization.* In birds, these structures are the pineal gland, the retinae, and the hypothalamic SCN, whose mutual interactions are critical for overt circadian organization.

42.4.1 Pineal gland and melatonin

Searching for the location of the intracranial, extraretinal photoreceptors, Gaston and Menaker (1968) surgically removed the pineal gland (PINX) from house sparrows (Figure 42.4). While the birds retained their ability to entrain to LD, they became arrhythmic when placed in DD, demonstrating that the pineal gland is necessary for self-sustained circadian rhythmicity. However, the data also showed that the pineal gland is part of a system of circadian clock components, since PINX sparrows could anticipate the time of lights on in an LD cycle and because birds only gradually became arrhythmic over 5−15 days following transfer from LD to DD (Gaston and Menaker, 1968; Binkley et al., 1971; Ebihara and Kawamura, 1981; Janik et al., 1992; Lu and Cassone, 1993a; Wang et al., 2012). Further, the effect of PINX is not universal among avian species. PINX of European starlings, *Sturnus vulgaris,* results in a range of behavioral changes ranging from arrhythmicity akin to those seen in house sparrows to slight disruption of behavioral locomotor rhythmicity (Gwinner, 1978; Gwinner et al., 1987). Circadian rhythms of locomotor behavior in columbiform and galliform birds are little or not affected at all by PINX (Ebihara et al., 1984; Underwood and Siopes, 1984).

Even so, the pineal gland represents both the capacity for rhythmicity and time of day. In an elegant experiment, Zimmerman and Menaker (1979) transplanted pineal glands from two groups of house sparrows into the anterior chambers of the eye of PINX, arrhythmic sparrows

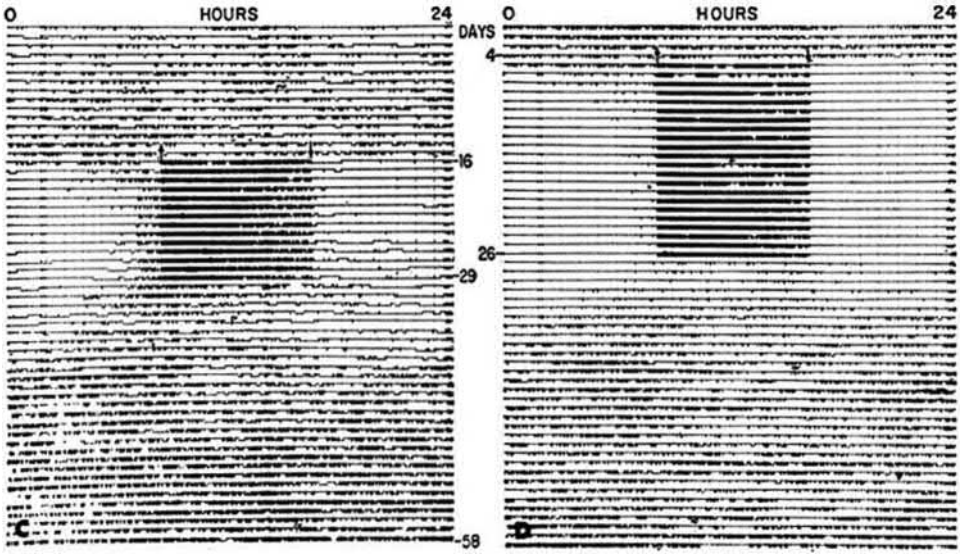

FIGURE 42.4 Effects of pinealectomy on locomotor activity rhythms in house sparrows. Birds are arrhythmic in constant darkness (DD) but are able to entrain to light:dark (LD) cycles (*small arrows up and down*, respectively). When birds are released into DD again, they take 5−15 days to become arrhythmic again. *From Gaston and Menaker (1968).*

maintained in DD. The first group of donor birds were entrained to an early LD cycle, with lights on at midnight, while the second set of donors were entrained to a late LD cycle, with lights on at 11 a.m. Transplantation restored circadian rhythms to both groups of recipients within 1 day. Moreover, birds that received pineal glands from early donors exhibited an early ϕ_i, while the recipients of late donor pineal glands exhibited a late ϕ_i. Thus, the pineal gland is not only necessary for circadian rhythmicity in these birds, but it contains a correlate that confers time of day to recipient birds.

That hormone was known even then to be the indoleamine melatonin from earlier work of Lerner and later of Axelrod, Klein, and their coworkers (cf. Klein et al., 1997), who explored the biochemical basis for melatonin biosynthesis in the pineal gland of the chick, *G. gallus domesticus* (Figure 42.5). Research from a large number of investigators has shown that pinealocytes, the photoreceptive, secretory cells of the avian pineal gland, take up the amino acid tryptophan, which is converted to 5-hydroxytryptophan by tryptophan hydroxylase (TrH; EC 1.14.16.4; Chong et al., 1998) and then decarboxylated to produce serotonin (5HT) by aromatic L-amino acid decarboxylase (AAADC; EC 4.1.1.28). During the night in LD and subjective night in DD, 5HT is converted to N-acetylserotonin (NAS) by arylalkylamine (or 5HT)-N-acetyltransferase (AANAT; EC 2.3.1.87; Bernard et al., 1997). NAS is then converted to melatonin by hydroxyindole-O-methyltransferase (HIOMT; EC 2.1.1.4; Bernard et al., 1991), alternatively named acetylserotonin methyltransferase. The genes encoding each of these enzymes have been isolated, cloned, and sequenced in several avian species. In chick, at least, TrH, AANAT, and HIOMT are regulated by both the molecular clockworks within the pinealocytes and directly by light at the transcriptional, translational, and posttranslational levels, so that the enzymatic regulation of pineal melatonin is a dynamic, rhythmic process (Klein et al., 1997).

Rhythmic administration of melatonin to PINX house sparrows, European starlings, and zebra finches, *T. guttata*, or to EX/PINX pigeons (Chabot and Menaker, 1992, Lu and Cassone, 1993b; Gwinner et al., 1997; Heigl and Gwinner 1995; Cassone et al. 1992, 2008; Wang et al., 2012) restores a daily pattern of locomotor behavior (Figure 42.6). Activity typically decreases following melatonin administration, and rebounds following the daily

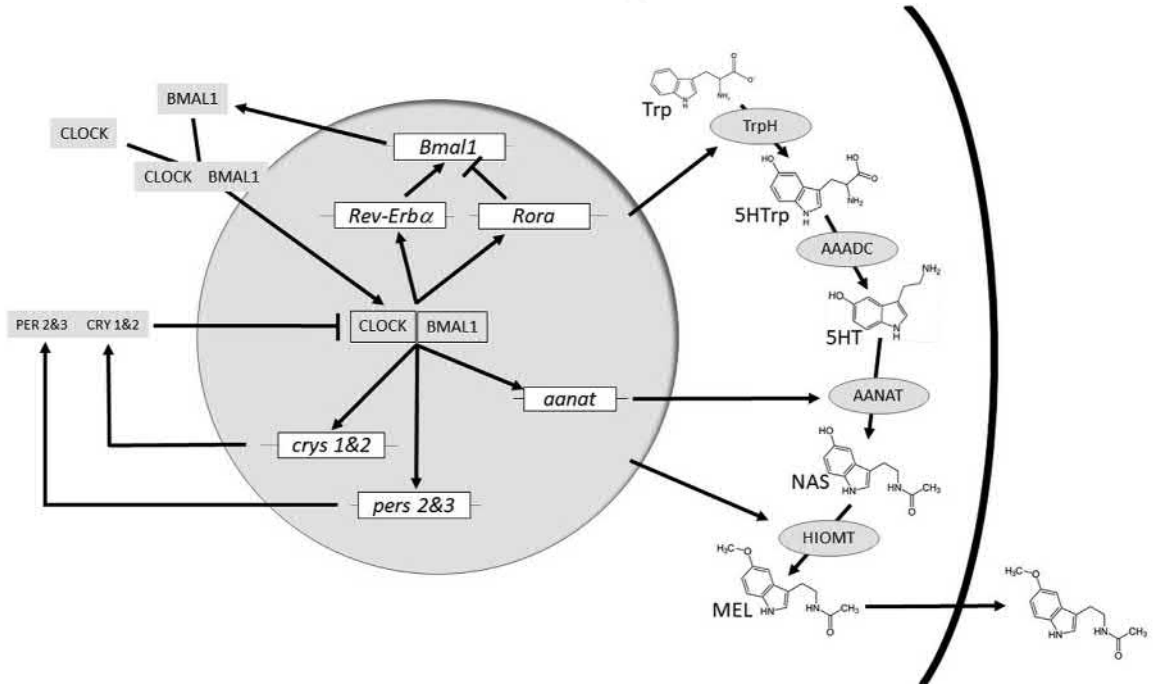

FIGURE 42.5 Schematic representation of the molecular clockworks regulating circadian patterns of melatonin biosynthesis in a pinealocytes or retinal photoreceptor. Positive elements CLOCK and BMAL1 enter the nucleus and activate expression of genes whose promoters contain an E-Box. Among these are the negative elements *period 2 and 3 (pers 2 and 3)* and *cryptochromes 1 and 2 (crys 1 and 2)*, *Rev-Erbα* and *Rora*, which form a secondary loop regulating *Bmal1* transcription, and output, clock-controlled genes such as arylalkylamine-N-actyltransferase (*aanat*). The *pers* and *crys* are translated, form heterodimers with other components, such as the casein kinases, and reenter the nucleus to interfere with CLOCK/BMAL1 activation. Melatonin biosynthesis pathways are indicated on the right. Amino acid tryptophan is converted to 5-hydroxytryptophan (Trp) by tryptophan hydroxylase (TrpH). AAADC then converts 5-hydroxytryptophan (5HTrp) to 5-hydroxytryptamine (5HT; serotonin). Then, during the night, AANAT converts 5HT to N-acetylserotonin (NAS), a substrate for hydroxyindole-O-methyltransferase (HIOMT), which produces melatonin (MEL) itself. Presumably, melatonin diffuses out of the cell at this time, although a release mechanism may exist.

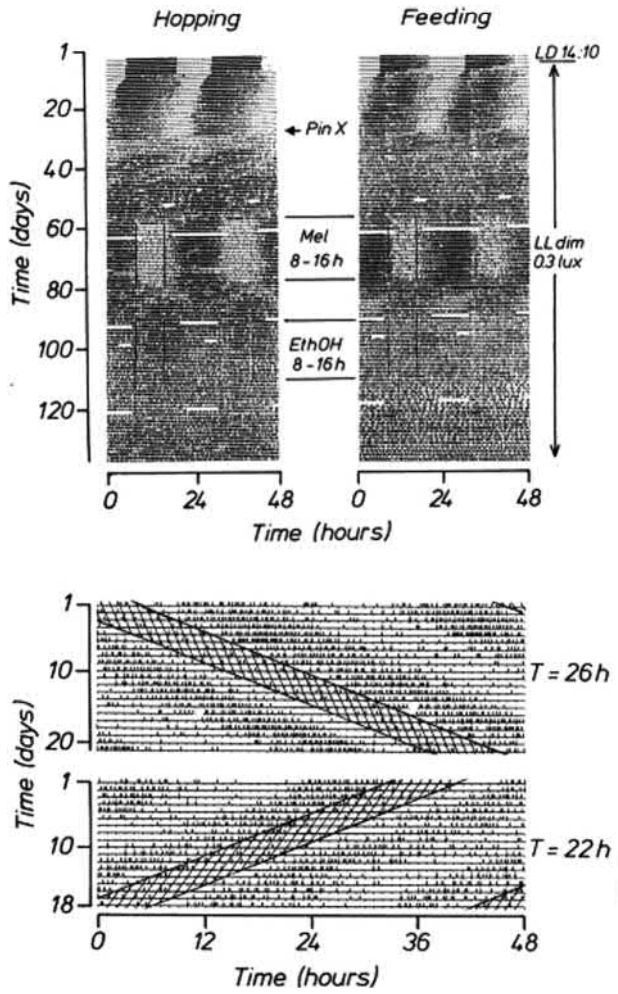

FIGURE 42.6 Effects of rhythmic administration of melatonin to house sparrows. Top. Actograms of perch-hopping and feeding behavior of house sparrows maintained in DD. Birds become arrhythmic in both behaviors following pinealectomy (PINX) and daily rhythms of behavior are reestablished with melatonin administration. Bottom. This synchronization is entrainment rather masking, because locomotor activity maintains a systematic phase relationship with the administration of the hormone. When melatonin is presented every 26 h, activity occurs after the administration, while a melatonin cycle every 22 h results in behavior that anticipates the melatonin. *From Gwinner et al. (1997).*

dosage, suggesting that melatonin induces a soporific state and/or sleep, which it may well do. In addition, however, the synchronization of locomotor behavior by rhythmic melatonin administration represents entrainment of circadian clockworks in the PINX bird, since melatonin administration in a T-cycle different from 24 h results in systematic changes in the phase relationship (ψ) of melatonin to the onset of locomotor activity (Figure 42.6; Chabot and Menaker, 1992; Gwinner et al., 1997). Further, administration of three different behaviors, locomotor behavior, call, and song, by a single melatonin regime results in entrainment at differential rates (Wang et al., 2012).

Further, constant administration of melatonin has profound effects on overt rhythmicity (Gwinner and Brandstatter, 2001). Subcutaneous implants of beeswax (Turek et al., 1976) or Silastic (Hau and Gwinner, 1995; Abraham et al., 2000) containing crystalline melatonin change τ at low concentrations and abolishe rhythmicity altogether at higher dosages. Interestingly, constant melatonin decreases the times taken to reentrain to food cycles (Hau and Gwinner, 1995) or LD cycles (Abraham et al., 2000). This is similar to the effect of PINX itself (Kumar and Gwinner, 2005), punctuating the view that it is the rhythm of endogenous melatonin that preeminently affects circadian organization and that this effect acts through the entrainment of downstream oscillators (Cassone and Westneat, 2012).

Avian pineal glands contain the circadian clockworks and photoreceptors to generate circadian patterns of melatonin biosynthesis in vitro as well as in vivo, which can be entrained to LD cycles directly (Binkley et al., 1978; Brandstatter et al., 2000; Robertson and Takahashi, 1988b; Natesan et al., 2002). Pineal tissue and pinealocyte cultures express circadian patterns of AANAT activity (Binkley et al., 1977; Deguchi, 1979), gene expression (Karaganis et al., 2008), and melatonin efflux (Figure 42.7; Takahashi et al., 1980; Robertson and Takahashi, 1988a; Li and Cassone, 2015) such that levels are high during the night and low during the day in LD. These rhythms persist for 4–10 days in DD before damping to arrhythmicity (Li and Cassone, 2015). Exposure to light has three effects on cultured pineal rhythms: (1) Light inhibits melatonin biosynthesis. (2) Light increases amplitude and decreases damping, and (3) light phase-shifts the clock within pineal cells (Zatz et al., 1988).

42.4.2 Retinae

Interestingly, the photoreceptors in the retinae of the lateral eyes also synthesize and release melatonin in many vertebrate species (Underwood et al., 1984; Iuvone et al., 1997). In fact, in Japanese quail and domestic pigeon, *C. livia*, the retinae release almost as much melatonin into the systemic circulation as does the pineal gland, and removal of this source by enucleation or retinectomy in addition to PINX results in arrhythmic circadian locomotor behavior, similar to the effects of PINX alone in passerine birds (Ebihara et al. 1984, 1997; Underwood and Siopes, 1984). Thus, the variability of the effects of PINX among birds may in part be due to this retinal component in some species and that it is not the pineal per se but rhythmic melatonin that is important for circadian locomotor behavior.

42.4.3 Suprachiasmatic nuclei

In birds, two sets of structures have been associated with SCN function: the medial suprachiasmatic nuclei (mSCN)

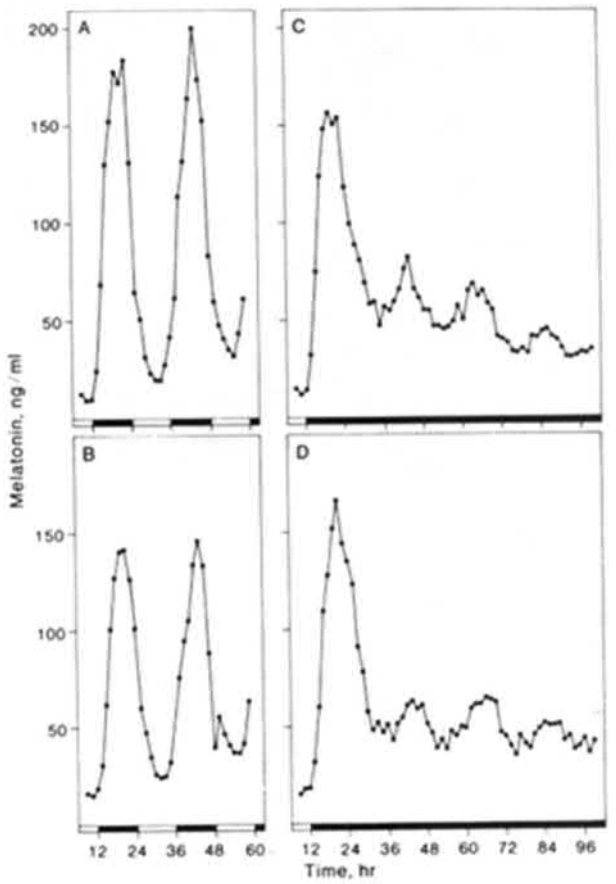

FIGURE 42.7 Melatonin rhythms from cultured chick pineal glands. Melatonin is released during the dark phase in glands maintained in LD in vitro (left). These rhythms continue in DD for several days at a lower amplitude but eventually damp out. *From Takahashi et al. (1980).*

and the visual suprachiasmatic nuclei (vSCN) (Cassone and Moore, 1987; Cantwell and Cassone, 2006a,b). These structures are connected via neuronal projections and are contiguous in terms of their cellular populations, especially in the distribution of astrocytes. The vSCN, but not the mSCN, expresses metabolic rhythmicity and electrical activity such that levels are high during the day and low during the night (Cassone, 1988; Lu and Cassone, 1993a,b; Juss et al., 1994; Cantwell and Cassone, 2002). Further, the vSCN, but not the mSCN, receives retinohypothalamic (RHT) input (Cassone and Moore, 1987; Cassone 1988, Cantwell and Cassone, 2002; 2006a,b), and the vSCN, but not the mSCN, contains melatonin receptor binding (Rivkees et al., 1989; Cassone et al., 1995). Administration of melatonin to chicks and house sparrows decreases glucose utilization within the vSCN (Lu and Cassone 1993b; Cantwell and Cassone, 2002). Finally, light activates *c*-fos expression in the vSCN, but not in the mSCN (King and Follett, 1997). In quail, only the mSCN expresses clock gene rhythmicity (Yoshimura et al., 2001; Yasuo et al., 2002), while in the house sparrow, both structures rhythmically express the expression of the "clock gene" *per2* (Abraham et al. 2002, 2003). Importantly, lesions directed at the mSCN in Java sparrows, *Padda oryzivora*, and house sparrows result in arrhythmicity similar to that observed following PINX (Ebihara and Kawamura, 1981; Takahashi and Menaker 1982). However, it is not clear whether these lesions also affected vSCN integrity.

42.5 Sites of melatonin action

42.5.1 Melatonin receptors

In the 1980s and 90s, high-affinity melatonin receptor binding using the radiolabeled agonist 2[^{125}I]-iodomelatonin (IMEL) revealed high densities of IMEL binding in retinal, retinorecipient structures, and visual integrative structures in the avian brain as well as peripheral tissues (Figure 42.8; Dubocovich and Takahashi, 1987; Rivkees et al., 1989; Cassone et al., 1995). Binding affinity studies indicated kD's in the pM range with high specificity for melatonin itself. Brain structures that bind IMEL included retinorecipient structures in the SCN of the circadian system, the ventrolateral, and dorsal geniculate nuclei of the thalamofugal visual pathway, the optic tectum of the tectofugal pathway, and the nucleus of the basal optic root or the accessory optic pathway. In all species, integrative structures of the tectofugal pathway such as nucleus rotundus and the ectopallium also bind IMEL (Rivkees et al., 1989; Cassone et al., 1995). In some but not all species, hyperpallial structures, including the visual Wulst, are sites of IMEL binding. In male passerine birds but not females, structures associated with bird song learning and control also revealed high affinity IMEL binding (Gahr and Kosar, 1996; Whitfield-Rucker and Cassone, 1996).

Reppert and colleagues were able to isolate and clone genes encoding two high affinity melatonin receptors; these were designated the Mel_{1A} and Mel_{1C} receptors (Reppert et al., 1995). Independent work isolated partial sequences encoding an ortholog of the Mel_{1B} receptor in the same year (Liu et al., 1995). Subsequent work has confirmed in birds that there are at least three melatonin receptors, the Mel_{1A}, Mel_{1B}, and the Mel_{1C} receptors (Reppert, 1997). All three melatonin receptor subtypes represent 7-transmembrane domain, GTP-binding protein structures, and all three are in the G_i GTP-binding protein category, although some cross-talk with G_q has been documented (Reppert, 1997). The distributions of these three receptor subtypes are not uniform in chicks, zebra finches, and house sparrows. The Mel_{1A} receptor predominates in central nervous neurons and peripheral tissues (Natesan and Cassone, 2002; Karaganis et al., 2009), while the Mel_{1B} receptor is expressed in inner retinal neurons and photoreceptors as well as other central nervous neurons (Natesan and Cassone, 2002). In passerines,

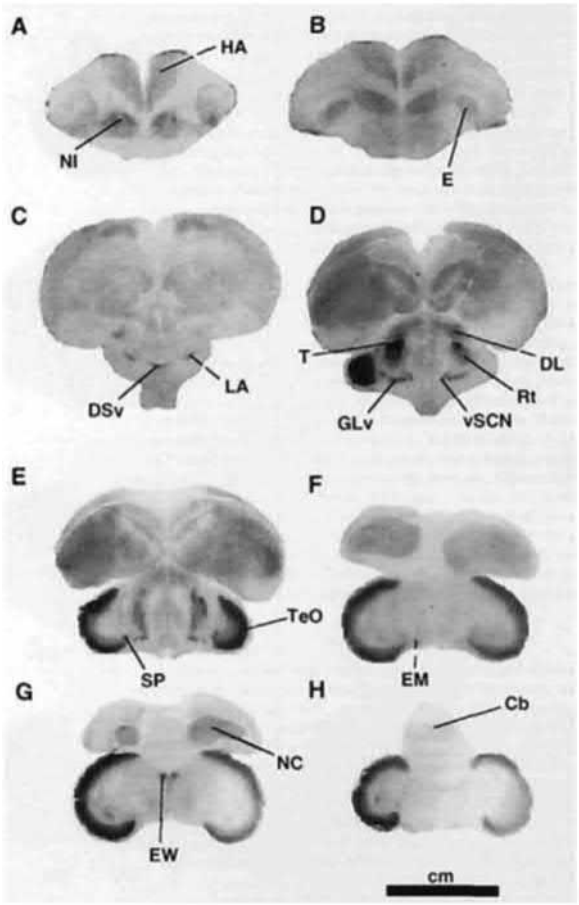

FIGURE 42.8 Melatonin receptor binding in the brain of the ring-necked pheasant, *Phasianus colchicus*. Video-digitized images of autoradiographs depicting 2[^{125}I]iodomelatonin binding (IMEL) at 50 pM from the rostral (A) to caudal (H) extents. Densest binding is present in retinorecipient and integrative structures of the circadian (vSCN), tectofugal (optic tectum (TeO), *nucleus rotundus* (Rt), and ectopallium (E)), thalamofugal (lateral anterior nucleus (LA) and dorsolateral nucleus (DL) in the thalamus and the hyperpallium anterior (HA)), and accessory optic (ectomammillary (EM; also called nucleus of the basal optic root) and nucleus of Edinger–Westphal (EW)) visual pathways. *From Cassone et al. (1995).*

the Mel_{1B} receptor is the major receptor subtype in song control nuclei, but the other two are expressed as well (Jansen et al., 2005; Bentley et al., 2013). The Mel_{1C} receptor, on the other hand, predominates in nonneuronal elements of the central nervous system (Reppert et al., 1995; Adachi et al., 2002). Culture studies with chick astrocytes (Adachi et al., 2002) show 95–100% diencephalic astrocytes express the Mel_{1C} receptor, while an overlapping 5–10% expresses Mel_{1A}. Astrocytes do not appear to express Mel_{1B}.

42.5.2 Mechanisms of action

Melatonin receptors, like all 7-transmembrane domain receptor proteins in the Gi GTP-binding protein group, act via inhibition of adenylyl cyclase activity in cells that express these receptors. There is some evidence for downstream cross-talk with other signaling pathways, however. For example, calcium signaling among chick astrocytes is mediated by a Mel_{1C} melatonin receptor through IP3-depending processes (Peters et al., 2005). In addition, there is evidence that melatonin may act via a receptor-independent and/or by receptor molecules as yet undiscovered. However, these have not been described in birds.

42.6 Avian circadian organization

Overt circadian rhythms in birds are controlled by multiple circadian pacemakers that are entrained by multiple photoreceptive elements in the central nervous system. The relative importance of these pacemakers varies among the few species studied, but in each, the core of the circadian system can be identified as the pineal gland, the retinae, and the SCN (mSCN and vSCN). Early analyses of the interactions of circadian pacemakers and photoreceptors suggested a hierarchical relationship in which the pineal gland imposes and/or entrains rhythmicity and phase on downstream processes or oscillators, respectively. The discovery of SCN and retinal pacemaker activity suggested a more complex relationship (Figure 42.9).

There is little doubt that the pineal gland and melatonin are important for circadian organization, but it is also clear that they are only part of a more complex system of structures and processes we shall call *avian circadian organization* or the *avian circadian system.* Although PINX indeed does abolish circadian locomotor, Tb, brain

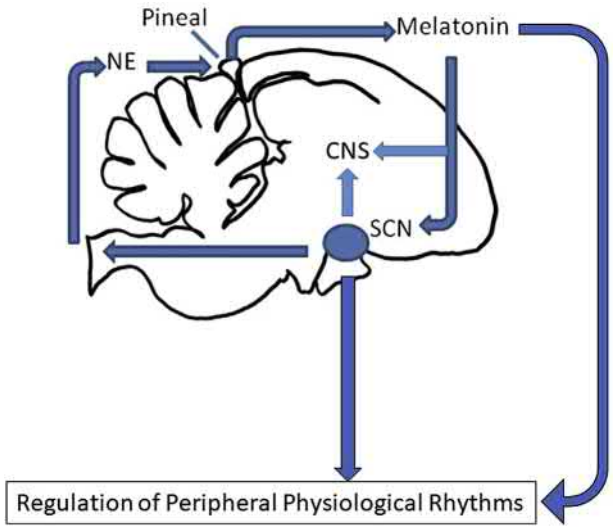

FIGURE 42.9 Neuroendocrine loop model for avian circadian organization. Pacemakers in the pineal gland and SCN interact via mutual inhibition to maintain a stable antiphase relationship. Each pacemaker can affect downstream oscillators and processes independently or in concert in the CNS and periphery. *Modified from Cassone and Westneat (2012).*

metabolism, and singing behavior rhythms in oscine passeriform birds, there is compelling evidence for other pacemakers in the system delineated above. Firstly, PINX birds entrain to LD cycles and typically commence locomotor and singing behavior before dawn (Gaston and Menaker, 1968; Menaker et al., 1978; Wang et al., 2012), indicating some capacity for time-keeping. Secondly, when PINX house sparrows, zebra finches, and other passerine birds (sparrows and finches) are transferred from LD to DD or dimLL, they express 5−10 days of damped activity that gradually descends into arrhythmicity (Figure 42.4), suggesting a remnant pacemaker underlying rhythmic behavior. Thirdly, sturnid passerines, such as starlings, and columbiform birds, such as pigeons, express a variable response to PINX, with some birds becoming arrhythmic, others disrupted, and still others unaffected (Gwinner 1978; Ebihara et al., 1984; Gwinner et al., 1994, 1997). Finally, as stated above, timed melatonin administration differentially entrains different behaviors in zebra finches (Wang et al., 2012; Prabhat et al., 2019).

At least one of the sites of melatonin action in synchronizing circadian locomotor rhythms is the vSCN. The vSCN express melatonin receptors (Rivkees et al., 1989; Reppert et al., 1995), and melatonin affects the vSCN physiologically. When intact house sparrows are placed in DD and injected with 2DG at different times during the subjective day to map metabolic activity, the vSCN expresses a rhythm in 2DG uptake for at least 10 days in DD (Lu and Cassone 1993a). However, when PINX birds are similarly placed in DD, 2DG uptake rhythms in the vSCN decline in amplitude and damp to arrhythmicity at the same rate as does locomotor activity (Lu and Cassone, 1993a). When PINX birds are administered melatonin on a daily basis, locomotor activity and vSCN 2DG uptake rhythms are both reestablished (Lu and Cassone, 1993b). Further, injection of melatonin during the late subjective day acutely decreases vSCN 2DG uptake (Cantwell and Cassone, 2002).

Conversely, while it is certain the avian pineal gland contains patent circadian oscillators and photoreceptors to establish overt circadian rhythms in melatonin secretion in vivo and in vitro (Binkley et al., 1977; Deguchi, 1979; Takahashi et al., 1980; Kumar and Follett, 1993; Csernus et al., 2005; Karaganis et al., 2008), these rhythms are not self-sustained in vitro in DD (Figure 42.7). Cultured pineal glands express rhythms of melatonin biosynthesis and secretion such that melatonin levels are high during the night and low during the day in LD, but the amplitude of this rhythm declines in DD, such that the rhythm damps to arrhythmicity in 2−8 days (cf. Cassone and Menaker, 1984; Csernus et al., 2005; Li and Cassone, 2015).

In vivo, the avian pineal gland is innervated by postganglionic sympathetic nerves (Ueck, 1979) and receives daily and circadian input through release of norepinephrine (NE) during the day and subjective day (Cassone et al., 1986). This rhythm of NE turnover is dependent on the vSCN, since surgical destruction of the vSCN, but not the mSCN, abolishes the circadian NE turnover rhythms (Cassone et al., 1990). When the pineal gland of domestic hens is denervated of its sympathetic innervation in vivo, plasma melatonin rhythms damp within 4 days (Cassone and Menaker 1983), similar to the situation of pineal glands in vitro. Administration of NE to chick pineal glands in vivo and in vitro has two effects on pineal melatonin rhythms: (1) NE inhibits melatonin biosynthesis and (2) NE increases amplitude and decreases damping, but does *not* phase-shift the pineal circadian clock (Cassone and Menaker, 1983; Zatz and Mullen, 1988; Li and Cassone, 2015).

To account for these observations in house sparrows, at least, Cassone and Menaker (1984); Cassone (1990) proposed the "neuroendocrine loop model" for avian circadian organization (Figure 42.9). In this scenario, pineal and SCN pacemakers are damped circadian oscillators. We do not know whether this damping is due to individual cells within these structures themselves damp or whether these cells are self-sustained oscillators that drift out of phase from one another. Light inhibits the output of the pineal gland oscillators through photoreceptors within the gland themselves, and light activates SCN output as well as possessing the capacity to phase-shift the clocks within each. During the night and subjective night in DD, pineal oscillators secrete melatonin and influence a wide array of downstream processes and structures. Among these are the vSCN, which are inhibited by melatonin. However, because the pineal is an endogenous oscillator, its output declines as dawn and subjective dawn in DD approach, disinhibiting SCN (vSCN and mSCN) output. The SCN in turn are active during the day and subjective day in DD, affecting a wide array of downstream processes and structures. Among these are the circadian rhythm in sympathetic outflow in NE turnover in the pineal gland at least, which are high during the day and low during the night. There, NE inhibits the biosynthesis and release of melatonin until, since the SCN are circadian oscillators, their output diminishes, and pineal oscillators are disinhibited. This mutually inhibitory relationship of SCN and pineal oscillators maintains stable phase relationships and enable each pacemaker to affect downstream processes singularly or in concert. Gwinner (1989) suggested that the relationship between pineal and SCN oscillators conveyed an "internal resonance" in which each oscillator increased the amplitude of its partner. This idea is not mutually exclusive from the neuroendocrine loop model. Indeed, it is clear that application of NE to chick pineal glands increases the amplitude of melatonin output in vivo (Cassone and Menaker, 1983) and in vitro (Zatz and Mullen, 1988) even as it inhibits melatonin output. The pineal gland releases rebounding high levels of

melatonin release following cessation of the NE administration. This effect is phase specific, since the effect of NE on in vitro melatonin releases during the subjective night as opposed to the subjective day (Li and Cassone, 2015), suggesting the pineal clock gates its sensitivity to sympathetic input.

Where do the retinae fit into this scheme? For columbiform and galliform species, whose retinae secrete melatonin rhythmically, at least part of their role is to serve as a "second (and third) pineal gland" (Menaker, 1985), secreting melatonin during the night, presumably influencing SCN and other downstream oscillators in parallel with pineal output. In addition, inner retinal photoreceptors and circadian oscillators may directly influence circadian patterns of visual perception and activity through RHT and other visual pathways (Guido et al., 2010.). It is clear however, that the retinae are the predominant pacemakers in galliform birds, but the nature of this function is not apparent at this stage (Steele et al., 2006).

The mechanism by which this system influences downstream processes is not at all clear at this stage. However, new and exciting data pointing to distributed capacities for rhythmicity are becoming available, and these are described below. First, however, we must explore the molecular aspects of avian circadian clocks.

42.7 Molecular biology

The idea that behavior and other complex processes derive from genes and their expression arises from early mutational analyses in search of mutants and the identification of the genes underlying the process. Among the early entrants in this study was the analysis of mutations affecting circadian rhythms in *Drosophila* (Konopka and Benzer, 1971; Rosbash et al., 2007).

42.7.1 Identification, characterization, and localization of molecular clockworks in birds

Circadian rhythms are regulated by a highly conserved set of genes, collectively called "clock genes," whose products are believed to dynamically interact to elicit rhythmic patterns of transcription, translation, biochemical and physiological processes, and behavior (Reppert and Weaver, 2002; Bell-Pedersen et al., 2005; Rosbash et al., 2007). In animals ranging from *Drosophila* to humans, the central core of this gene network can be broadly characterized as "positive elements" *clock* and *bmal1* and "negative elements" *period 1 (per1), period 2 (per2), period 3 (per3)*, and the cryptochromes *cryptochrome 1 (cry1)* and *cryptochrome 2 (cry2)*. In contrast to mammals, birds do not express a *per1* and have been shown to only express only *per2* and *per3* (Figure 42.10; Yoshimura et al., 2000; Yasuo et al., 2002; Bailey et al., 2003, 2004). *Clock* and *bmal1* are transcribed and then translated in the cytoplasm, where they dimerize and reenter the nucleus and activate transcription of the negative elements through the activation of E-box promoter elements (Figure 42.5; Haque et al., 2010). The *pers* and *crys* in turn are transcribed and translated in the cytoplasm, where the PER proteins are targeted for proteosomal proteolysis by a series of protein kinases, most notably casein kinase 1ε (CK1ε) and CK1δ. This process slows the accumulation of the cytoplasmic PER and thereby increases the period of the molecular cycle. In the cytoplasm, PER and CRY proteins form oligomers that reenter the nucleus and interfere with the CLOCK/BMAL1-mediated activation. A secondary cycle involving two genes containing E-box promoters, *Reverbα*, and *rorA*, amplify the cycle by activating and inhibiting *bmal1* transcription, respectively. Disruption or knockout of these genes' action has profound effects on the expression of circadian rhythms in animals in which these technologies are possible (i.e., mice and *Drosophila*) ranging from changes in period to arrhythmicity.

42.7.2 Peripheral oscillators in avian circadian clocks

While clock genes are expressed by cells within pacemaker tissues (Yoshimura et al., 2000; Yasuo et al., 2002; Bailey et al., 2002, 2003, 2004), it was surprising to find rhythmic expression of clock genes in other parts of the brain as well as in peripheral tissues, such as heart, liver, lungs, and gonads (Chong et al., 2003; Helfer et al., 2006; Karaganis et al., 2009; Zeman et al., 2009). To determine whether pacemakers in the pineal and eyes were responsible for peripheral clock gene rhythms, Karaganis et al. (2009) showed that PINX or EX of chicks decreased the amplitudes of clock gene expression and changed the ϕ_i of rhythms in *cry1*, *per3*, and *bmal1* rhythms but did not abolish them. At this stage, it is not clear whether combined PINX and EX would abolish these rhythms, but at this stage, one must conclude the peripheral oscillations persist and are only modulated by the pineal and retinae.

42.7.3 Prospects for transgenesis and molecular manipulation of avian clocks

At this stage, no stably transformed birds are available for circadian biology. However, there are now many reports of development of transgenic reporter and knock-out lines of chickens (cf. Poynter and Lansford, 2008; Nishijima and Iijima, 2013). Clearly, this is the line of future research in this field. Even so, some progress has been made with viral transductions in avian retina models (Semple-Rowland et al., 2010). Further, application of microRNA vectors associated with CLOCK and BMAL1 expression affects AANAT expression in chick retina (Haque et al., 2010).

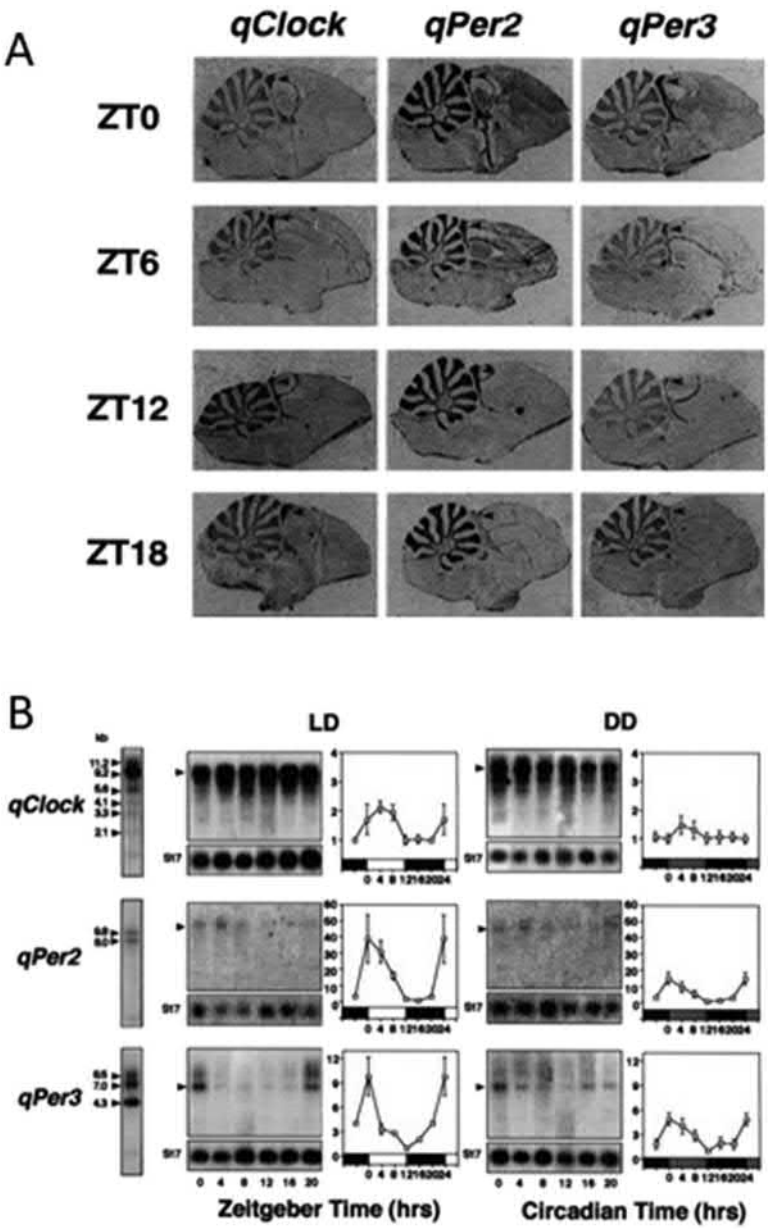

FIGURE 42.10 Circadian expression of clock genes in the (A) pineal gland by in situ hybridization and (B) retinae by northern blot analysis in the Japanese quail. In both tissues, *clock* is expressed during the day, while *per2* and *per3* are expressed in the late night. *From Yoshimura et al. (2000).*

Thus, it is possible to manipulate the avian circadian clock at the molecular level. The proof now will be in the pudding.

42.8 Conclusion and perspective

Biological clocks in birds are critical components of their physiology and behavior (Cassone 1990; Gwinner and Brandstatter, 2001). Early research studying avian circadian organization was critical in the understanding of structure–function relationships in the central nervous system. Indeed, the identification of the pineal gland as a "master pacemaker" conveyed a sense that the system was hierarchically organized. However, as the properties of the pineal gland's function became clearer and the identification of new pacemakers in the hypothalamus and retinae made the system appear more complex, it became clear that the avian circadian clock is a system of multiple circadian pacemakers in the SCN, the pineal gland, and in at least some species the retinae. Each of these was entrained to environmental light cycles by photoreceptors in the retinae, the pineal gland, and the brain. These were in turn thought to interact to accomplish a self-sustained oscillation that drove rhythmic processes downstream. The advent of molecular biological techniques revealed that even this distributed system of pacemakers acts via entrainment of

downstream oscillators rather than via direct action. It remains to be seen how molecular oscillations in the brain and peripheral tissues are coupled to physiological output, but this is the physiology of circadian clocks in the future.

Chapter 43

Circannual cycles and photoperiodism

Vincent M. Cassone[1] and Takashi Yoshimura[2]

[1]Department of Biology, University of Kentucky, Lexington, KY, United States; [2]Laboratory of Animal Integrative Physiology, Graduate School of Bioagricultural Sciences, Institute of Transformative Bio-Molecules, Nagoya University, Nagoya, Aichi Prefecture, Japan

As with daily patterns' effects on physiology and behavior, birds are also very sensitive to annual patterns in the abiotic and biotic environments. This is particularly true for species of birds in circumpolar and temperate zones, but annual cycles of avian physiology are also evident in subtropical and tropical zones of the Earth. In all cases, these annual cycles derive primarily from annual changes in solar irradiance due to the axial tilt of the Earth's rotation and the elliptical orbit of the Earth around the sun, resulting in *seasons* (Pianka, 1978). In addition, long-term trends in climate, such as global climate change, whether human-derived or astronomical, may have significant effects on avian physiology (Lockwood, 2010).

43.1 Annual cycles

43.1.1 Abiotic

43.1.1.1 Photoperiod

Seasons result from the annual revolution of the Earth around the sun and its axial tilt (Figure 43.1). When the Earth's axial tilt is *parallel* with the trajectory of the Earth's movement relative to the sun, all surfaces receive equal amounts of solar irradiance such that they receive 12 h of light and 12 h of darkness/24 h day (LD 12:12); these days are the *equinoxes*, occurring on March 20 and September 22. The duration of the day phase is the *photoperiod*, while the duration of the night phase is the *scotoperiod.* In the northern hemisphere, March 20 is the *vernal equinox,* or the beginning of *spring,* while in the southern hemisphere, it is the *autumnal equinox,* or the beginning of autumn. Conversely, September 22 is the autumnal equinox in northern hemisphere and the vernal equinox in the south.

As the Earth progresses in its orbit from March to June, the axial tilt exposes the northern hemisphere to more direct and longer durations (photoperiod) of solar illumination. Conversely, the southern hemisphere undergoes less direct and shorter photoperiods until June 21 of each year, when the Earth's axial tilt points the northern hemisphere toward the sun, perpendicular to its orbit. This is the *solstice*. In the northern hemisphere, it is the longest day, while in the southern, it is the shortest, corresponding to the beginning of *summer* and *winter*, respectively. As the Earth then progresses from June to September, the seasons progress to the autumnal equinox in the north and the vernal equinox in the south on September 22. As the Earth progresses from September to December, the Earth's axial tilt once again becomes perpendicular to the Earth's orbit, but this time, the axial tilt exposes the southern hemisphere to direct light and longer photoperiods, creating the southern summer solstice and conversely plunging the northern hemisphere into the winter solstice.

On Earth, a major result of these astronomical progressions is the annual change in photoperiod, which is in turn dependent on *latitude* (Figure 43.2). In contrast to the situation in the laboratory in which lights are turned on and off in a timed square-wave, described below, natural photoperiod depends on the definition of global illuminance one defines as *twilight*, in which the zenith angle of the sun ranges from 85° as in *civil twilight* (the sun is just below the horizon) to 105° as in *astronomical twilight* (the sun is 12° below the horizon). At the *Equator*, photoperiod at civil twilight remains static at LD 12:12 throughout the year, but as latitude increases toward the poles, the annual change in photoperiod increases in amplitude. At the Tropics of Cancer and Capricorn (23.4378°), the photoperiod at summer solstice is approximately LD 14:10, while the winter solstice is LD 10:14. At more temperate New York, NY, USA (43.5°), the photoperiod at summer solstice is approximately LD 15:9 with a winter solstice of LD 9:15, while the range of photoperiods above the Arctic Circle (66.6°) is from LD 24:0 to LD 0:24. Thus, as latitude increases from the Equator to the poles, the range of photoperiod dramatically increases over the year.

43.1.1.2 Temperature

One of the major consequences of changing photoperiod as seasons progress is a parallel change in ambient

Sturkie's Avian Physiology. https://doi.org/10.1016/B978-0-12-819770-7.00045-1

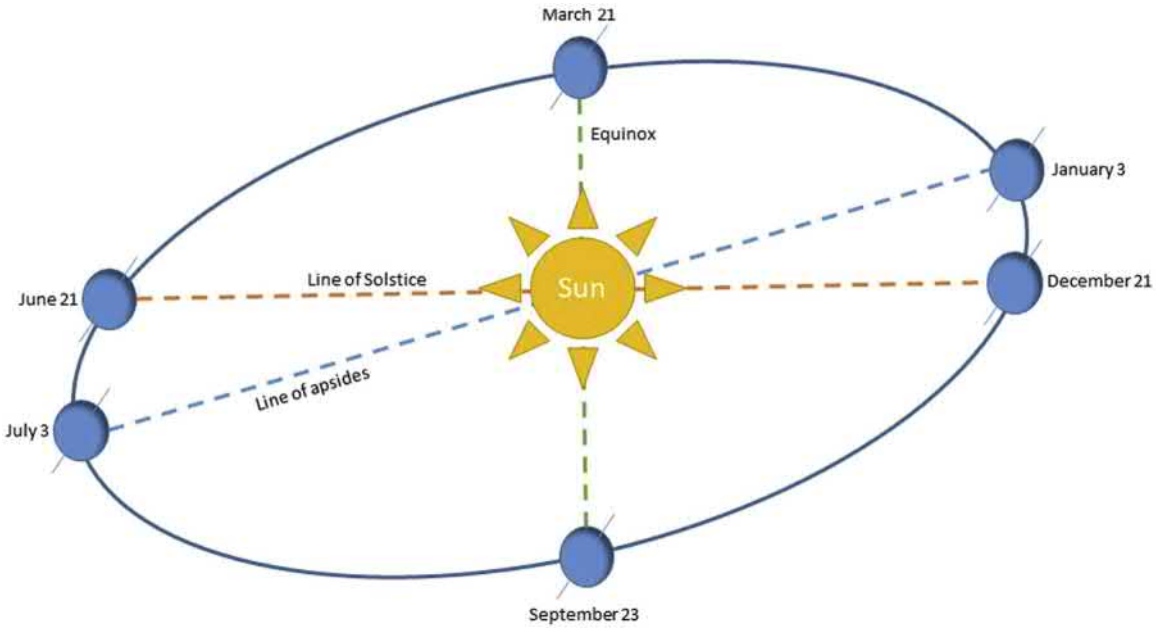

FIGURE 43.1 The astronomical basis for the seasons on Earth. Earth's rotation on its axis orients the poles asymmetrically toward or away from the sun depending on the time of year.

temperature (T_A). Average annual ranges in T_A (ΔT_A), the differences between the coldest month from the hottest month of the year (Glickman, 2000), increase with increases in latitude such that ΔT_A is 0 at the Equator to 40°C at 90° latitude in the northern hemisphere and 31°C in the south (Figure 43.5). The principal cause of the asymmetry in ΔT_A between north and south is that a higher percentage of Earth's surface is covered by ocean in the south, absorbing much of the heat. Earth's elliptical orbit in part moderates this difference because the Earth is closest to the sun in January (Figure 43.1) during the southern summer and northern winter.

In addition to latitude, altitude can dramatically affect T_A as well as ΔT_A. T_A decreases on average 6.4°C/km altitude, a phenomenon defined as the *lapse rate* (Glickman, 2000). The lapse rate depends on several variables, however, especially *humidity,* which decreases lapse rate. For example, an average *dry lapse rate* is 10°/km altitude, while wet lapse rates average 5.5 C/km altitude. Other abiotic factors that affect T_A and ΔT_A include urbanization, proximity to coasts (continentality), and precipitation.

43.1.1.3 Precipitation and wind

In addition to annual cycles of photoperiod and temperature, precipitation patterns can also provide temporal cues to birds and other organisms (Pianka, 1978; Glickman, 2000). This is especially the case in subtropical and tropical zones, which experience predictable wet and dry seasons. The *intertropical convergence zone* results from the Coriolis Effect from the Earth's rotation as well as the evaporation of oceanic water in equatorial areas. Variation in the intertropical convergence zone affects rainfall in many

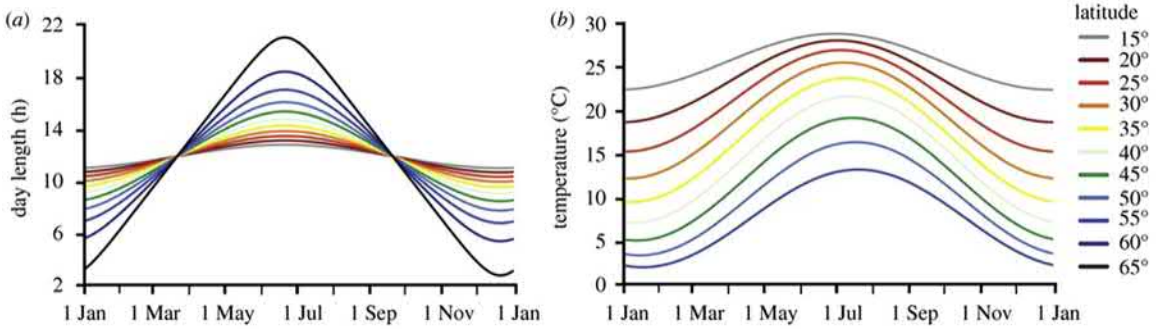

FIGURE 43.2 Annual changes in photoperiod depend upon the latitude (A) in which the amplitude of photoperiodic change is greatest at higher latitudes. Similarly, the seasonal changes in ambient temperature are also dependent on latitude (B). However, the average temperature at lower latitudes is higher than at higher latitudes. *From Wiltczek et al. (2010).*

equatorial regions, resulting in predictable wet seasons and dry seasons in subtropical and tropical zones as opposed to the cold and warm seasons at higher latitudes. For example, in tropical Queensland, Australia, precipitation ranges from 65% humidity and 400 mm rain/month the wet season (December to March) to only 17% humidity and 25 mm rain/month in the dry season (June to October). In West Africa, the rainy season extends from April to July, while the dry season falls between October and March. The absolute times of wet and dry seasons are not as predictable globally as is photoperiod because other factors such as wind direction, mountains, and other physical barriers affect them. However, they tend to be locally predictable, such that many organisms' reproductive processes are synchronized to these abiotic factors.

43.1.2 Biotic

Due to the fact that many abiotic factors vary depending on time of year, it is not surprising that aspects of birds' biotic environment are equally variable. These factors include, but are not limited to, presence and absence of food, competitors, predators, and mates. As a consequence, selective pressures for systems to tune physiological processes accurately to the timing of these biotic factors is very high (Pianka, 1978).

43.2 Annual cycles of birds

Birds' life history strategies must adapt to and predict these changing environmental factors. These life history strategies can be complex and species-specific, and the timing of the processes will determine birds' survival and fitness, perhaps more than any other vertebrate taxon. For an individual and species to survive, time must be allocated to each essential process such as reproduction, migration, molt, and other processes that may interfere with each other (King, 1974; Mewaldt and King, 1977). These processes are coordinated such that life history stages are timed to an appropriate time of year relative both to the external environmental conditions described above and among the diverse processes that are coordinated. For example, annual patterns of breeding, migration, body mass, and multiple molt patterns in long-distance migratory birds such as red knots, *Calidris canutus,* and ruffs, *Philomachus pugnax*, are orchestrated such that each stage of the species' annual cycle occurs at the appropriate time (Helm et al., 2012, Figure 43.3). Thus, birds exhibit hyperphagia and fatten up in anticipation of the vernal migration from southern hemisphere wintering grounds to northern hemisphere breeding grounds, where courtship, sexual behavior, and reproduction occur. Multiple molts occur to replace flight feathers following migratory stints, while breast molt occurs as incubation pads are prepared for incubation of young. *Phenological analyses* ["the study of the temporal aspects of recurrent natural phenomena and their relation to weather and climate of annual cycles" (Lincoln et al., 1998)], of multiple species of birds indicate similarly complex life history cycles. Obviously, transequatorial migrants such as ruffs and red knots exhibit more complex cycles, but these temporal programs are common among avian species.

43.3 Circannual rhythms

43.3.1 Circannual rhythms in the lab

How do birds synchronize their internal biological processes to prevailing environmental cycles? As with *circadian rhythms* described in Chapter 42, many physiological and behavioral rhythms in birds exhibit *circannual rhythms* (Gwinner, 2003). Circannual rhythms can only be demonstrated in the laboratory, but studies of circannual cycles in the laboratory likely reflect processes occurring in the field. Typically, birds are maintained continuously in equatorial photoperiods (LD 12:12) for several years. Under these conditions, many birds will express a "free-running" rhythm of approximately one year (hence, *circannual*), with periods of slightly less than or more than 365 days. As an example, circannual rhythms of testicular activity and molt in a single African stonechat, *Saxicola torquata axillaris*, maintained in captivity for up to 12 years in LD 12: 12 persisted with a period, τ, of approximately nine months until the bird died, presumably of old age (Figure 43.4; Gwinner, 2003). The expression of circannual rhythms is a widespread phenomenon among avian species, especially among species that experience transequatorial migration (Rani and Kumar, 2013), but circannual patterns are highly variable among species and among individuals within species (Hazlerigg and Loudon, 2008).

The mechanisms by which circannual rhythms are generated, however, are not known. System-level and molecular aspects of *circadian clocks* (Chapter 34) appear to interact with the expression of circannual rhythms, but they do not appear to be necessary. For example, pinealectomy (PINX) or constant light (LL), which abolishes circadian patterns of perch-hopping in the spotted munia, *Lonchura punctulata,* as well as other species of oscine passerine birds (Chapter 34) does not affect circannual patterns of testicular growth and regression, or premigratory fattening (Pant and Chandola-Saklani, 1992).

43.3.2 Synchronization of circannual rhythms to environmental cues

The expression of circannual patterns whose τ are different from 365 days in laboratory conditions but exactly 365 days under natural conditions suggests that, like

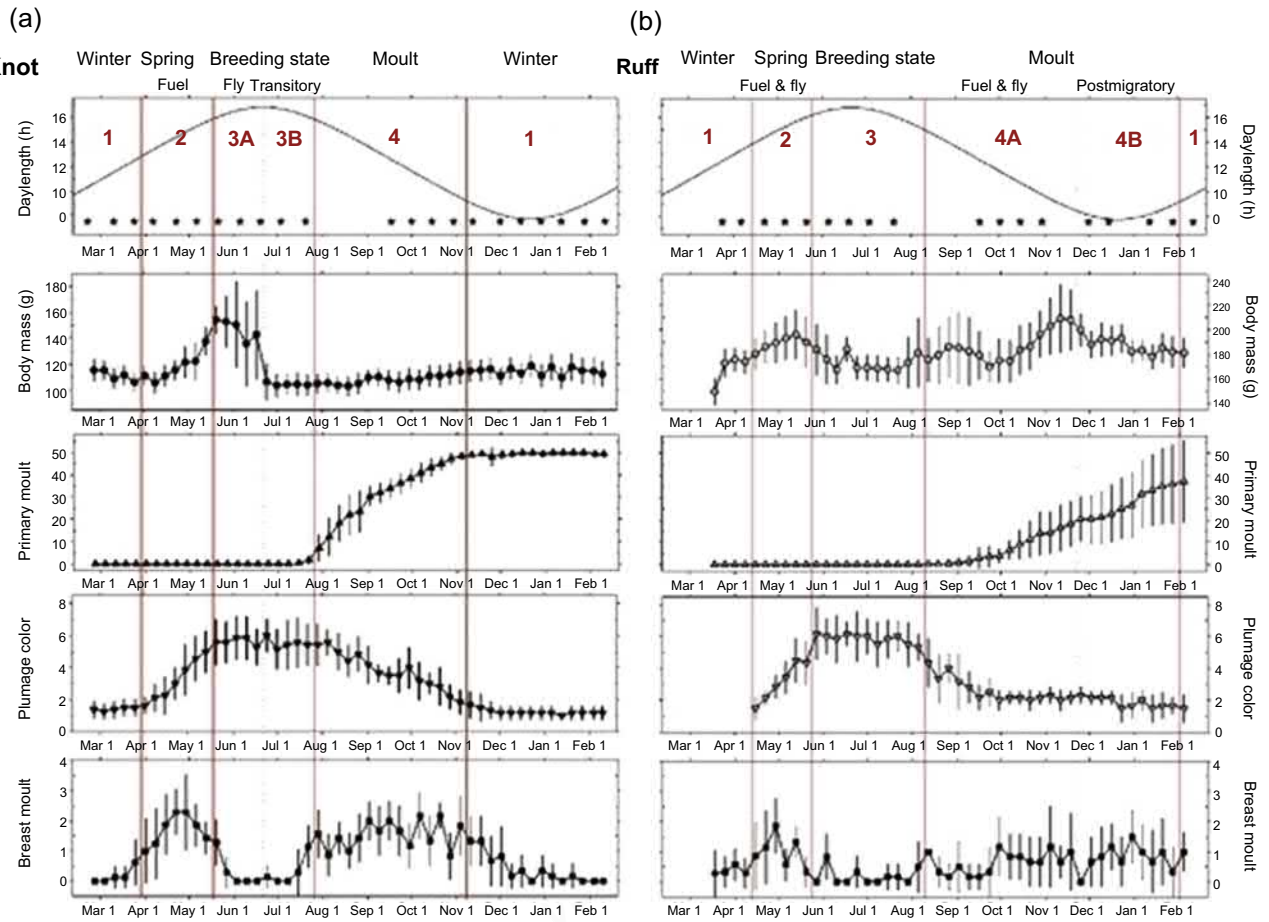

FIGURE 43.3 The complex annual life histories of two species of wading birds, the knot, *Calidris canutus*, (A) and the ruff, *Philomachus pugnax*, (B). Annual changes in body mass, vernal and autumnal molt, and plumage coloration occur in coordinated fashion in species-specific fashion. *From Helm et al. (2012).*

circadian rhythms (Chapter 34), circannual rhythms must be synchronized or entrained to prevailing environmental cues (Gwinner, 2003; Rani and Kumar, 2013). In most cases, alternating cycles of increasing and decreasing photoperiod synchronizes or entrains circannual rhythms of birds within a limit of entrainment. For example, exposure of European stonechats, *Saxicola torquata rubicola,* to alternating photoperiods of high amplitude (LD 16:6 to LD 10:14) entrain circannual patterns of testicular width and molt to 12 and 6 months in duration, respectively, but lower amplitude cycles of LD 13:11 to LD 11:13 were unable to entrain these processes to the six month cycle. There is little evidence of other zeitgebers entraining circannual rhythms in birds, although periodic presentation of novel food has transitory effects on circannual cycles in African stonechats (Gwinner and Scheuerlein, 1998; Scheuerlein and Gwinner, 2002).

43.4 Photoperiodism

43.4.1 Effects of photoperiod on avian physiological function

Aside from the entraining effects of photoperiod on circannual cycles, changes in photoperiod have direct effects on many annual cycles in birds, although it is not clear that these are necessarily mutually exclusive. In fact, it has been known for some time that seasonally breeding, temperate zone birds time reproduction and migration in a clock-like fashion in response to changing photoperiod (Rowan, 1926). Birds living in temperate zone latitudes generally restrict breeding to the spring and summer, maximizing the likelihood that young will be hatched during times at which food is plentiful (Gwinner, 1989, 2003; Hut et al., 2013).

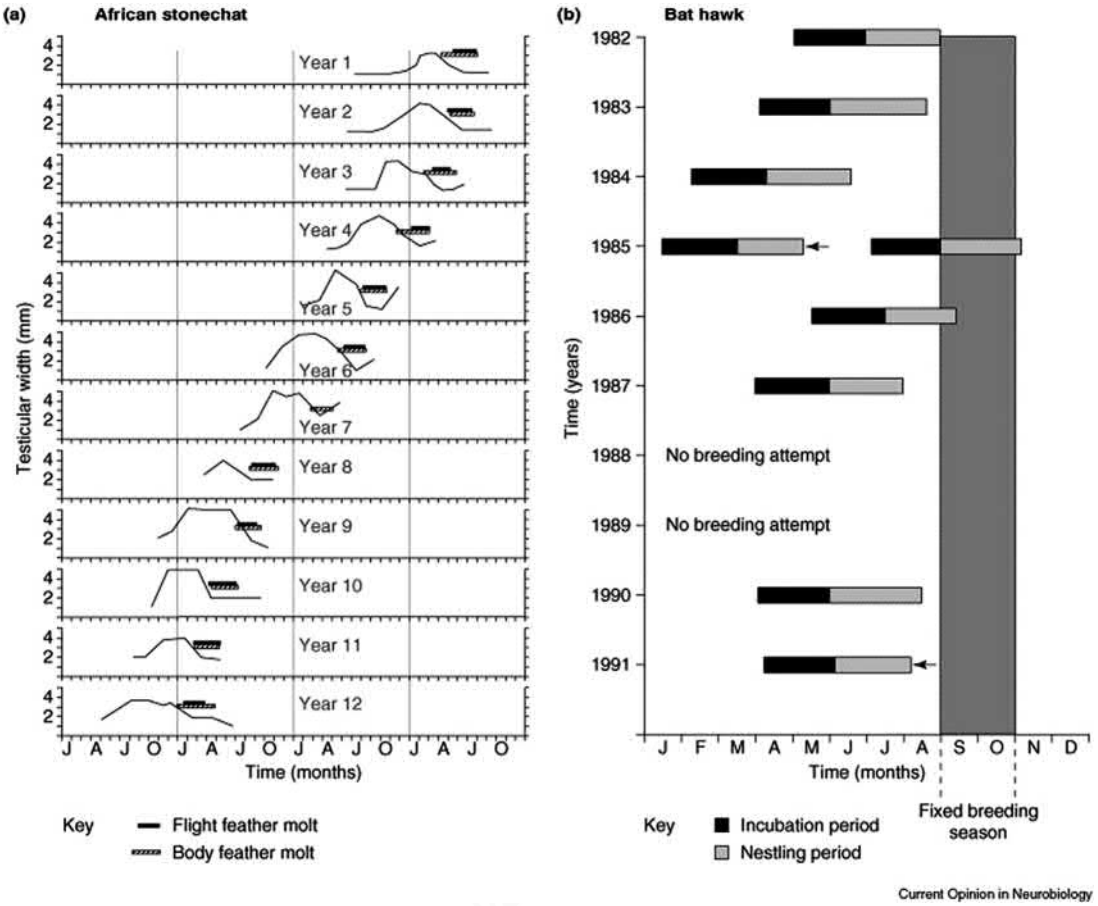

FIGURE 43.4 Circannual cycles of a single African stonechat, *Saxicola torquata axillaris*, of testicular size and molt through 12 consecutive years maintained in constant LD 12:12. *From Gwinner (2003).*

The vast majority of seasonally breeding birds are *long-day breeders*, that is, they begin sexual maturation, courtship, and mating as the photoperiod transitions from the winter solstice to longer and longer days. There is one well-documented *short-day breeding* species—the emu, *Dromaius novaehollandiae*, which breeds as the photoperiod shortens (Blache et al., 2001).

The exact photoperiod that induces or suppresses a particular function in birds is species-, latitude-, and function-specific, called the *critical photoperiod* (Siopes, 1994; Brandstatter, 2003; Hazlerigg and Loudon, 2008). This is the minimum photoperiod that induces or suppresses a seasonally regulated process (Figure 43.5). For example, annual testicular growth is induced earlier and by shorter photoperiods in the temperate zone European starling than in the Nearctic-breeding white-crowned sparrow (cf. Dawson, 2008). This corresponds to the likelihood of food availability occurring later in the season at higher versus lower latitudes at a species level. Similarly, within species, especially those that are widely distributed, critical photoperiod tends to be longer in individuals of the same species residing at higher latitudes than at lower latitudes (Dawson, 2013; Hut et al., 2013). Thirdly, the critical photoperiod that induces or suppresses different functions, such as reproduction, molt, metabolism, and migration usually differ among these processes. Obviously, molt during migration would be disadvantageous for any bird.

In seasonally reproducing, long-day birds, gonadal activity and gonad size regress (Wilson, 1986; Wilson and Reinert, 1993) and become inactive as the photoperiod decreases, while gonads recrudesce, becoming more active, in response to increased photoperiod (Figure 43.5A). If birds are maintained in long photoperiod for long periods of time, their reproductive systems become insensitive to the

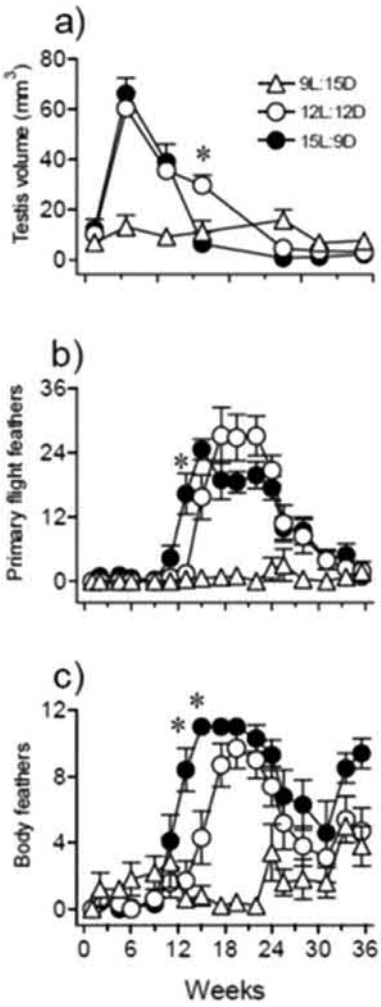

FIGURE 43.5 The effect of differing photoperiods on testes volume, primary and body molt in captive spotted munia, *Lonchura punctulata*. *From Rani and Kumar (2013).*

photostimulatory effects of long photoperiod and spontaneous regress (Figure 43.5A). This process is called *photorefractoriness*, and birds remain photorefractory until they are placed in short days for some time to make them photosensitive again (Dawson et al., 2001; Proudman and Siopes, 2002). Similarly, other photoperiodically regulated processes wax and wane depending on the photoperiod, although the absolute time at which they occur may differ from gonadal function (Figure 43.5B and C).

Subtropical and tropical birds are not immune to these changes, as the breeding seasons of these species are commonly timed as well (Scheuerlein and Gwinner, 2002; Rani and Kumar, 2013). Although the amplitude of photoperiodic change is much reduced at these latitudes (Figure 43.2), there are nonetheless many seasonal signals to which birds can synchronize reproductive and other processes. For example, the spotted antbird, *Hylophylax naevioides*, lives in Panamanian rainforests around 9°N, experiencing a very low-amplitude photoperiodic change. These birds breed in the rainy season (May−December), when insect prey are abundant (Wikelski et al., 2000). Although the rainy season occurs regularly from year to year, there is significant variation in its inception and duration (Hau et al., 2000). When male antbirds are experimentally transferred from LD 12:12 to LD 13:11, testes volume increases dramatically, while birds maintained in LD 12:12 do not, demonstrating these birds do respond to photoperiodic changes. Conversely, birds maintained in the equinoctial photoperiod stimulated with an additional dietary supplement of live crickets exhibit larger testes than birds maintained on the standard insectivorous diet of mealworms only (Hau et al., 2000). The scenario suggests that slight changes in photoperiod "primes" the birds' reproductive system to respond to the increase in diet necessary to raise young (Hau, 2001).

Similarly, in some desert species in which water may be a limiting commodity, photoperiodic control of reproduction may be triggered by access to water. Zebra finches, *Taeniopygia guttata,* are usually considered non-photoperiodic, opportunistic breeders, since these Australian desert birds breed rapidly following rainstorms (Bentley et al., 2000). Prior et al. (2013) found that severe water restriction of male zebra finches had no effect of testes size but did decrease plasma testosterone, while in females, the ovaries, oviduct size, and egg-laying was reduced by water restriction in female zebra finches. Water restriction further affects these birds' song control system (see below), since the acoustic structure of song syllables and calls of both male and female birds are decreased (Prior et al., 2019). However, these birds do respond to changes in photoperiod, since transfer of male zebra finches from short photoperiods to long photoperiods of increases plasma luteinizing hormone (LH), testicular volume, and body mass (Bentley et al., 2000). This is just one example of what is likely a wide array of adaptations to temporal changes in the subtropics and tropics, and since avian biodiversity is five times the level in the tropics than in Nearctic regions, the variability in these adaptations is likely just as diverse.

43.4.2 Role of photoreceptors

As described in detail in Chapter 34, multiple photoreceptors are involved in circadian entrainment, and these photoreceptors reside in the retinae, pineal gland, and at least three encephalic sites: lateral septal organ (LSO), preoptic area (POA), and tuberal hypothalamus/mediobasal hypothalamus (MBH) Foster and Hankins (2002). As with circadian entrainment, the retinae are not necessary for photoperiodic responses (Benoit and Assenmacher, 1954; Menaker, 1968; Menaker and Keatts, 1968; Menaker and Underwood, 1976), although there is some species

variability. In the house sparrow, *Passer domesticus,* and American tree sparrow, *Spizella arborea,* removal of the eyes, the pineal gland, or both has no effect on gonadal responses to increases or decreases in photoperiod (Menaker et al., 1970; Wilson, 1990). Enucleated Japanese quail, *Coturnix japonica*, exhibit normal photoperiodic responses to increases in photoperiod in egg-laying in females and enlargement of the cloacal gland in males, similar to the situation in sparrows. Still, termination of reproductive activity by exposure to short photoperiods requires that birds experience long days at or before the time of blinding (Homma et al., 1972). Since Japanese quail and house sparrows also differ in the role played by retinal melatonin in circadian organization (Chapter 34; Cassone and Menaker, 1984; Underwood and Siopes, 1984), it is not clear if this difference is due to differences in photoreceptors per se or due to differences in circadian organization.

Local illumination of the MBH or LSO leads to gonadal growth (Benoit, 1935; Benoit and Assenmacher, 1954; Homma et al., 1979). Nomographic analyses of the action spectra for photoperiodic responses suggest a rhodopsin-like photopigment with a peak sensitivity of 480 nm to ultraviolet wavelengths (Foster et al., 1985; Nakane et al., 2019). More recently, several genes encoding rhodopsin superfamily photopigments have been identified in the brains of several avian species, corroborating this view (Chapter 34). These include melanopsin (OPN4), vertebrate ancient opsin, neuropsin (OPN5), and rhodopsin itself (OPN2) (Silver et al., 1988; Bailey and Cassone, 2005; Chaurasia et al., 2005; Halford et al., 2009; Nakane et al., 2010; Kang et al., 2010; Davies et al., 2012; Wang et al., 2012). OPN5 is expressed in cerebrospinal fluid (CSF)-contacting neurons within the periventricular organ (PVO) of the Japanese quail (Figure 43.6; Nakane et al., 2010). OPN4-immunoreactivity and mRNA is widely expressed in the brain of the turkey, *Meleagris gallopavo*, including the POA, suprachiasmatic region [medial suprachiasmatic nucleus (mSCN) and visual suprachiasmatic nucleus (vSCN)] of the hypothalamus, lateral septal region, *pars distalis* of the *adenohypophysis*, and the premammillary nucleus (PMM) just dorsal of the PVO (Kang et al., 2010).

43.4.3 Role of circadian clocks in photoperiodic time measurement

The role of the circadian clock in annual cycles has been known for some time (Bünning, 1969; Follett et al., 1992; Menaker and Eskin, 1967). Although there are differences among species of birds and between birds and other taxa, neither the absolute length of the photoperiod, length of the scotoperiod (the duration of the dark phase) nor their ratio is the proximal causes of gonadal induction. Rather, it is the circadian phase (ϕ) at which light impinges on photoreceptive elements that causes reproductive changes. For example, male Japanese quail, *Coturnix japonica,* and white-crowned sparrows, *Zonotrichia leucophrys,* which are maintained in LD 6:18 will exhibit regressed testes. However, if the last hr. of the 6 h photoperiod is extended each long night to a specific "photoinducible phase," ϕ_{pi}, usually 11−12 h following the onset of the short photoperiod, reproductive activity is commenced. Thus, birds exposed to LD 6:18 or L5: D1: L1: D17 (a single 1 h light pulse interrupting the night) will retain regressed gonads, but if the 1 h pulse occurs 5 h later (L5:D6:L1:D12), gonads will recrudesce (Menaker and Eskin, 1967; Follett et al., 1974; Sharp, 2005). The same total amount of light (and dark) is present for each 24 h, but the effect is dramatically different. It is the *timing* of light coinciding with an internal process that induces or prevents

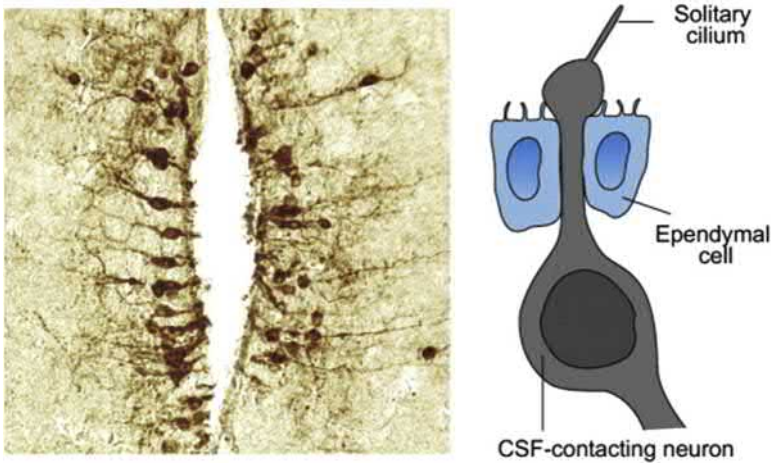

FIGURE 43.6 Expression of neuropsin (OPN5) in the periventricular organ of the mediobasal hypothalamus in the Japanese quail, *Coturnix japonica*. *From Yoshimura (2013).*

reproductive activity, suggesting a circadian clock underlies photoperiodic time measurement. Nanda and Hamner (1958) had shown this to be the case in plants through an elegant series of experiments in which soy bean plants exposed to a 6 h photoperiod coupled with scotoperiods of varying lengths that were multiples of a 24 h cycle (e.g., LD6:18; LD6:42 or LD6:66) did not flower. However, when plants were exposed to 6 h photoperiods followed by scotoperiods of lengths that did not resonate with 24 h (e.g., LD6:6; LD6:30 or LD6:54) flowering was observed. Similar studies in several species of birds showed that seasonal changes in both gonadal recrudescence and regression are regulated by a circadian clock (Follett et al., 1974, 1991; Kumar et al., 1996).

These and other observations have led to two competing models for a role of circadian clocks in photoperiodic time measurement (Figure 43.7). In one, the "external coincidence model" suggests that light has two complementary roles. First, light entrains the circadian clock with a stable ψ_{ie} such that the photoinducible phase, ϕ_{pi}, is also maintained with a stable ψ approximately 11.5 h following the beginning of the photoperiod (lights on). When light coincides with the ϕ_{pi} either because the photoperiod is long under natural conditions or through exposure to an experimental light pulse, the reproductive axis is induced (Pittendrigh, 1972, 1993). The competing notion (the "internal coincidence model") stems from the observation that many circadian systems behave as if they are composed of at least two oscillators, one entrained to dawn and the other to dusk. In the internal coincidence model, the phase relationship between the dawn oscillator and the dusk oscillator, $\psi_{dawndusk}$, induces seasonal changes in reproduction (Pittendrigh, 1972, 1993). Each of these models has support from different experimental systems in birds. However, until specific structures and/or molecules become associated with these models, they are essentially untestable at the physiological level.

43.4.4 Role of circadian system structures

As stated in Chapter 34, the avian circadian system comprises the pineal gland, the suprachiasmatic nuclei, the retinae and photoreceptors in the retinae, pineal, and brain (Cassone and Menaker, 1984). These structures mutually interact to elicit circadian patterns of a broad array of processes and to entrain them to LD cycles. In view of the fact that photoperiodic time measurement relies on circadian rhythmicity, one might expect that these structures are critical for photoperiodism as well. Intriguingly, in spite of the fact that the rhythmic production of melatonin is critical for the expression of circadian locomotor rhythms in birds, melatonin does not affect seasonal changes in primary reproductive function in these species. As in mammals, pineal melatonin levels faithfully reflect the length of the scotoperiod both in vivo and in vitro (Binkley et al., 1977; Brandstätter et al., 2000). However, PINX and/or EX of several species of birds has little effect on seasonal changes in gonad size or activity (Siopes, 1983; Bentley, 2001; Kumar et al., 2002). Moreover, administration of exogenous melatonin of different durations has little effect on primary reproductive function (Cassone et al., 2008). This corresponds to the relative absence of melatonin receptor activity in the tuberal hypothalamus and hypophysis (Cassone et al., 1995), in stark contrast to the situation in seasonally reproducing mammals, where 2[^{125}I]iodomelatonin (IMEL) binding and melatonin receptor expression in *pars tuberalis* is a major site of melatonin action (Goldman, 2001).

Circadian clock function has been localized within the MBH itself of Japanese quail controlling photoperiodic

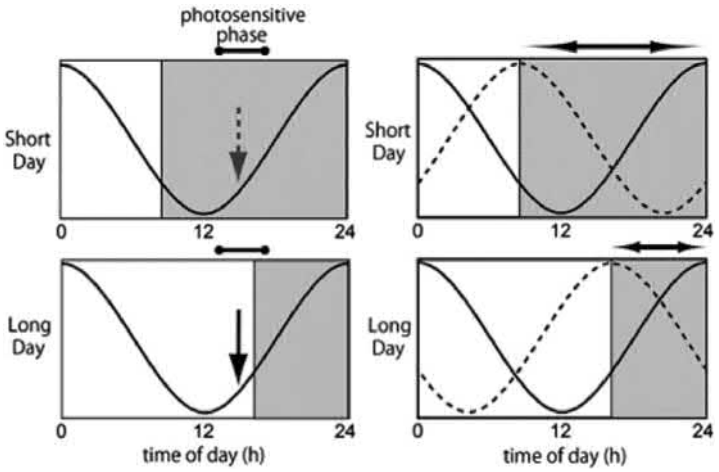

FIGURE 43.7 The difference between the external coincidence (left) and the internal coincidence (right) models for photoperiodic induction. In the case of external coincidence, light (1) entrains the circadian system to a stable phase relationship to the photoperiod and (2) stimulates or inhibits a process such as gonadal induction at a particular photoinducible phase. In the internal coincidence model, at least two circadian oscillators entrain to the photoperiod, and the phase relationship between these two oscillators induces or suppresses the seasonally controlled process. *From Yoshimura (2013).*

time measurement for reproductive function (Yoshimura, 2010, 2013). Earlier studies had shown that lesion of the MBH blocked testicular recrudescence in response to lengthening photoperiods (Sharp, 2005) and illumination of this area had resulted in excitation of the tuberal hypothalamus and testicular growth (Foster et al., 1985; Meddle and Follett, 1997). As stated above, the MBH of quail and the PMM of turkeys have been shown to express both OPN4 and OPN5 in CSF-contacting neurons (Kang et al., 2010; Nakane and Yoshimura, 2010; Nakane et al., 2010). Noting that PINX or EX or even SCN lesion had little effect on photoperiodic regulation of gonadal function, rhythmic expression of the clock genes *per2, per3, clock,* and *Bmal1* (Chapter 34) were identified in the MBH suggesting this structure contains the circadian pacemaker associated with photoperiodic time measurement (Yoshimura, 2010, 2013). Intriguingly, it has been reported that the PMM of turkeys also express the enzymes necessary for the biosynthesis in melatonin as well (Kang et al., 2007; El Halawani et al., 2009), although the significance of this observation is at this point unknown. Surgical destruction of the turkey PMM has no effect on photoperiodic control of reproduction (Moore et al., 2018).

43.5 Neuroendocrine regulation of photoperiodic time measurement

43.5.1 Photoperiodic control of gonadotropins and prolactin in seasonal reproduction

The circadian pacemaker presumably residing in the MBH controls seasonal changes in the release of *gonadotropin-releasing hormone* (GnRH) and *vasoactive intestinal polypeptide* (VIP) via the hypothalamohypophysial portal system (HHPS), which in turn regulate the synthesis and release the gonadotropin LH and *prolactin* (PRL), respectively (Sharp et al., 1998; Chapter 23). GnRH neurons predominate in the POA and anterior hypothalamus and project to the median eminence (Saldanha et al., 2001; Teruyama and Beck, 2001), while the VIP neurons are found throughout the basal hypothalamus. The GnRH cells, at least, are in direct contact with terminals arising from rhodopsin-immunoreactive cells, presumably extraocular photoreceptors in the LSO (Saldanha et al., 2001). The VIP cells project throughout the hypothalamus but also innervate the capillaries in the median eminence (Teruyama and Beck, 2001). GnRH- and VIP-immunoreactive terminals are more dense and in closer proximity to the median eminence during long-photostimulatory photoperiods than in short-photoinhibitory photoperiods.

In long-day breeding birds, lengthening photoperiods induce an increase in the release of GnRH from terminals in the median eminence into the HHPS. *Ex vivo* hypothalamic explants from male Japanese quail release GnRH in culture in response to long photoperiods (Perera and Follett, 1992). GnRH in turn induces the synthesis and release of LH, which remains high during the breeding season. However, when photoperiod decreases, LH levels also decrease. In addition, in long-day breeders, continued exposure to long days induces *photorefractoriness*, in which birds fail to respond to photostimulatory photoperiods, and LH levels decline (Sharp, 2005).

Lengthening photoperiod also presumably increases the release of VIP from median eminence terminals into the HHPS, although this has not been demonstrated directly. Even so, administration of VIP potently induces the synthesis and release of PRL by the adenohypophysis in several species of passerine, galliform, and columbiform species (Maney et al., 1999; Kosonsiriluk et al., 2008; Sharp and Blache, 2003). The rise in PRL is typically delayed relative to LH, declining only after LH declines. Immunization of European starlings, *Sturnus vulgaris,* against VIP delays and attenuates the decline in LH levels during photorefractoriness (Dawson and Sharp, 1998; Maney et al., 1999).

43.5.2 Role of the thyroid hormone in avian photoperiodism

Thyroidectomy induces gonadal recrudescence in starlings and Japanese quail (Follett and Nicholls, 1985; Dawson et al., 1986), and injection of T3 into the MBH induces quail gonadal growth (Follett and Nicholls, 1985; Yoshimura et al., 2003). Using differential subtractive hybridization, Yoshimura's group found type 2 iodothyronine deiodinase (*Dio2*) was induced in the MBH by a light pulse associated with long-day induction. *Dio2* encodes an enzyme that catalyzes the conversion of inactive thyroxine (T4) to active triiodothyroxine (T3) (Nakao et al., 2008 a,b). Later, they showed that type 3 iodothyronine deiodinase (*Dio3*), which inactivates T3, was induced in the MBH by exposure to short days. The scenario they envision is that photoperiod is perceived by photopigments in the MBH that entrain a circadian oscillator within the MBH. In long days, the circadian clock induces *Dio2*, while short days induce *Dio3*. These two gene-switches fine tune local thyroid hormone concentration within the MBH. Although precise mechanisms of thyroid hormone action remains unclear, it is proposed that locally activated thyroid hormone causes morphological changes in neuroglial interaction between GnRH nerve terminals and the endfeet of the glial processes in the median eminence that regulates or modulates the seasonal GnRH secretion (Figure 43.8; Yamamura et al., 2004).

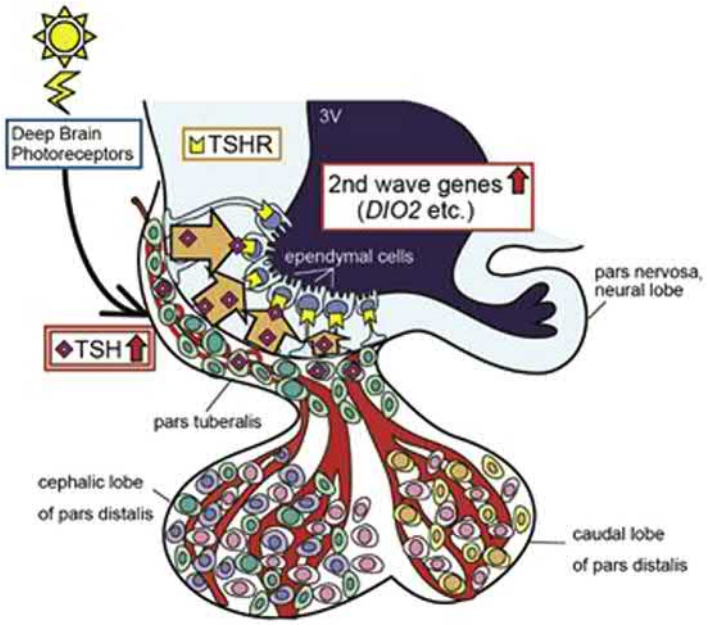

FIGURE 43.8 Schematic of the quail tuberal hypothalamus. Extraocular photoreceptors induce an increase in thyroid-stimulating hormone signaling in the *pars tuberalis* which in turn induce changes in ependymal cells or tanycytes. These cells affect the ability of neuroendocrine signals entering the hypothalamohypophysial portal system. *From Yoshimura (2013).*

43.5.3 Role of gonadal and neural steroids

As stated above, the reproductive systems of long-day breeders recrudesce as the photoperiod lengthens in response to gonadotropin activation. The exact timing of these is species- and gender-specific. For example in European starlings, seasonal testes growth begins more than a month earlier than does female follicle formation (Williams, 2012). As testes recrudesce, Sertoli cells synthesize and secrete *estrogens*, such as *estradiol,* while Leydig cells synthesize and secrete *androgens* such as *testosterone, androstenedione*, and *dehydroepiandrosterone* (Chapter 29). Ovarian granulosa cells begin to synthesize and secrete estrogens from androgens generated by adjacent thecal cells (Chapter 28). These gonadal steroids induce gender-appropriate seasonal growth and maturation of primary and secondary sexual characteristics (Adkins-Regan, 2012). In males, many of the genomic effects of testosterone are mediated by estrogens generated by local conversion by *aromatase.* When photoperiod decreases, LH also decreases, and the steroidogenic capacity of the gonads decline in parallel.

Among structures that annually recrudesce and regress are brain structures associated with reproductive behavior (Figure 43.9; Balthazart et al., 2009, 2010). The medial preoptic nucleus (POM) within the POA of Japanese quail has been well established as a structure involved in male sexual behavior (Ball and Balthazart, 2004; Balthazart and Ball, 2007), in which the size of the POM is greater in males than in females (Viglietti-Panzica et al., 1986; Ball and Ketterson, 2008). In male quail, the POM increases in volume during the spring and decreases in the fall

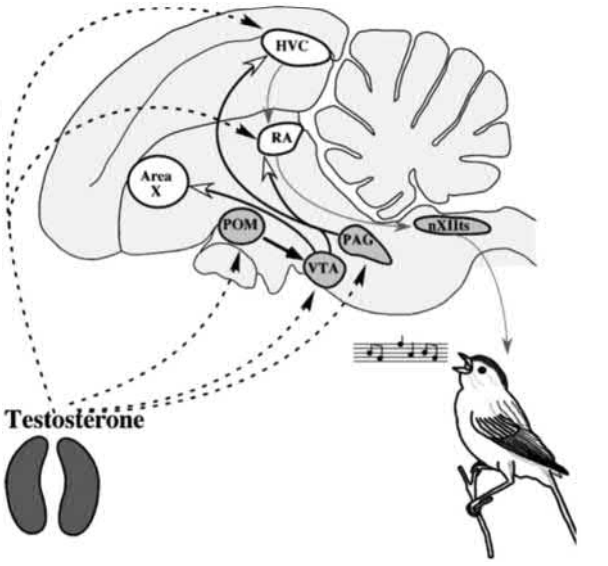

FIGURE 43.9 Schematic of the effects of testosterone on brain structures associated with reproduction and song. Steroid receptors residing in preoptic, brainstem, and forebrain structures mediate primary reproductive behavior as well as bird song. *From Ball and Balthazart (2004).*

(Thompson and Adkins-Regan, 1994). Castration of these birds abolishes this pattern, and administration of testosterone, mediated by aromatase-induced estrogens, increases POM volume through increases in cell size and dendritic branching within two weeks of administration. In contrast to the situation involving song control (see below), there is no evidence that POM growth involves de novo neurogenesis.

However, the gonads and adrenal glands are not the only sources of biologically active steroid hormone (Tsutsui et al., 1999; Schlinger and Remage-Healey, 2012). The brains of many species of birds express the enzymes capable of *neurosteroidogenesis,* biosynthesis of biologically active steroid hormones by the brain (Tsutsui et al., 1999). In the Lapland longspur, (*Calcarius lapponicus),* and song sparrow, *Melospiza melodia,* for example, the hypothalamus, hippocampus, and ventral telencephalon express aromatase, which converts androgens to estrogens, and 5-β-reductase, which deactivates testosterone (Soma et al., 1999, 2003). This suggests that the avian brain can convert circulating gonadal steroids into biologically active estrogens. Further, there is growing evidence that the brain can also synthesize steroids from circulating cholesterol (Schlinger et al., 2008; Schlinger and Remage-Healey, 2012).

The role(s) played by neurosteroids may be diverse. For example, there is evidence that estrogens synthesized by glial astrocytes may provide neuroprotection in response to traumatic brain injury, ischemia or anoxia (Pedersen et al., 2018). Steroids produced locally may enable rapid responses to local environmental changes within involving systemic responses that may have pleiotropic effects (Calisi and Saldanha, 2015).

43.5.4 Mechanisms of photoperiodic regulation of bird song

The song control system of oscine passeriform birds is a specialized network of brain nuclei involved in singing and song learning (Nottebohm, 1981; Mooney, 2009). This system receives auditory input from ascending, primary auditory pathways beginning in the cochlear nuclei, which project to the lateral dorsal mesencephalic nuclei (MLd). MLd in turn projects to the thalamic *nucleus ovoidalis*, which in turn projects to Field L in the forebrain. Song processing begins in secondary auditory areas in the caudal mesopallium and caudomedial nidopallium, which interact with the anterior forebrain pathway for song plasticity and learning. This pathway includes the HVC in the dorsal forebrain, which projects to Area X, whose projections form a loop between the dorsolateral thalamus and the lateral magnocellular nucleus of the anterior nidopallium (LMAN). Then, both HVC and LMAN project to the robust nucleus of the archipallium (RA), which forms the song motor output pathway.

This system enables birds to process a complex species-specific identification of both self and con-specifics as well as other dynamics in birds' acoustic environments (competitors, prey, predators, etc.) (Mooney, 2009). These acoustic environments as well as their reproductive and survival relevance are not constant. Territories change hands and the available range of mates fluctuates. In order to effectively interpret the acoustic features in song, the auditory system must structure its representation in such a way that allows for dynamic behavioral goals of the organism. At the same time, the structure and behavior of song itself must be tuned to reproductively appropriate situations.

Both the probability of a male bird to sing in response to a given stimulus as well as the size and complexity of the song control nuclei within its brain vary depending upon the time of year (Nottebohm, 1981). Photosensitive birds in the short days of winter possess small HVC, RA, and depending on the species other structures in the system. When birds are photostimulated as photoperiod increases, the song control nuclei grow in parallel with the growth of the testes, and, as they become photorefractory, these structures regress in both size and complexity. Some of the growth in these structures, especially in HVC, is due to de novo neurogenesis from neural stem cells residing in periventricular areas of the lateral ventricle (Alvarez-Buyla et al., 1988). These cells are born predominantly during the fall and migrate into the HVC over the course of the winter, where they differentiate and extend axonal projections to RA and other structures. In addition, increases in neuropil and glia contribute to this growth. Regression of these structures is characterized by programmed cell death as well as retraction of neuropil.

Seasonal fluctuations in androgens and estrogens appear to be critical for changes in song control (Figure 43.9). Song control nuclei contain both androgen receptors and both estrogen receptor subtypes (ERα and ERβ), as well as aromatase, capable of converting androgens into biologically active estrogens (Ball et al., 1997; Ball and Balthazart, 2010). Further, the rate of male song in several songbird species increases when testosterone levels are high, castration decreases this rate, and hormone replacement reestablishes vernal song patterns (Fusani, 2008; Balthazart et al., 2010).

Even so, a few studies have indicated gonad-independent regulation of song control nuclei under different photoperiods. In both American tree sparrows (Bernard et al., 1997) and house sparrows (Whitfield-Rucker and Cassone, 2000), HVC and RA increase in size in response to a change in photoperiod from a short day to long day (Figure 43.10). Castrated birds in these studies also exhibited photostimulated song control nuclei, although the level of induction was not as great as in the sham-operated birds. Thus, while the song system certainly responds to the seasonal changes in gonadal steroids, regulation of song control nuclei comprises a gonad-independent as well as a gonad-dependent aspect. As stated above, several studies have implicated neurosteroids in this supplemental signal to the song system (Soma et al., 1999, 2003).

Alternatively, studies employing in vitro receptor binding and IMEL in the 1980 and 1990s demonstrated high-affinity melatonin receptor binding and the identity of

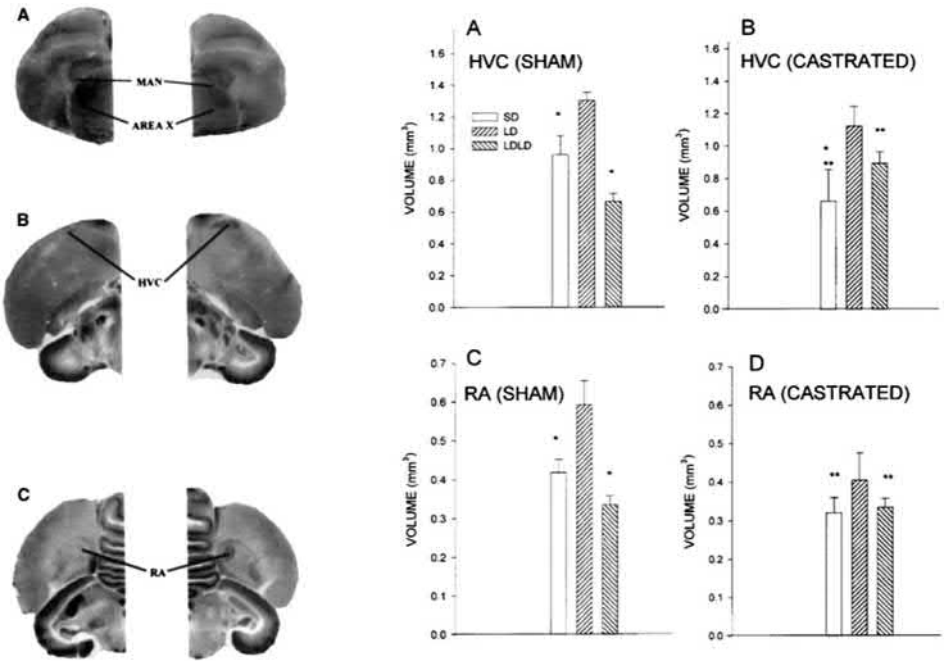

FIGURE 43.10 Bird song structures such as HVC and the nucleus robustus of the archipallium (RA) change in size and complexity depending on the photoperiod. HVC and RA are small in short days (left) and large in long days (right). Castration attenuates but does not abolish these seasonal cycles. *From Whitfield-Rucker and Cassone (2000).*

three receptor subtypes, Mel_{1A}, Mel_{1B}, and Mel_{1C} melatonin receptors, in a variety of vertebrates (Reppert et al., 1995, 1996). In birds and reptiles, IMEL binding predominates in retinorecipient and integrative structures within the visual system (Cassone et al., 1995), which has led to the view that visual sensitivity and contrast detection, are under circadian control. In male house sparrows (Whitfield-Rucker and Cassone, 1996) (Gahr and Kosar, 1996) and European starlings (Bentley and Ball, 2000) but not female birds, high-affinity IMEL binding was present in song control nuclei HVC, RA, LMAN and, to a lesser extent, Area X. Both HVC and RA express the Mel_{1B} melatonin receptor (Figure 43.11; Jansen et al., 2005).

These observations point to a role for melatonin in song behavior and in the growth and regression of song control nuclei. Bentley et al. (1999) have shown that continuous administration exogenous melatonin attenuated the long-day-induced volumetric increase in HVC and also decreased the volume of another song-control nucleus, area X, in European starlings. This effect was independent of the birds' reproductive state. House sparrows exposed to constant light (LL), which abolishes circadian patterns of behavior, and subsequent rhythmic administration of summer-like (short duration) or winter-like (long duration) melatonin, which entrains their behavior, also affects the volumes of song control nuclei HVC and RA (Cassone et al., 2008) and the distribution of song behavior (Harpole et al., 2020). Birds that received no melatonin or the short-duration melatonin cycle (who entrained to the regime) exhibited large HVC and RA, but birds that received the long duration melatonin entrained to the melatonin regime but showed regressed HVC and RA. This showed that melatonin affects song control nuclei independently of gonadal state.

43.5.5 Mechanisms of photoperiodic regulation of migration

One of the most iconic aspects of avian physiology and behavior is the biannual migration of birds from arctic and temperate zones to subtropical and tropical regions on a seasonal basis (Gwinner, 1967; Berthold, 1973) and/or from higher to lower altitudes and back (Rowan, 1926). Avian migration is an integrative process that involves circadian, circannual, and photoperiodic regulation at the genetic, epigenetic, and neuroendocrine levels, in which the timing of migration and directional navigation during migration are coordinated (Wiltschko and Wiltschko, 2012; Stevenson and Kumar, 2017; Merlin and Liedvogel, 2019). Further, it is embedded in a complex phenological pattern of integrated processes that must be coordinated precisely (Figure 43.3). These processes include hyperphagia in preparation for migration, migration itself, molt, and reproduction at appropriate times of year (Gwinner, 1989; Rattenborg et al., 2004).

The genetic bases for migratory behavior has been known for some time, due largely to the work of Berthold and colleagues (Berthold and Querner, 1981; Berthold, 1995). European blackcaps, *Sylvia atricapilla,* were selectively bred for strains that preferred a southwest autumnal

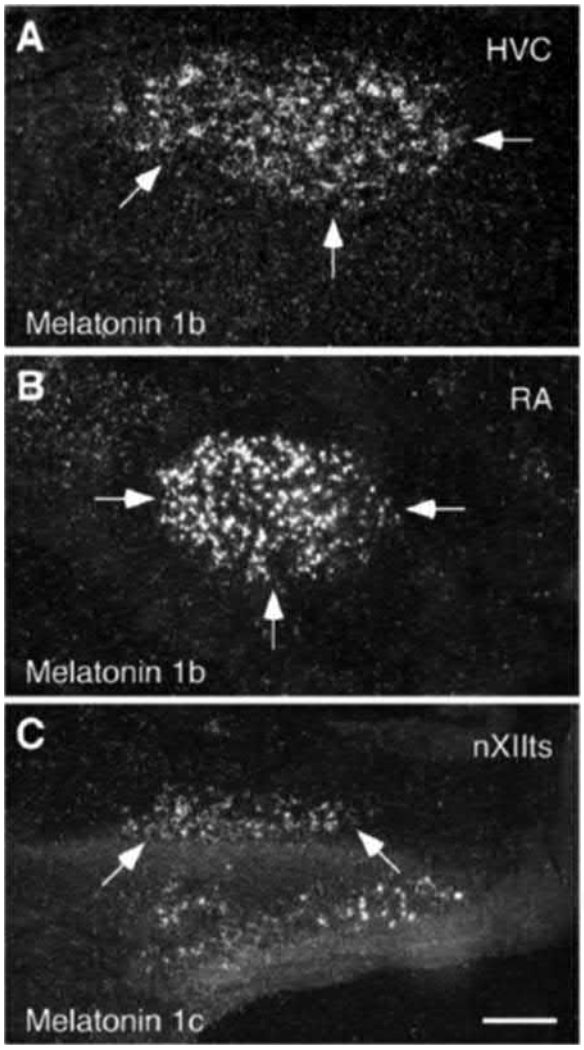

FIGURE 43.11 In situ hybridization of melatonin receptors in HVC, robust nucleus of the archipallium, and the nucleus tractus solitarius (nXIIts) of the zebra finch. *From Jansen et al. (2005).*

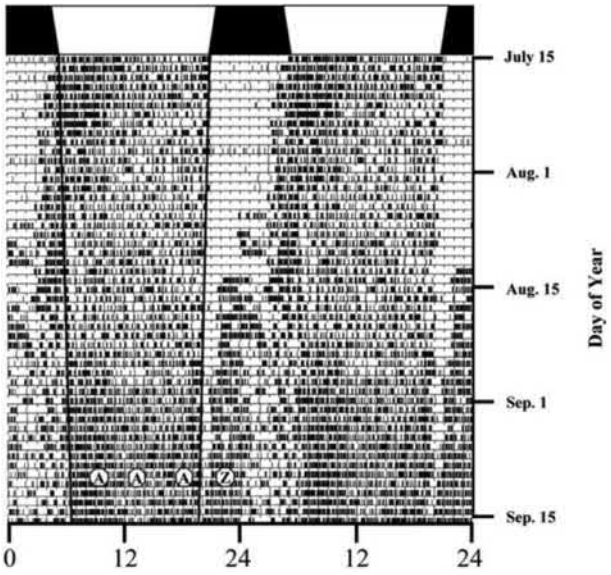

FIGURE 43.12 A double-plotted actogram of the activity patterns of a garden warbler exposed to gradually decreasing photoperiod. As photoperiod declines, nocturnal activity (*Zugunruhe)* emerges from August 5 until the end of the experiment. *From Bartell and Gwinner (2005).*

migratory direction and a southeastern autumnal migratory direction in the laboratory. When these strains were crossbred, the migratory vectors of the F1 hybrids were due south (Berthold and Querner, 1981; Berthold et al., 1992). These data strongly support the notion that migration and navigational vectors are genetically determined, but they have no bearing on the timing of migratory behavior nor do they identify candidate genes.

Many species of passerine birds migrate during the night and exhibit vernal and autumnal migrations on a semiannual basis (Rattenborg et al., 2004; Wiltschko and Wiltschko, 2012). These patterns of nocturnal behavior are expressed in the laboratory as nocturnal migratory restlessness or *Zugunruhe*, in addition to the daily diurnal pattern of activity (Figure 43.12; Gwinner, 1989; Stevenson and Kumar, 2017). *Zugunruhe* is controlled on a circadian basis in that it represents an increase in nocturnal activity that free-runs with a circadian period in constant dim light, which can be entrained to a light: dark (LD) cycle (DmDm; Bartell and Gwinner, 2005; Rani et al., 2006). Interestingly, under these conditions, the expression of the diurnal activity pattern and of *Zugunruhe* follows different circadian periods, suggesting that they are governed by separable circadian oscillators.

Zugunruhe is also governed by a circannual clock (Gwinner, 1967, 1989). For example, when willow warblers, *Phylloscopus trochilis*, were maintained in an equinoctial photoperiod for 28 months, the birds continued to display both vernal and autumnal bouts of *Zugunruhe* with periods of approximately 150 days (Gwinner, 1967). More recently, Helm et al. (2009) have established that stonechats also express circannual cycles of *Zugunruhe* under constant equinoctial photoperiods.

The annual change in photoperiod is likely to entrain circannual cycles of migratory behavior. In the laboratory, the experimental lengthening and shortening of photoperiod synchronizes the timing of vernal and autumnal bouts of *Zugunruhe* of many species, including willow warblers, garden warblers, stonechats, and other species (Gwinner, 1989; Bartell and Gwinner, 2005; Rattenborg et al., 2004). However, neither the mechanisms for the circannual clock guiding migration nor the pathways by which they entrain to time of year are well understood (Stevenson and Kumar, 2017).

Neural substrates for the expression and entrainment of migratory patterns are not completely understood either. Because the circadian clock is intimately associated with

migratory behaviors, several studies have asked whether the pineal gland in involved in the timing of *Zugunruhe*. McMillan (1970) showed that PINX of migratory white-crowned sparrows, *Zonotrichia leuchophrys*, abolishes both circadian patterns of perch-hopping behavior and circannual patterns of *Zugunruhe*. Fusani et al. (2011) found that the presence of food increases *Zugunruhe* in garden warblers even as it increases blood melatonin content, and suggested that food, rather than pineal melatonin increases or decreases the expression of migratory behavior. However, in a later paper, these authors showed that melatonin decreased the expression of *Zugunruhe* (Fusani et al., 2013). It is clear that the circadian pattern of melatonin influences the expression of *Zugunruhe*, but it is not at all clear that it affects the timing of the behavior.

Other neuronal substrates for migratory behavior have been suggested based upon neuronal activity. Black-headed buntings maintained in long days (LD 16:8) exhibited either nonmigratory behavior, when only diurnal activity was present, or migratory behavior, when *Zugunruhe* was expressed (Rastogi et al., 2011). Birds were sacrificed and processed for *c-fos* immunoreactivity (fos-lir) at midday and at midnight. Nonmigratory birds exhibited fos-lir in olfactory and visual system structures that were higher during the day than at night. In migratory birds, fos-lir in olfactory and visual system structures were higher at night. In a subsequent study, these authors (Rastogi et al., 2013, 2016) found that fos-lir was dramatically increased in the hypothalamic dorsomedial nucleus during *Zugunruhe*. Interestingly, there was no evidence for *Zugunruhe*-associated fos-lir in either circadian system pacemakers such as the mSCN or vSCN (see Chapter 34).

43.6 Molecular mechanisms of photoperiodism

Yoshimura and coworkers envision an external coincidence model in which circadian oscillators within the MBH are entrained by photoperiod co-localized in that structure (Nakao et al., 2007). When the length of the photoperiod coincides with a ϕ_{pi}, *Dio2* is induced, enabling a metabolic cascade in response to T3 hormone, and gonadal induction occurs. It is not clear, at this stage, what molecular components link the circadian clock to *Dio2* or *Dio3*. The MBH of quail and the PMM of turkeys rhythmically express clock genes (Ikegami et al., 2009; Ikegami and Yoshimura, 2012; Leclerc et al., 2010). The availability of chicken genome sequences has permitted the expansion of studies from single-gene to genome-wide transcriptome analyses in avian species. Microarray analysis of photoperiodism have identified waves of genes that were induced or reduced by long day stimulus, and long day-induced thyrotropin [thyroid-stimulating hormone (TSH)] in the pars tuberalis of the pituitary gland induces *DIO2* expression and reduces *DIO3* expression through the TSH receptor (TSHR)-Gαs-cAMP signaling pathway (Nakao et al., 2008b). Since chronic administration of TSH into the hypothalamus causes full testicular development, it is suggested that the thyrotropin secreted from the *pars tuberalis* is the master factor regulating seasonal reproduction. This result was unexpected because of the well-known function of thyrotropin in stimulation of thyroid gland.

Attempts to identify molecular components timing annual migratory patterns have been mixed. Studies focusing on allelic differences in C-terminal polyglutamine repeats in the circadian CLOCK protein in breeding and migratory patterns of barn swallows, *Hirundo rustica*, suggest a negative selection on "deviant" genotypes (Caprioli et al., 2012; Saino et al., 2013). However, other studies in several different swallow species in the genus *Tachycineta* failed to show similar associations (Dor et al., 2012).

Singh and Kumar (2017) have asked whether daily rhythms in expression of canonical circadian clock genes in the brain of black-headed buntings are altered by *Zugunruhe*. These authors measured mRNA expression of *per2, cry1, Bmal1,* and *Clock* in buntings maintained in short days (LD 8:16), when birds were nonmigratory, and in long days (LD 16:8) in both nonmigratory and migratory states. They found that daily *per2* expression patterns in the telencephalon, optic tectum, and cerebellum were unaffected by photoperiod or migratory state. In the optic tectum and cerebellum, the amplitude and phase of *cry1* and *Bmal1* rhythms were increased in *Zugunruhe*. The data show that clock gene expression in extra-hypothalamic areas of the brain is expressed rhythmically and that they are affected by photoperiod and migratory state, but they fail to provide causal clues to the mechanisms of seasonal migration.

43.7 Comparison to other vertebrate taxa

In marked contrast to nonmammalian vertebrates (Figure 43.13), the eyes are the only photoreceptor organs in mammals. Light information received by the eye is transmitted to the pineal gland through the suprachiasmatic nucleus. Melatonin is secreted during the night as in the case of birds, but the mode of melatonin action on seasonal reproduction had been unclear until recently. It has been demonstrated that melatonin receptors are expressed in the *pars tuberalis* of mammals and that melatonin suppresses TSH expression in the *pars tuberalis* via the MT1 melatonin receptor (Ono et al., 2008; Hanon et al., 2008; Yasuo et al., 2009).

Most fish living in temperate zones also exhibit a photoperiodic response and the involvement of thyroid

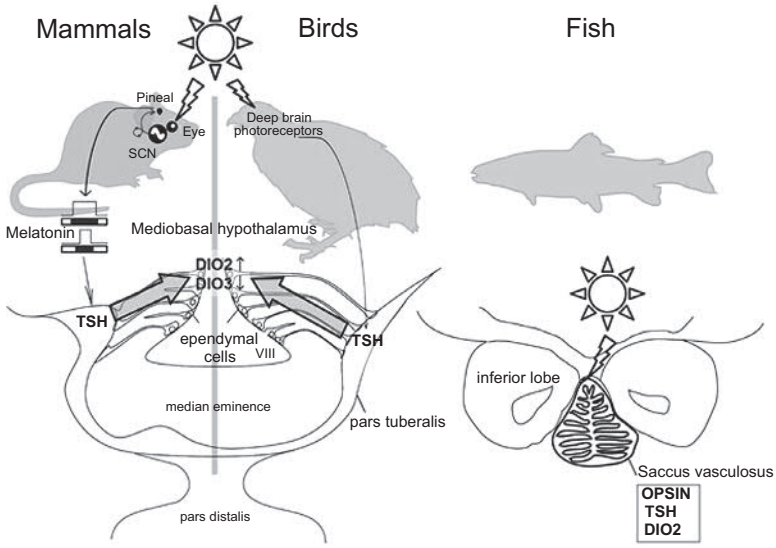

FIGURE 43.13 Vertebrates share common pathways for reproductive seasonality, but vary in several aspects. In mammals, light information arrives in the tuberal hypothalamus via transduction of the pineal hormone melatonin within the *pars tuberalis*, while in birds and fish, tuberal hypothalamic structures are directly light sensitive. The signal converge, however, through a common regulation of DIO2 and DIO3.

hormone in seasonal reproduction has been reported extensively. However, fish do not possess anatomically distinct *pars tuberalis*. Recent work has demonstrated that the *saccus vasculosus* (SV) of fish acts as a sensor of seasonal reproduction (Nakane et al., 2013). All the photoperiodic signaling pathways from photoreceptors (opsins) to neuroendocrine output (thyrotropin and DIO2) are localized in the coronet cells of the SV, and isolated SV responds to photoperiodic changes in vitro. Thus, the coronet cells of the SV may be the ancestral seasonal sensor in vertebrates.

43.8 Conclusion

The selective pressures to breed and reproduce at the most advantageous times of year, when food is most likely to be present for the provision of young are particularly strong in the many species of birds that express seasonal rhythms. This is largely due to the relatively large effort birds expend raising their young. In addition, birds' complex life cycles require a concerted orchestration of seasonal events, ranging from migration to molt to courtship to reproduction and so on. This complex phenology shares a variety of mechanisms, but these are not completely known. In oscine passeriforms, for example, the mechanisms by which primary reproductive function, which appear to be regulated by oscillators within the tuberal hypothalamus, are regulated appear to have been functionally separated from those associated with courtship and song, which in part involve pineal melatonin. Future research focused the coordination of other processes such as migration, molt, and female reproduction will go a long way toward fully understanding the complex seasonality of birds.

44.1 Introduction

Research into the mechanisms underlying the annual cycles of birds began in the 1920s with the pioneering work of Rowan (1925, 1926) exploring effects of changing photoperiod on migratory and reproductive physiology and behavior. Subsequent studies have progressed toward a deep understanding of these mechanisms at the organismal, cellular, and molecular levels. In recent decades, there has been a push to move beyond the breeding and migration stages and study the entire annual schedule, as well as seasonal changes in important processes such as immune function, stress responsivity, and metabolic restructuring. Climate change is leading many researchers to ask how timing mechanisms may influence the response of avian taxa to a rapidly changing environment. This chapter will focus on the current state of research on avian annual schedules, highlighting these areas of recent progress and interest. Birds continue to be exciting and productive models for understanding the basic mechanisms by which organisms respond to the environment and for revealing the importance of these proximate mechanisms in evolution.

44.2 Background: patterns of environmental variation and avian annual schedules

Long-term changes in physiology, behavior, and morphology, orchestrated by the neuroendocrine and endocrine systems, are prominent in most species of birds. In many cases, these changes create consistent annual schedules. This is typically the case for animals that experience predictable seasonal changes in environmental conditions that can exert selective pressures on timing (the "Ultimate Factors" of Baker, 1938), such as species that spend all or part of the year at mid to high latitudes (Figure 44.1A and B) or those in tropical areas with regular seasonal patterns of rainfall (Figure 44.1C). Less consistent long-term changes in physiology, behavior, and morphology prevail in species occupying environments where conditions change more erratically, such as certain deserts where rainfall is unpredictable (see Perfito et al., 2007 and also Figure 44.1D) or even in otherwise seasonal environments where variation in the food supply is not regularly seasonal (see Hahn et al., 1997, 2008). In at least some of these species (e.g., crossbills; *Loxia* spp.), temporally flexible changes in physiology, behavior, and morphology are superimposed on underlying seasonal cycles (Hahn, 1995, 1998; Hahn et al., 1997, 2008; Cornelius and Hahn, 2012; Cornelius et al., 2021). In others (e.g., Darwin's finches), it remains unclear to what extent changes in reproductive physiology are entirely opportunistic versus based in part on an underlying seasonal program (Hau et al., 2004; Hahn et al., 2008).

Whether regularly seasonal, flexible, or erratic, all annual schedules must coordinate reproduction and plumage molt, and many incorporate migrations and a nonbreeding "overwintering" stage (Wingfield, 2008). Timing and coordination of these processes is crucial to fitness and the regulatory mechanisms responsible for this can respond to selection (Bradshaw and Holzapfel, 2007, 2010; Helm et al., 2019). The timing mechanisms that evolve are based on cue response systems that link neuroendocrine and endocrine regulatory mechanisms to "Proximate Factors" (c.f. Baker, 1938)—cues such as daylength, temperature, food supply, and social interactions—that provide predictive information either in the short- or long-term regarding fluctuating Ultimate Factors in the surrounding environment. These cue response systems generally include a long-term component that sets the time

Sturkie's Avian Physiology. https://doi.org/10.1016/B978-0-12-819770-7.00039-6

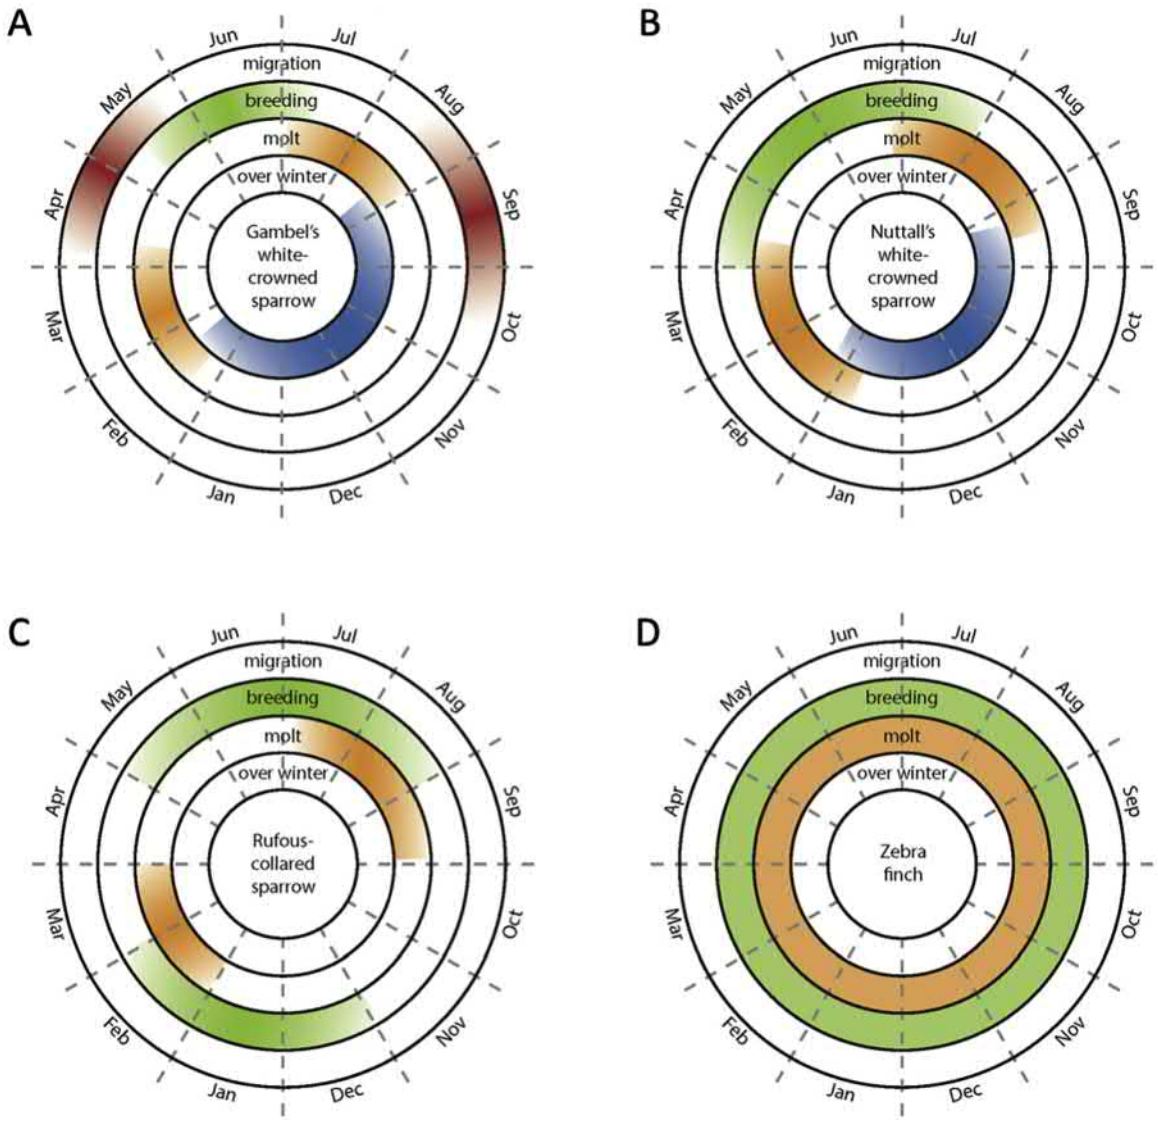

FIGURE 44.1 Diagrammatic representation of the annual schedule of the Gambel's white-crowned sparrow (A), Nuttall's white-crowned sparrow (B), Rufous-collared sparrow (C), and Zebra finch (D). Each concentric ring represents a life history stage: migration, breeding, molt, and overwintering (from outer ring to inner ring). The shading of life history stage represents the relative occurrence of that life history stage at the population level (higher intensity shading represents more birds in the population exhibiting that stage). Gambel's white-crowned sparrows are long-distance migrants and exhibit a constrained breeding season in northwestern North America. Nuttall's white-crowned sparrows also live in temperate climates but lack migration and exhibit greater flexibility in timing of breeding. The rufous-collared sparrow exhibits two defined breeding periods per year, both following seasonal rains. In contrast, zebra finches in arid Australia breed rapidly after unpredictable rain events, and therefore could be found breeding throughout the year depending upon local conditions.

windows when particular cycle stages can occur, and that dictates general features of physiological preparation for and termination of the stages. This long-term component is based on some combination of response to changing photoperiod and an endogenous program (so-called Initial Predictive cues of Wingfield, 1980, 1985; Gwinner, 1986; Wingfield and Kenagy, 1991; Wingfield and Farner, 1993; Dawson, 2002; Bradshaw and Holzapfel, 2007; Wikelski et al., 2008; Helm et al., 2013). Long-term timing is refined by responses to more immediate cues that provide accurate short-term information about local conditions, such as changing temperature, weather, food supply itself, and behavioral cues from other individuals (Wingfield, 1980, 1985 and below in Section 44.3).

Annual schedules of different species vary in their complexity and therefore potentially in the mechanisms required to orchestrate them. As shown in Figure 44.1, different species may exhibit one or more stages of migration, reproduction, or molt over the course of the year. The different components can theoretically overlap

temporally (within an individual or across the population) or occur in distinct time periods (Jacobs and Wingfield, 2000; Wingfield, 2008). Certain activities simply cannot overlap (e.g., egg-laying, incubation, and care of nestlings are incompatible with migration), but many components of "breeding," such as the gonadal maturation process (Wingfield et al., 1992; Bauchinger et al., 2007, 2008, 2009), pair formation (Ganter et al., 2005), and extended parental care of fully mobile youngsters can be compatible with migration, and plumage molt need not be incompatible with any stage of reproduction (Bond et al., 2013) or migration (Yuri and Rohwer, 1997; Voelker and Rohwer, 1998). The degree of overlap between reproduction, migration, and molt can be viewed as a continuum, from near-complete temporal separation at one extreme to near-complete temporal overlap (within constraints noted above) at the other. This variation in overlap of seasonal stages represents a critical trade-off between temporal flexibility and tolerance for environmental variation. Two relatively extreme examples illustrate this concept (Wingfield, 2008, Figure 44.1A and D). A regular seasonal migrant, the Gambel's white-crowned sparrow (*Zonotrichia leucophrys gambelii*) displays a six-part annual schedule consisting of separate and minimally overlapping stages of overwintering, partial prealternate molt, vernal migration, breeding, complete prebasic molt, and autumnal migration (Figure 44.1A). The phenotypic traits expressed during each of these stages broaden the scope of environmental variation the birds can tolerate (e.g., temperatures that can be endured, foods that are acceptable) across the entire year as compared to tolerances within any one stage. This benefit comes at a cost of temporal flexibility; however, breaking the year into multiple stages, each with unique phenotypic characteristics requiring time and energy to initiate and terminate, reduces how nimbly the animal can adjust to any environmental changes that deviate from the normal routine it has evolved to track. In contrast, certain desert-dwelling reproductive opportunists such as zebra finches (*Taeniopygia guttata*) in parts of the arid interior of Australia display such extensive overlap between stages that no truly separate stages exist (Figure 44.1D). Although the birds do not breed continuously, they can maintain near-readiness to breed for long periods of time and they display a low-intensity but essentially continuous plumage molt that may overlap with both breeding and any short-distance nonmigratory movements that do occur (Cornelius et al., 2011). Expression of this single chimaera stage confers high-temporal flexibility, since any activity is possible at any time, but at the cost of scope for tolerating environmental extremes. This strategy is an example of the jack-of-all-trades being master of none (Huey and Hertz, 1984).

The capacity to express these different patterns depends on coordination mechanisms. Specifically, separation of the annual schedule into distinct stages requires synchronization mechanisms that align the cycle and environment, as well as coordination mechanisms that limit overlap between stages, maintain stages in an adaptive sequence, and orchestrate transitions from stage to stage so that processes involved in termination of one do not interfere with processes involved in development and onset of the next (Wingfield, 2008). In contrast, if components are to overlap partially or completely, mechanisms that facilitate this overlap must be present. The next section will address recent advances in understanding the mechanisms by which diverse annual schedules are generated. We will return below to the question of whether these diverse patterns reflect adaptively specialized mechanisms or plastic outputs of common mechanistic underpinnings.

44.3 Effects of environmental cues on annual scheduling and underlying mechanisms

44.3.1 Photoperiodic response

Annual schedules that track consistent seasonal changes in the environment depend on proximate responses to changing photoperiod (Rowan, 1925, 1926; Dawson et al., 2001; Dawson, 2002; Dawson and Sharp, 2007; Bradshaw and Holzapfel, 2007). A system that uses photoperiod as a proximate cue for regulation of annual schedules (either as a driver or as an entrainer of an endogenous program, see Chapter 43) requires: a mechanism for detecting light (photoreceptors); a mechanism for determining the length of the day (known in birds to depend on a circadian clock) and; a mechanism for transducing the photoperiod information into neuroendocrine and endocrine signals that regulate the different components of the schedule, such as the septo-infundibular gonadotropin-releasing hormone (GnRH) system that regulates reproduction (see Follett, 1984).

Most birds breed seasonally on long days, and their annual reproductive cycle breaks naturally into three stages: (1) sensitivity, (2) stimulation, and (3) refractoriness (Ball, 1993; Dawson et al., 2001; Goodson et al., 2005). The transition from being *sensitive* to long days, but reproductively inactive, to *stimulated* by long days depends on responding to increasing daylength as an activational cue. Birds possess a circadian cycle of photoinducibility, whereby light occurring during a window of circadian time acts as a stimulatory long day, and activation of the hypothalamo–pituitary–gonad (HPG) axis results (Hamner, 1963, 1964; Follett et al., 1974, Figure 44.2).

Early studies demonstrated that detection of the light cue regulating seasonal cycles of birds is not retinal (Benoit, 1935) or pineal (Wilson, 1991). For example, all key

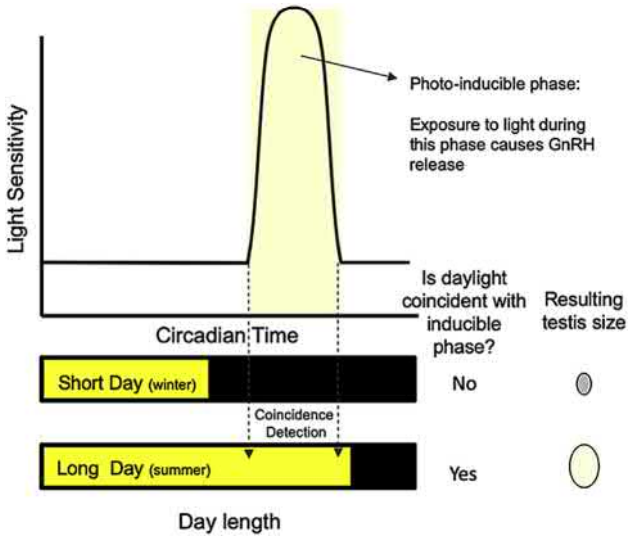

FIGURE 44.2 Illustration of the 24 h circadian cycle of photoinducibility displayed by photoperiodic birds. The reproductive system is responsive to the stimulatory effects of light during a particular phase of the circadian cycle, represented by the peak between about circadian hours 12 and 20 in the top panel. On short days, the light period always ends before this inducible phase begins; hypothalamo-pituitary activity remains minimal and gonads remain small (middle panel). On long days, the light period extends beyond the beginning of the inducible phase; hypothalamo-pituitary activity increases, and the gonads grow (bottom panel). Experiments manipulating the circadian time when short pulses of light (8 h or less) occur demonstrate that it is not light duration, but light exposure relative to circadian time that determines whether the bird activates the reproductive axis (e.g., Hamner, 1963, 1964; Follett et al., 1974).

components of avian photoperiodism—photostimulation and photorefractoriness in response to long days, and dissipation of the refractory state in response to short days—are expressed normally in pinealectomized/enucleated American tree sparrows (*Spizella arborea*; Wilson, 1991). Deep brain photoreceptors are responsible for photodetection regulating seasonality in birds and other nonmammalian vertebrates (Silver et al., 1988, see reviews in Foster et al., 1994; Foster and Soni, 1998). These cerebrospinal fluid (CSF) contacting neurons are thought to reside in the mediobasal hypothalamus (MBH) and/or lateral septum (LS); recent studies increasingly point to the cells in the LS as the key photodetectors in the avian photoneuroendocrine system (Li et al., 2004). Details of how the long day cue is transduced are emerging, although virtually all of the work to date is restricted to Japanese quail (Figure 44.3). In quail, these photoreceptors (Opsin 5-positive CSF-contacting neurons) detect light (Nakane et al., 2014). When light occurs during the inducible phase of the circadian cycle of photoinducibility (Figure 44.2), this long day signal is transmitted to thyroid-stimulating hormone (TSHB)-producing cells in the pars tuberalis (PT). TSH from these cells putatively acts on the nearby ependymal cells lining the third ventricle, inducing transcription of the iodothyronine deiodinase 2 (*Dio2*) gene, and downregulating the iodothyronine deiodinase 3 (*Dio3*) gene. These genes code for Type 2 and Type 3 deiodinase enzymes which regulate the availability of T3 (3,5,3′-triiodothyronine), the physiologically active form of thyroid hormone (Figure 44.3). Under short-day conditions (low-*Dio2* expression, high-*Dio3* expression), T3 is low and glial endfeet appear to ensheath axon terminals of GnRH cells, separating them physically from the basal lamina in the median eminence (ME) and presumably obstructing GnRH secretion into the hypothalamo-hypophysial portal blood. As a result, gonadotropin release from the anterior pituitary remains low under short days. In contrast, under long days, *Dio2* expression in the ependymal cells is enhanced (and *Dio3* expression is reduced). Thus T3 release is high under long days, and this may cause retraction of the glial endfeet sheathes so that GnRH axon terminals are closely apposed to basal lamina and GnRH release is high, leading to high-gonadotropin secretion and gonadal growth (see Ikegami and Yoshimura, 2012 for review). More recent studies have reported the existence of another neuropeptide involved in regulating reproduction (gonadotropin-inhibiting hormone), which inhibits GnRH, and research on its role in seasonal timing is ongoing (reviewed in Tsutsui et al., 2013; Kriegsfeld et al., 2018).

Whether the scenario outlined above applies generally to photoperiodic regulation of avian seasonality or only to Japanese quail exposed to abrupt changes in photoperiod remains unclear. Recent studies using quantitative PCR of whole hypothalamic punches in red-headed buntings (*Emberiza bruniceps*) report results comparable to those found in Japanese quail (Trivedi et al., 2019), with an increase in TSHB and a reciprocal switch in *Dio2* and *Dio3*

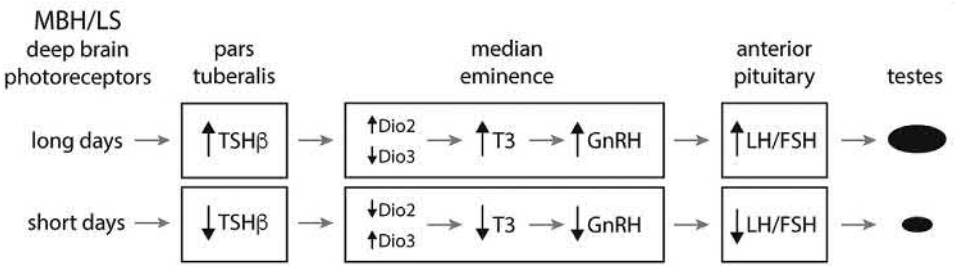

FIGURE 44.3 Illustration of the key components of the photoneuroendocrine system of the Japanese quail (*Coturnix japonica*). Full explanation in text.

expression upon exposure to an LD photoperiod. However, seasonal changes in *Dio2* and GnRH expression in European starlings (*Sturnus vulgaris*) allowed to breed in outdoor aviaries on naturally changing photoperiod are not consistent with the quail-based model (Bentley et al., 2013). Specifically, breeding males with maximal testis volume and GnRH expression did not have significantly higher *Dio2* expression in the MBH than did refractory individuals on declining photoperiod. Further, photosensitive individuals with small gonads on still-declining photoperiod in autumn had higher *Dio2* expression than did photostimulated individuals in spring. It is not known whether the distinct patterns in quail and starlings result from phylogenetic differences, differences in photoperiodic characteristics (starlings becoming absolutely refractory, whereas quail become only relatively refractory-see discussion below), or differences in the experimental conditions used (naturally changing photocycles for starlings, stepwise changes in photoperiod for quail). Regardless of the explanation, it is clear that more work testing the effects of different photoperiod conditions on a wider range of species is needed to identify robust general features of the neural mechanisms underlying photoperiodic regulation of annual schedules in birds (Bentley et al., 2013).

In the last decade, several studies have sought to further refine our understanding of the connection between a circadian cycle of photoinducibility and the decision of the photoneuroendocrine system to increase TSHB within the PT. EYA transcriptional coactivator and phosphatase 3 (EYA3; a molecule in the "eyes absent" family of proteins that may function in transcription activation) is one potential link between photoperiodic time measurement and TSHB expression under preliminary investigation (Nakao et al., 2008; Majumdar et al., 2014; Trivedi et al., 2019). While the exact link is still under study, it is clear that circadian systems and the photoneuroendocrine system are closely connected. Cells within the MBH maintain steady expression profiles of key clock genes under different photoregimes, consistent with the possibility that they are fundamentally responsible for maintaining the temporal phasing of photoinducibility (Yasuo et al., 2003, see also Ikegami and Yoshimura, 2012). These details apply to the process of photostimulation, which leads to development of the reproductive axis as well as preparations for spring migration. However, there may be critical differences in how photic induction of reproduction and migration are controlled as one recent study suggests that photoperiodically induced migratory development can be dissociated from gonadal development under different wavelengths of light (Wang et al., 2013).

At the end of the reproductive season, gonads regress and lose reproductive functionality in seasonal breeders. The transition out of the reproductive state generally depends on the development of photorefractoriness (Nicholls et al., 1988; Hahn et al., 1997; Hahn and MacDougall-Shackleton, 2008). In birds, photorefractoriness is a physiological state in which the reproductive axis is unresponsive to the stimulatory effects of long-day photoperiods (Nicholls et al., 1988). The extent to which different species become refractory is variable. In absolute refractoriness, even stimulation with constant light cannot cause gonads to grow or be maintained, while in relative refractoriness, unseasonably long photoperiods and sometimes stimulatory nonphotoperiodic cues (e.g., food) may cause gonadal maintenance or recrudescence (reviewed in Nicholls et al., 1988; Hahn and MacDougall-Shackleton, 2008).

Expression of absolute photorefractoriness is a two-stage process involving cessation of release of GnRH at the ME followed by a dramatic decline in the presence of the GnRH peptide and reduction in transcription of the GnRH gene (Ubuka et al., 2009; Stevenson and Ball, 2009; Stevenson et al., 2012a; see Stevenson et al., 2012b for review). Return of photosensitivity is associated with reappearance of the GnRH-I peptide first in the preoptic area, and then in the ME in European starlings (Dawson and Goldsmith, 1997); as refractoriness dissipates, birds become progressively more responsive to long days (Hamner, 1968). Species vary in the extent to which steroid feedback during fall and winter helps to keep gonadotropin secretion of photosensitive individuals in check until days increase sufficiently for photostimulation (Cockrem, 1995). Importantly, development of photorefractoriness of the reproductive axis does not necessarily mean that photoperiod is unimportant in the postbreeding season. The decrease in daylength can impact autumnal migration, including in first-year birds: migratory juvenile long-tailed tits exposed to an accelerated decline in photoperiod during their autumn migration increased their diurnal migratory activity relative to those on a normal photoperiod (Bojarinova and Babushkina, 2015). Similarly, daylength appears to influence food-storing behavior outside the breeding season in chickadees and titmice (e.g., Clayton and Cristol, 1996; MacDougall-Shackleton et al., 2003).

44.3.2 Processing of nonphotic cues

Overwhelmingly, research into the effects of nonphotic cues on annual schedules focuses on the initiation and termination of breeding. Here we review that literature, while also calling attention to an important body of work evaluating how nonphotic cues affect molt and migration. Such cues are also sometimes called supplementary and synchronizing cues, to differentiate them from the photoperiodic cues that initiate life history stage transitions (Wingfield 1980, 1985 and see Section 44.3.3). In general, there is much more information on the phenomenology and physiological consequences of nonphotic cues than there is

on the mechanisms by which these cues are processed. We highlight work on the effects of temperature, food, and social information on the annual schedule, which have been investigated in detail. Importantly, these are not the only nonphotic cues that regulate timing decisions; water (Perfito et al., 2006; Wingfield et al., 2012; Prior et al., 2013; Quispe et al., 2018), cues from predators (Monkkonen et al., 2009), and interactions with nesting material (Slater, 1969; Gwinner et al., 1987) also affect the annual cycle.

44.3.2.1 Effects of temperature

In many mid and high-latitude ecosystems, ambient temperature is correlated with local variation in vegetation and food phenology and is a reliable proximate cue that can be used to fine-tune timing of transitions between life cycle stages. Experimental studies in photoperiodic species suggest that while temperature manipulations can have variable effects on gonadal development and initiation of egg laying, high temperatures fairly consistently advance the onset of gonadal regression (reviewed in Chmura et al., 2020) and prebasic molt (Blackmore, 1969; Wingfield et al., 2003; Dawson, 2005). Fewer experimental studies have investigated effects of temperature on the timing of migration, but a growing body of descriptive work using tracking technologies suggests that temperature is important for at least some substages of migration.

The effects of temperature on reproductive development appear to be locally adapted as a function of breeding latitude (Wingfield et al., 1996, 1997, 2003; Silverin et al., 2008, Figure 44.4) elevation (Perfito et al., 2005), and status as a migrant or resident (Meijer et al., 1999; Dawson, 2005). These findings support theoretical predictions that populations inhabiting more predictable environments will be less responsive to supplementary environmental cues than those inhabiting less predictable environments (Wingfield et al., 1992, 1993). Response to temperature cues may be sex-specific. A few studies suggest that the annual schedule of males and females responds differently to temperature cues. High temperature advanced brood patch and follicular development in female Puget Sound white-crowned sparrows, while testis development in males was unaffected (Wingfield et al., 1997). This supports theoretical predictions that female reproductive development will be more responsive to nonphotic cues than male reproductive development (Ball and Ketterson, 2008). Birds appear to be more responsive to temperature increases across the season than to average daily temperature or daily temperature fluctuations (Schaper et al., 2012). It is important to note that different results have been obtained when using different artificial fixed photoperiods (Silverin and Viebke, 1994; Silverin et al., 2008), or using naturally changing photoperiods versus artificially long or short days (Dawson, 2005).

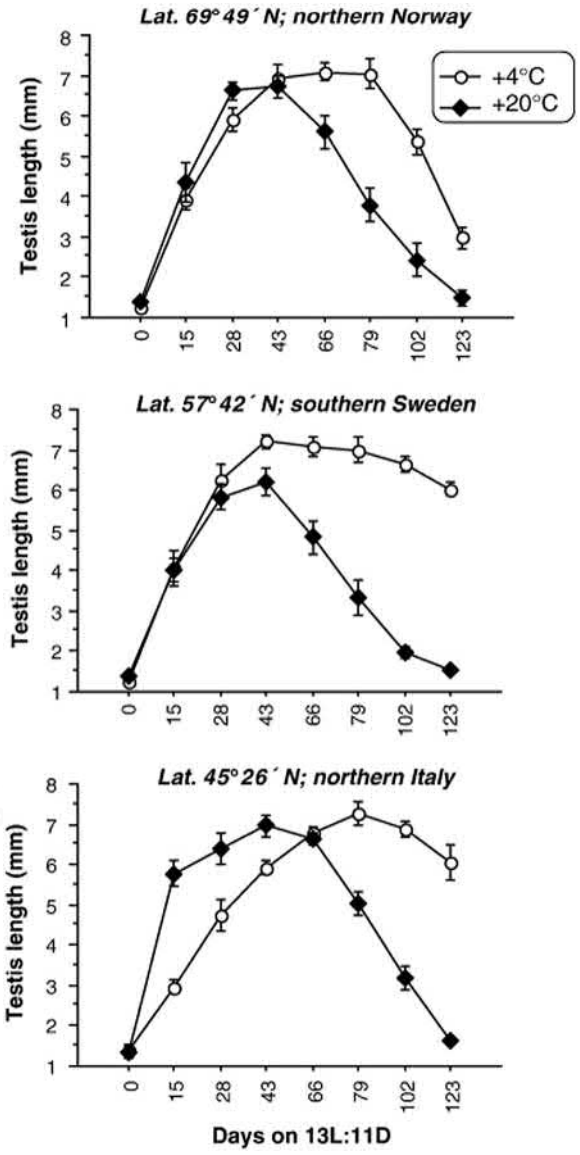

FIGURE 44.4 Effects of different temperature treatments on photoinduced gonadal development in male great tits (*Parus major*) from populations living at three different latitudes. Low temperature delayed termination of reproductive competence in all three populations but only affected rate of gonadal development in the lowest latitude population. *From Silverin et al. (2008).*

Typically, ambient temperature is detected by thermoreceptors in the periphery and while these receptors may detect seasonal changes in temperature, this has not been tested (Caro et al., 2013). Most research on supplementary cues has examined the effect of temperature on the HPG axis and other hormonal mediators associated with reproduction. Only a few studies look at hypothalamic regulators of temperature responsiveness; however, a recent study in

red-headed buntings found that a high-temperature manipulation increased expression of TSHB, *Dio2*, and GnRH in whole hypothalamic punches relative to controls (Trivedi et al., 2019). Findings in circulating hormones, for example, the effect of temperature manipulations on luteinizing hormone (LH) secretion (Wingfield et al., 1996, 1997, 2003; Silverin et al., 2008) and prolactin secretion (Maney et al., 1999; Perfito et al., 2005; Dawson and Sharp, 2010), are inconclusive. Thyroid hormones are also likely candidates for mediating temperature effects (Caro et al., 2013). In one strain of domesticated Japanese quail, the transition to refractoriness appears to require temperature-dependent conversion of T4 to T3 (Wada et al., 1990; Wada, 1993). It would be particularly interesting to explore the temperature dependence of local production of T3 in the MBH of this strain of quail in light of recent discoveries regarding this process in quail photoperiodism (see Section 44.3.1).

Additional studies propose that thyroid hormones, as mediators of metabolism, may play a role in reproductive timing through changes in energy balance. One model proposes that low temperatures, and associated thermoregulatory costs, constrain the resources available to modify aspects of physiology needed for transitions between cycle stages (Meijer et al., 1999). Though this is an intriguing possibility, this hypothesis has not been rigorously tested and the mechanisms by which physiological decisions about energy allocation are made remain largely unknown. Great tits exposed to high and low-temperature treatments did differ in oxygen consumption, but without coincident differences in testis growth rate (Caro and Visser, 2009). This implies no significant energetic constraint of temperature on gonadal growth in males, but an impact of temperature on female reproductive investment may be more relevant given the high-energy cost of yolk deposition. Further, other trade-offs may have buffered the impact in males (e.g., a decrease in immune function). In house sparrows, basal metabolic rate (BMR) and thyroid hormone levels were positively associated, and early breeding birds had an earlier peak in thyroid hormone than late breeding birds (Chastel et al., 2003). Perhaps late breeders face a metabolic constraint that prevents them from breeding early, and thyroid hormones play a role in mediating this relationship (Chastel et al., 2003). Further studies, especially investigations including females who face greater energy demands during follicle maturation, are needed.

A growing body of research indicates that temperature impacts migratory arrival in the north-temperate zone. While timing of departure is thought to be largely influenced by circannual rhythms in concert with stimulatory photoperiods and permissive flight conditions, the progression along the migratory route and arrival at remote breeding grounds is more influenced by local supplementary cues. Timing of arrival of migrant shorebirds at arctic breeding grounds, for example, is tightly correlated with snow-cover, which is in turn closely related to temperature. Ely et al. (2018) argues that temperature is the most likely cue inducing the final stage of migration from the staging grounds. Interestingly, the order of arrival remains species specific even across years that vary in absolute arrival dates—suggesting that different species have different thresholds to supplementary cues like temperature and/or that they may be using different supplementary cues (e.g., interspecific social cues) to fine-tune arrival. Migratory geese similarly use local temperature cues to infer information about the advancement of spring and to make departure decisions from stopover locations while en route (Bauer et al., 2008). Songbirds breeding at north-temperate latitudes also appear responsive to climate and temperature. Many studies have argued that arrival of migrant birds at breeding sites in Europe and North America correlates with large-scale climatic events like North Atlantic Oscillations (Forchhammer et al., 2002; MacMynowski et al., 2007), but a recent meta-analysis casts substantial doubt on that theory and instead argues that finer-scale differences in local weather conditions may be more important for predicting arrival of migrant species (Haest et al., 2018). Indeed, local temperature outperforms large-scale climate cues as the best predictor of arrival in several studies utilizing data from long-term ringing of passerines (Marra et al., 2005; Tøttrup et al., 2010).

Studies of free-living birds, however, are correlational, and it is unclear if these results are due to direct responses to temperature or indirect responses linked to changes in other cues, such as food availability. Experimental studies concerning effects of temperature on development of migratory behavior in captivity are fewer in number and somewhat equivocal in result. Some experimental investigations find that warmer temperatures advance the onset or intensity of nocturnal migratory activity in captive birds (Lewis and Farner, 1973; Nakamura and Kitahara, 1983; Metcalfe et al., 2013) and others that warmer temperatures attenuate migratory behavior and reduce premigratory fattening (Singh et al., 2012; Berchtold et al., 2017). In some of these studies, very high or very low temperatures completely suppress migratory activity (Eyster, 1954; Lewis and Farner, 1973). Thus, temperature appears to be permissive, allowing for fine-tuning of progression along the migratory route following induction by photoperiod and circannual rhythms.

The effects of temperature on the termination of reproduction and onset of prebasic molt are more consistent across species studied to date. Exposure to biologically relevant, warmer temperatures advances gonadal regression

and onset of prebasic molt in multiple studies (Storey and Nicholls, 1982; Wingfield et al., 2003; Dawson, 2005; Visser et al., 2011; Watts et al., 2018). The adjustment of molt timing in response to temperature is probably closely tied to changes in the timing of reproduction. Many field studies document advanced onset of prebasic molt that is coincident with advanced termination of breeding (Dawson, 2005; Barshep et al., 2011; Jukema and Wiersma, 2014). Similarly, delayed onset of molt is associated with delayed termination of reproduction (Barshep et al., 2011; Morrison et al., 2015) and with faster, more intense molt schedules (Morrison et al., 2015). Scheduling of breeding thus influences molt schedules, with later onset leading to more rapid molt schedules as the autumnal migration approaches.

44.3.2.2 Effects of food

The entire photoneuroendocrine timing system in birds has presumably evolved as a consequence of selection for tracking seasonal changes in food supply. However food itself is also a potent supplementary proximate factor (Hahn et al., 2005) that can assist in fine-tuning transitions of the annual schedule to local conditions. Studies of the proximate effects of food on annual schedules include correlative field studies, experimental field studies, and experimental studies with captive birds.

There is some evidence that natural changes in food supply affect migration schedule. For instance, free-living American redstarts (*Setophaga ruticilla*) alter spring departure date across years as a function of variation in rainfall and arthropod abundance (Studds and Marra, 2011). Likewise, redstarts wintering in higher quality (wetter, better food supply) habitats arrive on the breeding grounds earlier than those from lower quality wintering habitat (Marra et al., 1998; Tonra et al., 2011) and experimental reduction of food on wintering territories delays onset of migration (Cooper et al., 2015). Drought in stopover areas has been implicated in dramatic delays in arrival on breeding grounds by trans-Saharan migrants, probably because of reduced refueling rates owing to poor food supplies (Tøttrup et al., 2012). Some experimental evidence also supports the interpretation that food supply can affect timing of migration. Free-living American redstarts that are experimentally "upgraded" from low-quality winter habitat by creating vacancies for them in nearby high-quality habitat show earlier spring migration departure (Studds and Marra, 2005). Likewise, dark-eyed juncos brought temporarily into captivity and subjected to experimental diets (restricted vs. copious) vary in migration departure date (inferred from resighting surveys after release), with individuals displaying higher body condition indices departing earlier (Bridge et al., 2010). Together these data are consistent with the idea that food supply can act as a supplementary cue, influencing details of migration timing under major control by photoperiod and/or an endogenous program perhaps through changes in body condition. The mechanisms whereby food supply and body condition impact decisions are still being worked out. Recent work suggests a role for the hormone ghrelin, which relates to fat stores (a strong predictor of migratory condition) and can enhance migratory restlessness in captive birds when given exogenously (Goymann et al., 2017), but a field study in migratory blackbirds did not find correlations between ghrelin and either fat levels or departure time (Eikenaar et al., 2018b). Corticosterone has also been implicated in departure decisions (Cornelius et al., 2013), and several studies link plasma concentrations to timing of departure (Eikenaar et al., 2017, 2018a, 2020). The migratory behavior of some irruptive species, such as red crossbills, may be tied even more closely to food supply as they appear to cease breeding and initiate long-distance movements in direct response to declines in food supply (Benkman, 1990; Hahn, 1998). Experimental studies with captive crossbills indicate that these birds are very sensitive to changes in food supply, modifying activity, fat deposition, and circulating corticosterone levels in ways consistent with the hypothesis that they use food availability as a cue to regulate timing of migratory movements (Cornelius et al., 2010).

Numerous studies in the field, and a few in captivity, have manipulated aspects of food supply to determine how responsive the reproductive axis is to food as a proximate cue. Food supplementation of free-living birds generally advances timing of egg-laying (Arcese and Smith, 1988; Meijer et al., 1990; Nager and van Noordwijk, 1995; Schoech, 1996; Ruffino et al., 2014). Availability of calories is not all that matters. For instance, in calcium-poor environments, calcium supplementation can significantly advance egg-laying date (Mand et al., 2000). Even in captive birds fed ad libitum, the presence of preferred foods can modulate reproductive physiology (e.g., Furlonger et al., 2012). Some elegant field experiments have provided groups of free-living Florida scrub jays with isocaloric food supplementation that differs in protein content. Although food supplementation with either high protein or low-protein pellets advances egg-laying date compared with unsupplemented controls, the high-protein supplement advances lay date significantly more than the low-protein supplement (Schoech et al., 2004). More recent studies have examined the effects of antioxidants on reproductive timing and gonadal development and report mixed results (Costantini et al., 2016; Carbeck et al., 2018). Meta-analyses of the results of field experiments reveal a latitude effect on responsiveness to food supplementation; high-latitude populations are less responsive to the advancing effects of food supplementation than low-latitude populations (Schoech and Hahn, 2007; Ruffino et al., 2014). However, the

representation of low-latitude populations in both analyses is very small. Further, one study suggests that the apparent latitude effect could be the consequence of whether populations are single or multiple brooded (Dhondt, 2010), although this result was not duplicated in a recent meta-analysis (Ruffino et al., 2014). In any case, these analyses are consistent with the interpretation that populations vary locally in responsiveness to supplementary cues fine-tuning reproductive timing.

Captive studies suggest that the effects of food on reproductive development, in the absence of concomitant photostimulation, are subtle. This is the case even in flexible breeders such as crossbills (Hahn et al., 2005). However, effects of food manipulations in photostimulated birds can be quite dramatic. For instance, pine siskins (*Spinus pinus*) living on modestly stimulatory photoperiod and provided seeds in addition to commercial pellets show dramatically advanced gonadal development compared with those lacking seeds, and this effect occurs irrespective of social environment (Watts and Hahn, 2012, Figure 44.5). In tropical spotted antbirds (*Hylophylax naevioides*), food cues can have dramatic effects on timing of reproductive development (Hau et al., 2000; O'Brien and Hau, 2005), and at least part of this effect appears to be via non-nutritional pathways; exposure to live insect food, even if it cannot be eaten, has a pronounced positive effect on singing behavior (Hau et al., 2000). This is similar to some flexibly breeding temperate zone species, such as pinyon jays, which can show late summer reproductive development if allowed to handle as well as consume seeds from fresh developing pinyon pine cones (Ligon, 1974). However some work in canaries (*Serinus canaria*) indicates that multimodal presentations of food are a more potent stimulus of reproductive development than unimodal presentations of food cues (Voigt et al., 2011). It is important to note that effects of long days on reproductive development could potentially be explained in part by increases in food intake under longer days; however, experimental restriction of time available to feed or amount of food provided to short-day levels reveal only modest effects of food as compared with photoperiod, even in the very flexible crossbills (Dawson, 1986, 2018; Hahn, 1995; Hahn et al., 2005). Davies and Deviche (2014) provide an exhaustive review detailing how hormonal mechanisms may connect food cues to reproductive timing.

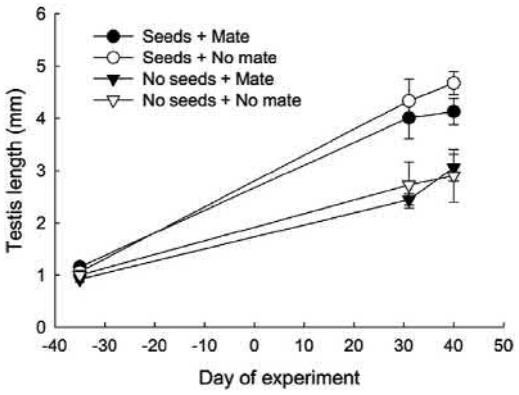

FIGURE 44.5 Effect of provisioning with sunflower and thistle seeds in addition to commercial pellet diet, as compared with pellet diet alone, in pine siskins (*Spinus pinus*). Access to seeds accelerated photoinduced gonadal development comparably whether or not the males were housed with a conspecific female. *From Watts and Hahn (2012).*

It remains important to consider the extent to which effects of food are direct ("income" effects) or operate indirectly through effects on body condition and reserves ("capital" effects; Drent and Daan, 1980; Meijer and Drent, 1999). At least part of the effect of elevated protein on laying date in scrub jays is likely to be through improved condition and protein reserves in females (i.e., may be a capital effect; see Schoech et al., 2004). Capital effects on reproductive output are well-known in large birds (e.g., snow geese; Ankney and MacInnes, 1978), but some of the effects in food supplementation experiments are consistent with nutrient reserves (capital effects) influencing reproductive timing of small passerines (see Arcese and Smith, 1988).

Food availability in north-temperate species may similarly impact molt, either through the rate of individual feather growth (Murphy et al., 1988; Swaddle and Witter, 1997) or through impacts on timing of molt onset or duration (Murphy et al., 1988; Meijer, 1991; Swaddle and Witter, 1997; Freed and Cann, 2012; Class and Moore, 2013; Danner et al., 2015; Faccio et al., 2018). However, the effects of food cues on timing of molt have not received a lot of attention.

44.3.2.3 Effects of behavioral factors

Behavioral interactions between conspecifics can provide valuable information for fine-tuning timing of transitions of physiology, behavior, and morphology, and are essential for coordination of pair, family, and group activities (Wingfield and Marler, 1988). Migration, for example, can occur in groups and many studies have found evidence of social cues permitting the synchronization of migratory timing and route selection among group members (reviewed in Helm et al., 2006). Less research examines the mechanisms by which social cues impact migratory behavior, but social cues about food can impact activity levels, corticosterone levels, and expression of corticosterone receptors in the brain in a facultative migrant (Cornelius et al., 2010, 2018). Perhaps because of the interest in the avian song system, and the use of birds as a model in studies of sexual selection, there is an especially robust body of literature examining the role of social cues

on reproductive scheduling (reviewed in Bentley et al., 2000; Helm et al., 2006; Chmura et al., 2020).

Although there are multiple sensory modalities through which behavioral interactions might influence individual schedules, acoustic stimuli from conspecifics have received the most attention. Male song has potent effects on female reproductive development (see Bentley et al., 2000 for a review), and these effects can be very rapid. For instance, female white-throated sparrows (*Zonotrichia albicollis*) exposed to male song show rapid (within 1 h) elevation of circulating LH and enhanced early growth response protein1 (Egr-1 or ZENK) immediate early gene expression in the mediobasal hypothalamus (Maney et al., 2007a,b). Other studies have investigated the effects of social cues by manipulating the presence of a prospective mate, the mate's reproductive status, visual cues provided by a mate, the presence of a social group, and the status of a mate within a social group, among other factors (reviewed in Chmura et al., 2020). Several of these studies also provide evidence for a rapid effect of social cues on reproductive preparation. Work in European starlings suggests that the presence of a male can affect the expression of *Dio2* and *Dio3* in the hypothalamus of females, which is novel in that it was previously thought that only photoperiod influenced this aspect of the HPG axis (Perfito et al., 2015). Note, however, that social cue manipulation did not affect *Dio2* or *Dio3* after a brief period of social exposure in zebra finches (Ernst and Bentley, 2016). In general, presence of a positive social stimulus enhances reproductive development and onset of laying in females, while more variable results have been reported in males. The few studies that have produced negative social environments, for example, by separating social partners ("divorce studies") (Adkins-Regan and Tomaszycki, 2007; Crino et al., 2017) or creating forced pairings with a nonpreferred partner, report retarded gonadal growth and egg laying (Bluhm et al., 1984).

Two excellent examples of the influence of social factors on annual scheduling come from experimental studies of the transition from reproduction to molt in songbirds. Photostimulated captive male European starlings delay gonadal collapse and onset of molt when housed with females (Schwab and Lott, 1969). Co-habiting with photostimulated females is now known to affect GnRH gene transcription in the septo-infundibular GnRH system of male starlings (Stevenson and Ball, 2009), supporting a centrally mediated signalized mechanism for the delaying effects of females on males' transition out of the breeding state to refractoriness and molt. Likewise, free-living male song sparrows (*Melospiza melodia melodia*) delay gonadal collapse and molt when paired to females whose reproductive competence is experimentally prolonged with exogenous estradiol (Runfeldt and Wingfield, 1985). This effect is unique to males: female song sparrows paired with testosterone-implanted males show no such socially mediated delay of the breeding-molt transition, despite their mates remaining reproductively active, territorial, and delaying molt themselves (Runfeldt and Wingfield, 1985). Prealternate molt is studied infrequently; however, a recent study suggests that auditory social cues may affect the timing of prealternate molt in Gambel's white-crowned sparrows (Chmura et al., 2017).

44.3.3 Integration of multiple cue types: parallel or serial processing?

One fundamental question about how different kinds of cues are processed and integrated relates to whether there is a hierarchy of cues, one or more of which must be stimulatory or at least permissive before others can have their effects (i.e., cues acting in series), or whether different cues can substitute for one another (i.e., cues acting in parallel). As noted above, at least for many species, the general role of endogenous mechanisms combined with seasonal changes in photoperiod take a primary role in a hierarchy of cue processing; days must first be above a certain threshold in length and/or the bird must be at the correct phase of an annual program before other cues can have an influence. This fits well with the general paradigm envisioned by Wingfield (1980, 1985) in which Supplementary Cues and Synchronizing and Integrating Cues serve to fine tune the development of a life cycle stage that has been initiated by Initial Predictive Cues. Few studies permit evaluation of whether this cue hierarchy exists, but female white-crowned sparrows (*Z. l. gambelii*) only show enhanced reproductive development with exposure to male song if they are also photostimulated (Morton et al., 1985). Similarly, high temperature only increases testis growth in photostimulated black-capped chickadees (Martin et al., 2020). It is possible, however, for cues to operate in parallel. That is, the same outcome of initiation of a life cycle stage might be achieved either through stimulation with one type of cue or with another, but both are not necessary, and neither takes hierarchical priority. Red crossbills (*Loxia curvirostra*) provide a possible example of this type of processing. These birds can be in full reproductive condition and breed in the wild on both the shortest and longest days of the year—despite a cessation of breeding in the autumn (Berthold and Gwinner, 1978; Hahn, 1998). In outdoor aviaries, they can come into full breeding condition in January, when days have barely begun to increase in length and when temperatures are low, as long as they have unlimited food and a mate (Hahn, 1995). They also come into near-full breeding condition under long-day stimulation even if they do not have mates (Hahn, 1995). These findings are consistent with the interpretation that long days and some combination of abundant food and mates can essentially substitute for one another in terms of stimulating the reproductive system in some species.

Classic models of serial processing often suggest that photoperiod is the critical initial cue; however, this may not be the case in all species exhibiting serial processing. An experimental study of zebra finches showed that enhanced food alone or in combination with long days could accelerate reproductive development, whereas long days were not stimulatory if food supply was mildly restricted (Perfito et al., 2008). These data are consistent with the interpretation that changes in food may actually act as the initial predictive cues for certain opportunists (Hahn et al., 1997), and any effects of photoperiod may either be permissive or mediated through time available to eat, unlike in many temperate zone photoperiodic species. Recent findings that social cues (Perfito et al., 2015) and temperature (Trivedi et al., 2019) can influence the activity of thyroid hormone pathways known to activate reproduction suggest that there may be some commonalities in how photoperiodic and nonphotoperiodic cues are integrated in the reproductive axis, but much more work remains to be done in this area.

It is unclear whether it is more productive to think of endogenous programs and photoperiod—both considered to be forms of Initial Predictive Cues by Wingfield (1980, 1985)—as interacting in a hierarchical fashion, or simply as complementary components of the annual scheduling process. The phase of the annual cycle (e.g., whether refractory or not) definitely determines the nature of the response to photoperiod, but photoperiodic history also has dramatic effects on whether and when transitions between stages of the annual schedule occur (Gwinner, 1986). However, the fact that annual schedules of many species persist in the absence of clear timing cues from the environment seems consistent with the idea that it may be most appropriate to consider the endogenous component as primary, and the modulatory effects of the environment as secondary, at least for some species.

44.4 Adaptive variation in cue processing mechanisms as it relates to life in different environments

There is abundant evidence of adaptive variation in life cycle scheduling in different environments, and some evidence of adaptive variation in underlying mechanisms. Many studies have examined variation in photoperiodic regulation of reproductive development (Lofts and Murton, 1968; Lambrechts et al., 1996, 1997; Lambrechts and Perret, 2000; Liedvogel et al., 2009; Hahn et al., 2009; Helm, 2009; Caprioli et al., 2012), photorefractoriness (Lofts and Murton, 1968; Nicholls et al., 1988; Hahn and MacDougall-Shackleton, 2008; Hahn et al., 2009), and timing of molt and migratory restlessness (see Gwinner, 1986 for a review).

One of the key distinctions that must be established in order to assess whether adaptive variation exists is whether interpopulation variation in annual schedules is the consequence of evolved differences in endogenous timing mechanisms and responsiveness to environmental cues or simply a result of populations experiencing different environmental conditions. This problem can be addressed in several different ways. Examination of the phylogenetic distribution of reproductive photorefractoriness is consistent with the interpretation that failure to demonstrate refractoriness is a derived trait associated specifically with the most flexible or opportunistic annual schedules (Hahn and MacDougall-Shackleton, 2008). Thus, birds such as crossbills, zebra finches, and some tropical taxa with particularly flexible annual schedules fail to develop absolute photorefractoriness when exposed to extended periods of constant long days. Such taxa wait for input from the environment before making the transition from reproduction to molt and reproductive quiescence. In contrast, most temperate zone seasonal breeders spontaneously enter molt and collapse the reproductive system after some period of reproductive activity, even if the environment provides no direct information about impending deterioration of environmental conditions (Nicholls et al., 1988). Evolutionary loss of absolute photorefractoriness can, then, be interpreted as adaptive specialization in these highly flexible taxa (Hahn and MacDougall-Shackleton, 2008)—although additional information from tropical species, which are largely untested in this regard—could change this framework.

Another way to investigate whether intertaxon variation in schedules represents adaptation to different environments is to look for evidence of a genetic basis for the observed variation. This has been reviewed copiously in the context of avian circannual rhythms by Gwinner (1986); a number of species of migratory songbirds display good evidence of robust differences in timing of diverse elements of their annual schedules (e.g., molt, migratory restlessness, body mass, reproductive condition) that persist in the absence of changing environmental conditions (Gwinner, 1986). In addition, many studies demonstrate persistent interpopulation differences in scheduling under common garden constant conditions, and intermediate phenotypes in F1 hybrids of different populations (see Gwinner, 1986 for a review). Some more recent studies look specifically at heritability (a prerequisite for adaptive change in response to selection) as well as population-level response to artificially applied selection. For instance, variation in timing of onset of autumn migratory activity of blackcaps (*Sylvia atricapilla*) is heritable, and two generations of directional selection for later migration onset led to a 10 day shift in mean date of onset of autumn migratory restlessness (Pulido et al., 2001). Recent selection line studies in great tits have shown that it is possible to select for shifts in

breeding timing (Verhagen et al., 2019). While research into how genetic variation creates variation in seasonal timing (Liedvogel et al., 2009; Saino et al., 2013; Bazzi et al., 2017) is just beginning, results from these common garden studies support the interpretation that at least some populations contain heritable variation in scheduling traits that is responsive to selection.

A recent elegant demonstration of adaptive variation in annual scheduling combined common garden manipulations of photoperiod with studies of hybrids between two subspecies of stonechats (*Saxicola torquata*) that differ in natural annual schedules (Helm et al., 2009, Figure 44.6). European stonechats undergo earlier reproductive development, remain in reproductive condition longer, and show a more protracted postbreeding plumage molt than do Siberian stonechats. In theory, these differences could result from environmental condition-dependent plasticity. However, birds from the two different populations show persistent differences in schedules when held under identical constant photoperiod, and F1 hybrids between the two display intermediate scheduling characteristics. Further, exposure to the subtly different photocycles that the two subspecies experience on their distinct wintering grounds and migratory paths produces different scheduling outcomes in the two subspecies. European stonechats exposed to seasonal photoregimes typical of Siberian stonechats shift onset of reproductive development even earlier than European stonechats on a typical photocycle and retain their prolonged period of reproductive competence and protracted molt. In contrast, Siberian stonechats exposed to the European stonechat seasonal photoregime only slightly advance onset of reproductive development, and retain their brief periods of reproduction and molt (Helm et al., 2009). This study shows that the specific annual schedules of these two subspecies differ due to subspecific variation in mechanism (both in endogenous programming and in the phase-dependent response of the system to environmental inputs) as well as differences in the experienced environment.

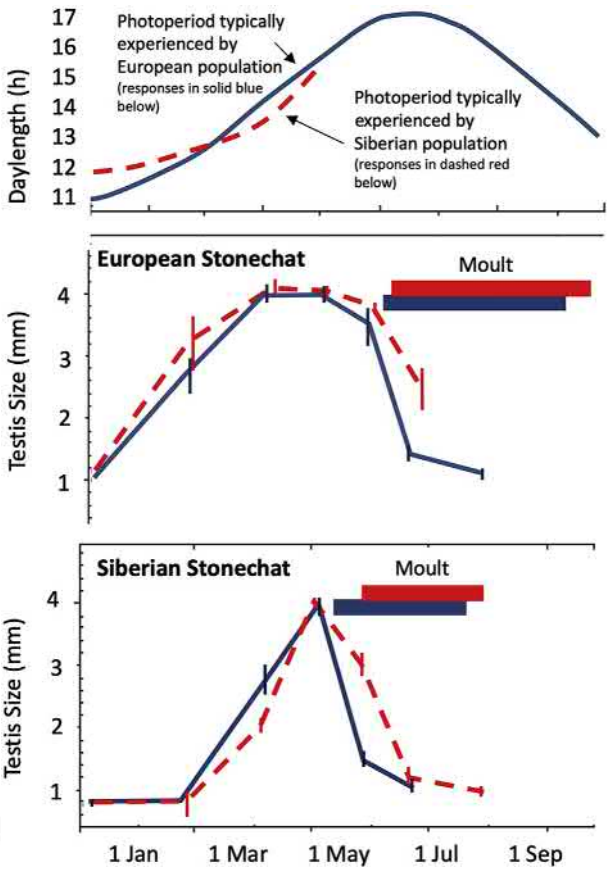

FIGURE 44.6 Comparison of gonadal development and plumage molt from a full factorial experiment conducted in European and Siberian stonechats (*Saxicola torquata*) under two different photoperiodic regimes. The top panel illustrates the daylength conditions used in the experiment: the *dashed red line* indicates the photocycle experienced by free-living birds in the Siberian population and the *solid blue line* represents the photocycle typically experienced by free-living birds from the European population. The middle panel illustrates the gonadal development (*red dashed and blue solid lines*) and molt progression (*red and blue solid bars*) of European stonechats under the two photoregimes. The bottom panel depicts the gonadal development and molt progression of Siberian stonechats under the two treatments. A detailed description of this study can be found in text. *Modified from Helm et al. (2009).*

44.5 Integrated coordination of stages and carryover effects

As noted above, stages of the annual cycle do not exist as separate entities but are intricately linked with the stages preceding and following them. Transitions between stages involve termination of one stage and development of the next (Wingfield, 2008), each of which requires mechanistic control. This may involve one mechanism controlling both termination of one stage and development of the next, or separate mechanisms. This first scenario could ensure that stages follow in the correct sequence throughout the year. For instance, in the transition from breeding to prebasic molt, the inactivation of the HPG axis as photorefractoriness develops leads to a precipitous decline in circulating sex steroids. This decline results in regression of secondary sex characteristics (e.g., cloacal protuberance, beak color, and brood patch) and declines in song and courtship as well as facilitating the final stages of parental care in males (Nicholls et al., 1988; Hahn et al., 1997; Hahn and MacDougall-Shackleton, 2008). Since sex steroids inhibit molt, the decline in their levels allows molt to proceed (Schleussner et al., 1985; Nolan et al., 1992; Dawson, 1994, 2004). However, stages occurring in the correct sequence could also result from two separate

mechanisms controlling termination and development phases of adjacent stages. This is possible if one mechanism provides a trigger for the next. As with the breeding-molt transition example above, while photorefractoriness and the resulting decline in sex steroids is important for terminating breeding and the onset of molt, other physiological changes are occurring. Changes in prolactin and thyroid hormones have long been thought to be necessary for molt, but whether these are simply correlated events or play causal roles remains unresolved (Mishra et al., 2004; Dawson, 2006,2008).

How transitions between stages are coordinated—e.g., whether stages overlap or remain distinct—has important consequences. One major source of these consequences is a phenomenon called **carry-over effects**, which occur when processes or conditions in one stage affect timing or performance in subsequent stages (Norris and Marra, 2007; Harrison et al., 2011). Most studies of carry-over effects examine individuals, but population-level consequences also may occur (Norris and Marra, 2007; McKellar et al., 2013). At the individual level, carry-over effects often result from the constraint that transitional stage overlap can place on energy or resource allocation. For example, many physiological changes take place during the transition between migration and breeding, including changes in musculature, nutrient and energy reserves, fat deposition, organ size and functioning associated with gonadal development and migration termination, as well as hormone and yolk precursor level changes (e.g., Arizmendi-Mejía et al., 2013). Female Macaroni penguins (*Eudyptes chrysolophus*) initiate vitellogenesis (yolk production) while they are still at sea migrating to the breeding territory (Crossin et al., 2010). With greater overlap of breeding preparation during migration, Macaroni penguins are able to start laying eggs sooner upon arrival. However, simultaneous expression of these functions constrains the rate of egg formation, as evidenced by lower vitellogenin (VTG) levels, and therefore lower reproductive readiness, upon arrival in late-arriving females.

Similarly, the transition from migration to breeding stages in female black-browed albatrosses (*Thalassarche melanophrys*) involves a carry-over effect on the breeding stage as a result of processes occurring during migration. Postmigratory condition (weight and hematocrit) and reproductive readiness [progesterone (P4), testosterone (T), and VTG levels] were lower in females that ended up deferring breeding compared with those who did lay eggs. This suggests a resource or condition-based allocation trade-off underlying this carry-over effect in which returning females in better condition (i.e., those that cope more effectively with the metabolic demands of migration) are more likely to initiate breeding. Furthermore, of the birds that attempted breeding, success was associated with low T and high-VTG levels, compared with failed breeders whose eggs did not hatch. This finding suggests another possible mechanism underlying carry-over effects: conflicting physiological processes. The differences in T and VTG levels between successful and failed breeders indicates a potential difference in the levels of aromatization from T to estradiol (E2), a necessary step in the process of vitellogensis (E2 stimulates vitellogenesis in the liver). The inhibition of aromatization, possibly by a stress-related mechanism (Dickens et al., 2011, 2013), may be influencing the migration-breeding transition and its resulting carry-over effects.

Reproductive decisions and outcomes are influenced by processes occurring during the migration stage that immediately precedes reproduction. However, processes even earlier, such as during the wintering stage, can have carry-over effects on migration and breeding (Marra et al., 1998; Norris et al., 2004; Studds and Marra, 2005; Reudink et al., 2009; McKellar et al., 2013). For example, American redstarts wintering in low quality, drier scrub habitats are in poorer body condition and have higher corticosterone levels than those in wetter habitats (Marra et al., 1998). Both males and females wintering in drier areas, as well as those in poorer physical condition in general, tend to depart for migration later (Marra et al., 1998). This effect was shown experimentally in two studies. Birds that were upgraded from low to high-quality winter habitats had higher body mass and departed earlier than controls (Studds and Marra, 2005) and experimental reduction of food on territories delayed migratory departure by one week (Cooper et al., 2015). High-quality wintering grounds translate into earlier arrival on breeding grounds and higher reproductive success (Norris et al., 2004; Reudink et al., 2009). Males arriving earlier from better wintering grounds sired more offspring, both within-pair and extra-pair, and had greater fledging success (Norris et al., 2004; Reudink et al., 2009). Male redstarts are predicted to decrease their chances of successful reproduction by as much as 11% with every day migration is delayed (Tonra et al., 2011). Early arriving females started laying and fledging young earlier; high-quality winter habitat predicted production of at least two more young than poor quality wintering grounds (Norris et al., 2004). These findings are complemented by similar results in other species (see above Section 44.3.2.2 on food supplementation and Arcese and Smith, 1988; Meijer et al., 1988; Schoech, 1996).

Carry-over effects such as these often are presumed to result from resource allocation trade-offs. However, studies documenting such tradeoffs often lack direct evidence to support this underlying mechanism (Harrison et al., 2011). An exception is work in Cassin's auklets (*Ptychoramphus*

aleuticus), which indicates a resource allocation trade-off, based on quality of prebreeding diet, influences laying date (Sorensen et al., 2009). Female auklets that consumed more energy-rich copepods during the period prior to breeding began laying earlier and laid larger eggs than those that consumed more energy-poor juvenile rockfish (Sorensen et al., 2009). While studies like these help to illuminate the potential mechanisms responsible for carry-over effects (and also provide additional examples of responses of annual schedule timing to food cues), much more research is needed (Norris and Marra, 2007; Harrison et al., 2011). Most studies involve observational field work, but experimental manipulations are necessary to learn more about the physiological mechanisms (Harrison et al., 2011).

Breeding can also have carry-over effects on subsequent stages. For example, late breeding can lead to delayed molt or increased overlap of breeding with prebasic molt (Morton and Morton, 1990; Sanz, 1999; Stutchbury et al., 2011). As tracking technology has improved, many new studies are investigating carry-over effects across the whole annual cycle, sometimes across multiple years. Late reproduction in savannah sparrows (*Passerculus sandwichensis*) (Mitchell et al., 2012) and delayed molt in wood thrushes (*Hylocichla mustelina*) (Stutchbury et al., 2011) can carry-over to result in later migratory departure. The extent to which these differences persist across fall migration and into arrival on the nonbreeding grounds may vary. Late departing wood thrushes did not arrive late to wintering grounds (Stutchbury et al., 2011). In contrast, Hudsonian godwits (*Limosa haemastica*) that departed late from the breeding grounds arrived late to stopover sites along their southbound migration and the wintering grounds, but this effect did not carry-over to affect timing of northbound migration in the spring (Senner et al., 2014). A study of tree swallows investigating annual scheduling in multiple populations across the species' range suggests that while timing of breeding influences timing of fall migration and arrival on the wintering grounds, the timing of departure from the wintering grounds is not influenced by timing during the preceding life cycle stages (Gow et al., 2019).

A similar pattern of "resetting" the annual cycle of activities has been found in a few experiments studying carry-over effects in free-living populations. Clutch manipulation studies in pied flycatchers suggest that birds with larger clutches delayed fall migration and had a shorter overwintering period, but did not delay the subsequent spring migration (Briedis et al., 2018). A similar pattern of carry-over effects was seen in Manx shearwater (*Puffinus puffinus*) with experimentally extended periods of parental care (Fayet et al., 2016, Figure 44.7). However clutch removal in Cory's shearwaters (*Calonectris diomedea*) led not only to earlier fall migration, but also earlier spring migration the following year (Catry et al., 2013). (Note this species does not renest).

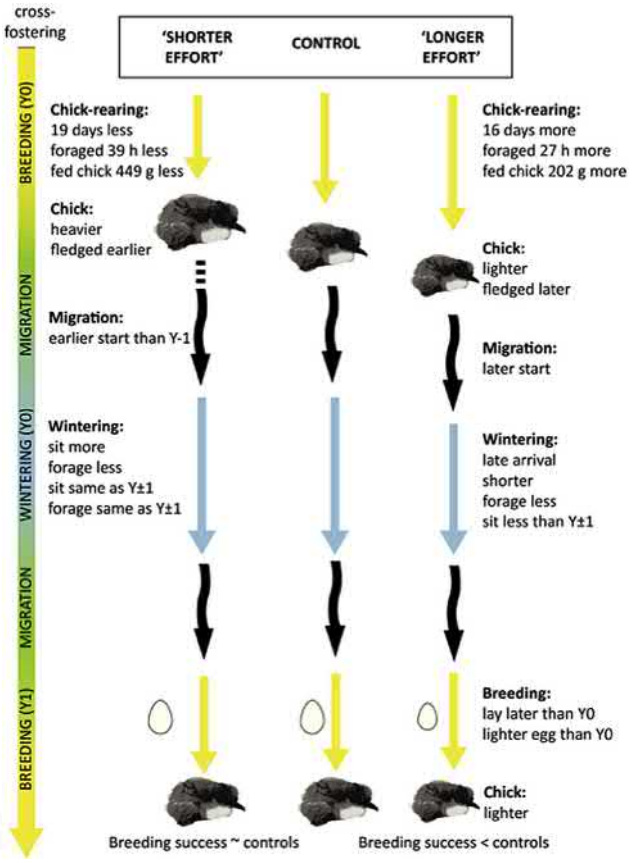

FIGURE 44.7 Infographic of results from a study investigating carry-over effects in Manx shearwater (*Puffinus puffinus*) using an experimental clutch manipulation. Cross-fostering nestlings extended or reduced the length of parental care by about 25% in manipulated nests compared to controls. *From Fayet et al. (2016).*

44.6 Variation in scheduling mechanisms and responses to rapid environmental change

Changes in phenology, or the timing of key events in the annual cycle, are one of the most commonly documented responses to climate change in both birds and other taxonomic groups (Crick et al., 1997; Parmesan, 2007; Usui et al., 2017). This has led to a plethora of studies seeking to document shifts in phenological timing with global climate change in diverse avian taxa and a smaller but strong body of recent literature examining different timing mechanisms that could affect the ability of birds to respond to climate change either through phenotypic plasticity or evolutionary change.

There are several proximate causal mechanisms that are hypothesized to influence the capacity of animals to adjust seasonal timing with climate change using existing phenotypic plasticity—either in the form of developmental plasticity or plasticity in adulthood, hereafter referred to as

flexibility (Piersma and Drent, 2003). Many studies hypothesize that because photoperiod is not shifting with climate change, birds that rely heavily on photoperiod or an endogenous rhythm to time seasonal transitions may be constrained in their ability to adjust (Both and Visser, 2001). Accordingly, flexible responses to nonphotic cues (such as temperature or food availability) that closely track climatic change are expected to facilitate adjustment of the annual cycle (Charmantier et al., 2008). Even in cases where birds have the capacity to respond to nonphotic cues, the inherent time-lag between physiological preparation for a stage and initiation of that stage complicates predictions about how birds will respond to climate change. Research suggests that climate change is heterogeneous across the year (Easterling et al., 1997), so for phenotypic plasticity and/or flexibility to provide effective routes by which birds can adjust seasonal timing, nonphotic cues must change similarly across an annual cycle stage. Similarly, spatial variation in climate change can complicate the responses of migratory birds. If climate change is not experienced similarly on breeding and wintering grounds, as well as along the migratory route, plastic changes occurring in one stage may not be adaptive for the environment that birds encounter during the next phase of the annual schedule (Knudsen et al., 2011).

The importance of studies integrating multiple annual cycle stages to accurately assess the response of birds to climate change is made clear by pioneering work by Both and Visser (2001) whose studies in pied flycatchers suggest that adjustment of breeding timing with climate change was constrained by the absence of a change in spring migratory timing (Ouwehand and Both, 2017). As our discussion on nonphotic cues illustrates, different stages may show different kinds of responses to photic and nonphotic cues. Indeed another recent analysis of long-term phenology data from pied flycatchers suggests that molt has shifted more than breeding, and that spring migratory arrival has not changed at all (Tomotani et al., 2018). Researchers attribute these differences to different responses to temperature. On nonevolutionary time-scales, asymmetric phenological shifts across the annual cycle may limit the ability of birds, particularly migrants, to respond to climate change. Hatching environment could have a developmental influence on the timing of subsequent spring migration, and this could be a transgenerational developmental mechanism by which shifts in reproductive timing with climate change could also influence timing of migration and mitigate other mechanistic constraints on migration timing (Gill et al., 2014). However, experimental hatch delays in pied flycatchers do not reliably lead to changes in spring migration and reproduction, casting doubt on this hypothesis in at least one species (Ouwehand et al., 2017).

Timing adjustments to the annual cycle, or lack thereof, with climate change become especially important when they influence individual survival and offspring recruitment into the breeding population. One of the primary ways in which phenological shifts may influence recruitment is via trophic mismatch, a hypothesis that proposes that if birds shift phenology at a different rate than the primary food source for young, young may have insufficient resources to survive and recruit into the breeding population. This may be especially likely when the two interacting trophic levels rely upon different cues to time life history stages. Over 23 years of spring temperature increase in the Netherlands, great tit egg-laying dates did not shift as much as the peak in abundance of caterpillars that they use to provision young (Visser et al., 1998). The extent to which this is the case for many or most avian species is under study (Knudsen et al., 2011), and some studies suggest that trophic mismatch is not occurring in other systems (Dunn et al., 2011; Dunn and Møller, 2014). For example, different degrees of dietary specialization may affect whether a system is likely to be affected by trophic mismatch, and different environments may exhibit different seasonal patterns in resource abundance. Additionally, most avian species must contend not only with seasonal fluctuations in resource availability, but also with fluctuations of predator abundance. While most climate change studies assume trophic match is the evolutionary default and that trophic mismatch is necessarily maladaptive, some researchers assert that mismatch may actually be advantageous in some predator-prey environments (Visser et al., 2012). Thus, a sufficiently long time series of data is important to assess the impact of trophic mismatch on birds. This is made especially clear by recent work suggesting that changes in trophic level asynchrony in 21 species of British birds over the past 30 years did not explain long-term population declines (Franks et al., 2018) despite the finding that species that had shifted their arrival earlier in Britain had more positive population growth (see also Newson et al., 2016). Clearly, this will remain an active area of research in coming years.

Seasonal timing in birds may evolve in response to climate change. However, there is strong support for evolutionary adjustments in only a few systems; this is likely due in part to the challenges associated with gathering the evidence that is required to demonstrate an evolutionary response to climate change (Charmantier and Gienapp, 2014). Nussey et al. (2005) report evidence that climate change is causing increased selection for flexibility in breeding timing in a population of great tits. Similarly, a common garden experiment in pied flycatchers conducted first in 1981 and repeated 21 years later, finds that breeding timing had advanced by nine days, which researchers

propose is evidence for evolutionary change in the endogenous circannual clock (Helm et al., 2019).

As we come to understand the mechanisms by which species are altering the annual schedule of behaviors with climate change and the implications this has for local populations, we will better be able to predict how avian populations will respond to ongoing climate change.

44.7 Effects of seasonality on constitutive processes

Although annual schedules often consist of several distinct life cycle stages, birds also adjust investment in processes that span multiple stages. These processes may be maintained during every stage, yet the appropriate level of investment may vary as a function of resource availability, environmental conditions, individual age or condition, and so forth. In this section, we will briefly discuss how birds vary investment in immune function, responses to stressors, and metabolism seasonally.

44.7.1 Seasonal modulation of immune function

Across the annual cycle, dynamic environments expose organisms to extensive seasonal variation in weather, resource availability, and disease potential (King, 1974). Natural selection dictates that longer-lived organisms, such as birds, should time costly energetic processes to maximize fitness by balancing seasonal allocation to both reproduction and survival-related processes such as immune function. Immune function contributes to survival by detecting pathogens and limiting infection, but because maintenance of immunity can be costly (e.g., Sheldon and Verhulst, 1996; Schmid-Hempel and Ebert, 2003; Klasing, 2004; Nelson, 2004), especially if immune activation is overused (Lochmiller and Deerenberg, 2000) or not sufficient to clear an infection (Nelson et al., 2002), investment in immunity is often variable (Martin et al., 2008). Many environmental and physiological variables can play a proximate role in regulating these changes in investment patterns in immunity (Nelson, 2004; Martin et al., 2008; Buehler et al., 2008a,b). Examples of these contributing environmental factors include endogenous and/or photoperiodically regulated annual cycles, changes in disease threat or parasite pressure, food availability, and weather and temperature conditions (Nelson and Demas, 1996; Nelson et al., 2002; Hasselquist, 2007; Martin et al., 2008; Adelman et al., 2013). Other factors that contribute to changes in immune function include competing physiological processes such as reproduction (Sheldon and Verhulst, 1996; Lochmiller and Deerenberg, 2000) and other survival-related processes such as plumage molt (Buehler et al., 2008b; Moreno-Rueda, 2010) growth (Prendergast et al., 2004) or migration (Nebel et al., 2012, 2013).

While studies on seasonality of immune function have been conducted in mammals, particularly small rodents (Demas and Nelson, 1998; Bilbo and Nelson, 2004; Zysling et al., 2009), the literature on seasonality in avian immunity has been growing rapidly over the last decade. Most published studies focus on single components of the annual cycle, such as breeding compared to nonbreeding, or breeding compared to molting (reviewed in Martin et al., 2008). This review will focus on studies that have been sampled more holistically across the annual cycle. Most research on seasonality in immunity has been conducted in captivity and these studies report variable findings: some have shown that cellular immunity is higher during the winter months while others report no difference across sampled timepoints (Lee, 2006; Martin et al., 2008). In a study of red knot (*Calidris canutus*) immunity sampled over the annual cycle (Buehler et al., 2008b), both higher energetic cost phagocyte-based (cellular) immunity and lower-cost lymphocyte-based (antibody) immunity were higher during periods of mass change (i.e., during fattening and spring migration in wild birds), but there was a clear shift toward lower-cost lymphocyte-based immunity during peak molt. Due to the high costs associated with synthesizing feathers (Haake and Sawyer, 1986), it is preferable for birds to use a lower cost, less phagocytic-based immune strategy, during molt. A recent study showed that lipopolysacharide (LPS which induces a "sickness response") injected house sparrows grew lower quality feathers than control birds, which supports the idea that investment in molt and immunity may trade-off against each other (Ben-Hamo et al., 2017). In a subsequent experiment in red knots using low, high, and variable temperatures, there was little effect of temperature on annual variation in immune function (Buehler et al., 2009), perhaps due to the presence of ad libitum food. However, when food levels were restricted without temperature manipulation in a follow-up experiment, no change in constitutive immunity (natural antibody and complement levels) was observed, although food restriction did diminish investment in the acute phase or induced immune response that is substantially more energetically demanding (Buehler et al., 2009). A study in red crossbills found that long days increased white blood cell counts and bacterial killing ability but did not find an effect of food restriction on constitutive immunity (Schultz et al., 2017). Conversely, a captive study of white-crowned sparrows found that seasonal changes in the acute phase response were not driven by photoperiod per se, but seemed to be associated with sex and changes in body condition (Owen-Ashley et al., 2006).

Because captivity can reduce both inflammatory and phagocytic (cellular)-based immunity (either by reducing

the pathogen pressures or due to the increased stress associated with being held in captivity; Buehler et al., 2008a), it is important to study immunity both in the wild and captivity, however few studies do so (Adelman et al., 2013). In free-living birds, few studies have looked at multiple immune indices over several components of the entire annual cycle. One study on nonmigratory great tits (*Parus major*) (Pap et al., 2010) found significant seasonal changes in immunity. Specifically, total immunoglobulin and heterophil levels were highest during the summer breeding months and continued to increase until September when the birds began molting and then decreased until the following spring. Lymphocyte levels, however, were higher in the winter than in the summer. Some immune parameters can vary quite rapidly during a season; song sparrows shift from innate defenses immediately following spring migration to acquired defenses with increasing time at the breeding grounds (Kelly et al., 2017). Few published studies to date look at multiple immune indices over several years in free-living birds. In skylarks (*Alauda arvensis*), metrics of constitutive innate immunity (complement, natural antibody, and haptoglobin levels) varied interannually but were consistently lower during fall migration than during the breeding season (Hegemann et al., 2012). However in purple-crowned fairy wrens (*Malurus coronatus coronatus*), researchers found no differences in immune parameters (haptoglobin, complement, natural antibodies, heterophil:lymphocyte ratio) between wet and dry seasons (Roast et al., 2019). The effects of precipitation on immune measures is variable across studies: precipitation and ambient temp do not predict haptoglobin, complement, or natural antibodies in red-capped larks (*Calandrella cinerea*) (Ndithia et al., 2017) but led to higher microbial killing ability in neotropical house wrens (*Troglodytes aedon*) (Tieleman et al., 2019) and lower haptoglobin, ovotransferrin, complement, and natural antibodies in common bulbuls (*Pycnonotus barbatus*) (Nwaogu et al., 2019).

Migration is an important and energetically demanding component of a bird's life history (Wikelski et al., 2003). Thus, energetic trade-offs with immune function often occur, as has been documented in several studies. For example, studies in thrushes (Owen and Moore, 2008) and Bewick's swans (*Cygnus bewickii*) (Gills et al., 2007) found that migratory activity can be immunosuppressive. Similarly, a field study of six migratory species found that long-distance migrants had a lower measure of complement immunity than short-distance migrants and the authors suggest that long-distance migrants may suppress immunity in favor of preserving energy for migration (Hegemann et al., 2018). Another recent study reports that microbial killing ability and haptoglobin levels are lower in migrant common blackbirds than residents (Eikenaar and Hegemann, 2016). Correlations between individual variation in migration distance (and stopover duration) and immune function have yielded mixed results (Kelly et al., 2016, 2017; Hegemann et al., 2018).

Correlational field studies are limited in testing whether immune function and migration trade-off because flight can affect immune function and infection can affect migratory flight. Two recent studies using a flight chamber found that simulated migration depresses several aspects of immunity. The first study on European Starlings (*Sturnus vulgaris*) found that three of four immune measures (haptoglobin, natural antibody, and complement levels) decreased after the birds were placed in the wind tunnel for 1−4 h of continuous flight (Nebel et al., 2012). Another related study on long-distance migrant western sandpipers (*Calidris mauri*) found that flight performance (flight duration of 3 h) was not diminished by a previous immune challenge of LPS, but flight while mounting a sickness response negatively affected other aspects of immune function including bacterial killing ability and natural antibody levels (Nebel et al., 2013). In addition to experimental flights affecting immune function, experimental infection with avian malaria has effects on migratory preparation and migratory restlessness (Kelly et al., 2018, 2020).

Mechanistically, these effects have been attributed to changes in seasonal hormone profiles, such as glucocorticoids (GCs), androgens, and estrogens (reviewed in Martin et al., 2008). These hormones, which can affect timing of territory establishment, reproduction, parental care, and molt, can also affect immune function (reviewed in Martin et al., 2008; Koustos and Klasing, 2013). For example, both GCs and androgens can depress immunity, but their effect on the immune system is highly dependent on the overall level and duration of increase, as well as what immune component is measured (reviewed in Koustos and Klasing, 2013). In general, acute stress or quick elevations of GCs increase levels of immunity, while chronic or persisting levels of stress dampen immune responses. For testosterone and other androgens, it is difficult to disentangle the direct effects from the indirect effects of GCs, i.e., elevated levels of testosterone may depress immunity by elevating levels of GCs (Koustos and Klasing, 2013).

As the field of avian ecoimmunology continues to grow, scientists can test hypotheses about how diversity in annual schedules is related to diversity in immune investment. A recent review proposes that seasonal variation in microbial risk varies as a function of a bird's annual schedule of activities and the environments that it encounters over the course of the year (Evans et al., 2017). Specifically authors propose that resident tropical species will exhibit a relatively high and constant investment in immune defenses year-round, while migrants and seasonal breeders will vary investment over the year (Evans et al., 2017). While data are currently insufficient to test these expectations, this is a promising area for continued work.

44.7.2 Seasonal modulation of responses to stressors

As covered in Chapter 38, birds have multiple ways to cope with environmental stressors. Here, we will focus on seasonal variation in activity along the hypothalamic–pituitary–adrenal (HPA) axis in response to stress, as it is well represented in the literature. Most studies of vertebrates, including birds, find that at least one of the two sexes shows seasonal variation in GC secretion (Romero, 2002; Romero et al., 2017 but see González-Gómez et al., 2013; Deviche et al., 2014). Seasonal variation is seen both in baseline GC secretion (i.e., samples uninfluenced by the stress induced by handling and sampling) as well as "stress-induced" GC levels (i.e., those taken after an animal experiences a standardized stressor such as handling and restraint, thought to indicate the response the HPA axis may mount in response to a natural stressor). While seasonal variation in GC secretion is a common finding, elements of seasonal variation in GC secretion can vary even among closely related species. However, in birds, most studies find that both baseline and stress-induced levels of GCs are depressed during molt (Romero, 2002), any studies find that GCs are elevated during breeding (Romero, 2002) although there is an ongoing discussion in the field as to exactly how GCs are regulated on fine temporal scales within the breeding period [e.g., between territorial establishment, egg-lay, incubation, and onset of parental care (Krause et al., 2016)].

While total circulating GC levels are studied commonly, a growing body of literature suggests that other points along the HPA axis may be regulated seasonally. A collection of studies in house sparrows indicates that there is seasonal variation in corticosteroid-binding globulins in plasma (Breuner and Orchinik, 2001) as well as seasonal variation in mineralocorticoid (MR) and glucocorticoid (GR) receptor distribution, which differ by tissue type (skin and spleen Lattin et al., 2013, brain and gonads Lattin and Romero, 2013, metabolic tissues Lattin and Romero, 2015).

There are numerous hypotheses as to why HPA activity should be modulated seasonally (Harris, 2020). Many of these hypotheses focus on the unique demands created by reproduction and the needs of parents to balance their own survival against successfully raising young. For example, the Parental Care Hypothesis (Wingfield et al., 1995) proposes that parents suppress stress-induced GC levels during periods of offspring dependence to facilitate parental care and minimize the risk of abandoning a nest. A study of an opportunistic breeder has found that reproductive suppression of the HPA axis can itself vary across seasons, with greater suppression occurring in harsher conditions (Cornelius et al., 2011). Other hypotheses focus broadly on seasonal changes in energetic demands caused by both internal processes and factors in the surrounding environment. The Energy Mobilization Hypothesis (Romero, 2002) proposes that since GCs are involved in energy mobilization, they should be highest at the most energetically demanding time of year. A related hypothesis, the Preparative Hypothesis, suggests that GC levels are modulated in anticipation of adverse changes in environmental conditions (Sapolsky et al., 2000; Romero, 2002). Given the interconnectedness of the HPA axis with many physiological systems, it seems likely that there is not a single universal explanation for temporal changes in HPA activity and that multiple mechanisms may be at play within and across avian taxa.

44.7.3 Seasonal modulation of metabolic machinery

Birds must meet daily energy demand to survive and reproduce in dynamic and seasonal environments, but there may also be costs to maintaining expensive metabolic machinery. Although the underlying mechanisms are incompletely understood, phenotypic flexibility in various metabolic traits has been documented in a wide variety of temperate and tropical species (Swanson, 2010; Pollock et al., 2019). Seasonal variation in metabolic traits is thought to largely reflect variability in energy demand of different stages and variability in environmental conditions. For example, the high cost associated with breeding or migration may be partially offset by the more benign conditions in which those events typically occur (Masman et al., 1986). Indeed, while some studies have found that birds may have similar daily energy costs during summer breeding as when overwintering, others have found that birds in the temperate zone may have much higher costs in winter—and particularly smaller birds that have lower thermal inertia (reviewed in Swanson, 2010; McKechnie et al., 2015). This may hold true even for those wintering in relatively benign locations (Weathers et al., 1999), although the seasonal changes in metabolic traits in the tropics are much more variable in direction and confer some uncertainty on how the environment and organism are interacting to influence metabolic capacity (McKechnie et al., 2015).

The Climatic Variability Hypothesis predicts that the larger the variation in temperature in a species range the more seasonally flexible metabolic traits will be (Bozinovic et al., 2011). These traits include BMR, breadth of the thermoneutral zone, and peak metabolic performance—as measured by either maximum thermogenic capacity during cold challenge (M_{sum}) or by the maximum metabolic rate (MMR) achieved during intensive exercise. Alternatively, the Cold Adaptation Hypothesis predicts the minimum temperature experienced within a species range drives the evolution of peak thermogenic rates and metabolic flexibility (Swanson and Garland, 2009). Although metabolic traits like BMR and M_{sum} can change in similar directions and degree across seasons, they may also be somewhat independent of each other: BMR is thought to reflect nonskeletal organ structure and function whereas M_{sum} and MMR are thought to reflect changes in skeletal muscle structure and function (i.e., through shivering

thermogenesis and muscle performance, respectively) (Petit et al., 2013; Dubois et al., 2016; Barceló et al., 2017). Indeed, BMR and M_{sum} do not always agree with respect to tests of the Climatic Variability and Cold Adaptation Hypotheses. Whereas variability in M_{sum} correlates with temperature variability in and across many species (Swanson and Garland, 2009; McKechnie et al., 2015)—thus supporting the Climatic Variability Hypothesis—BMR does not (McKechnie et al., 2015). Similarly, while M_{sum} predicts the minimum temperature exposure in a comparison of 40 bird species—thus supporting the Cold Adaptation Hypothesis—BMR does not (Stager et al., 2016). Therefore, flexibility in M_{sum} is thought to be the main way that metabolic scope might be increased (Swanson, 2010; Stager et al., 2016) in turn allowing birds the ability to cope with a wider array of environmental conditions (Piersma and Drent, 2003).

Metabolic traits can change in direct response to immediate energy demand, such as occurs when birds are exposed to cold winter temperatures (Swanson and Olmstead, 1999; Swanson and Vézina, 2015), or in response to photoperiodic or endogenous circannual cues in preparation for winter (Petit et al., 2013). Other local, supplementary cues that impact thermogenesis such as rainfall can also impact metabolic traits (Maldonado et al., 2012). Therefore, species may incorporate metabolic restructuring into their annual schedule in the autumn or early winter, but also show significant flexibility in response to local conditions that allow for adjustment to changing conditions. The preparative processes in anticipation of winter are not well described, but the high-energy costs observed during the autumn molt may in part be due to such processes—particularly given that feather growth cannot account for a large portion of the costs (Buttemer et al., 2019). More research concerning the timing and mechanistic processes underlying seasonal metabolic restructuring (Laplante et al., 2019; Vézina et al., 2019) would contribute important information to the understanding of annual schedules in birds, particularly as it relates to constraints or trade-offs with other processes or annual cycle stages.

45.1 Introduction

Birds maintain some of the highest body temperatures (T_b) of any animals, using internal metabolic heat production (MHP) to balance heat loss to the environment under cold conditions and multiple avenues of heat dissipation under hot conditions. The range of environmental temperatures over which birds can defend an approximately constant T_b is wide, with the cold extreme involving values more than 100°C below T_b in penguins resident year round in Antarctica. At the opposite extreme, nightjars and shorebirds incubating eggs in exposed nest sites in Earth's hottest deserts may defend T_b more than 20°C below environmental temperature via rapid evaporative heat dissipation (Grant, 1982; O'Connor et al., 2018).

That the capacity for endothermic homeothermy evolved in birds (and independently in mammals) is remarkable when one considers the energetic cost of this mode of thermoregulation. Compared to similarly sized reptiles, the daily energy requirements of birds may be 30- to 40-fold higher in very small species (Nagy, 2005). These substantial costs of endothermic homeothermy in comparison to the ectothermic thermoregulation that characterizes the vast majority of animals reiterate the fundamental

Sturkie's Avian Physiology. https://doi.org/10.1016/B978-0-12-819770-7.00025-6

benefits conferred by the capacity to regulate T_b independently of environmental temperature, thereby maintaining a constant thermal milieu for the biochemical processes that determine physiological performance.

The study of avian thermoregulation and the underlying physiological and behavioral mechanisms is essential for understanding the ecology and evolution of the planet's ~10,000 extant bird species. This field of enquiry has taken on increased urgency in the face of rapid global heating associated with anthropogenic climate change (see Section 45.9). This chapter explores the physiological and behavioral mechanisms involved in the regulation of avian T_b, the diversity of patterns of thermoregulation among extant birds, and the multitude of ways in which thermoregulation interacts with diverse aspects of avian ecology and evolution. I start by considering the sequence of evolutionary events spanning 250 million years that gave rise to the patterns of T_b regulation in extant birds.

45.2 The evolution of avian endothermy

The major models for the evolution of avian endothermy have focused on aerobic capacity (Bennett and Ruben, 1979) or parental care (Farmer, 2000; Koteja, 2000), with additional models based on niche expansion (Crompton et al., 1978) and body mass (M_b) miniaturization (McNab, 1978) also proposed for mammalian endothermy. A new model integrating the above single-cause models has recently been developed by Lovegrove (2017, 2019), who took advantage of the dramatic recent expansion of the fossil record and new methods for inferring morphology and physiology of extinct species to develop a detailed phenology of the major evolutionary events involved. Lovegrove's three-phase iterative model argues that major developments and transitions occurred in parallel in the sauropsid and synapsid lineages leading to birds and mammals, respectively, beginning around 250 MYA at the Permian–Triassic boundary.

According to this model (Figure 45.1), the first phase of the evolution of avian endothermy involved selection for constant T_b and bipedal locomotion in large-bodied archosaurs around 250–230 MYA in the early Triassic. The highly efficient avian respiratory system characterized by continuous ventilation of parabronchi appears to have its evolutionary origins at around the same time, likely conferring significant benefits to sauropsids during the extremely hot, hypoxic and hypercapnic conditions of the early Triassic. The second phase involved rapid miniaturization of body size, increases in relative brain size, and the development of insulation during the late Triassic and Jurassic. Over the course of 50 million years commencing at the start of the Jurassic, the average M_b of the avian lineage plummeted from 163 kg in early theropod dinosaurs to < 1 kg in the earliest birds capable of powered flight (Lee et al., 2014). The Jurassic also saw several pulses of increasing brain size (encephalization), likely requiring elevated resting metabolic rates (RMR) to meet the energy requirements of neuronal tissue. Another key late-Jurassic innovation was feathers, whose initial purpose was likely insulation.

The third phase, spanning the Cretaceous and Cenozoic, involved diversification of avian locomotion subsequent to the evolution of powered flight, likely associated with strong selection for enhanced aerobic capacity of pectoral muscles as well as stable muscle temperatures (Lovegrove, 2017). A second major event driving the evolution of homeothermic endothermy during this phase was climate adaptation during the second half of Cenozoic, when high-latitude cold habitats appeared within the last ~33 million years (Zachos et al., 2001). Another aspect of Lovegrove's model that has considerable relevance for understanding

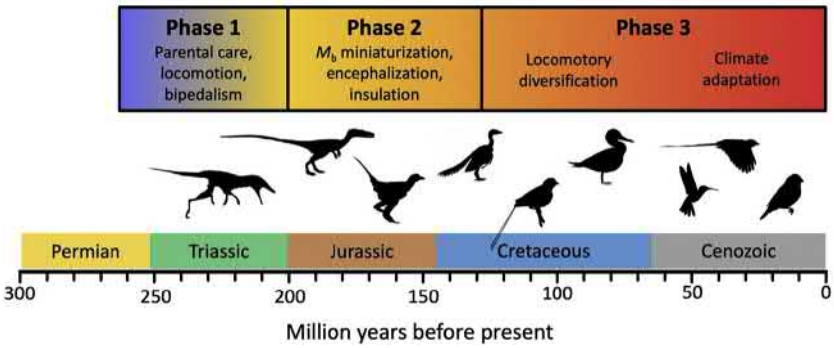

FIGURE 45.1 Summary of Lovegrove's three-phase iterative model for the evolution of avian endothermy, redrawn from Lovegrove (2017), with most of the same silhouettes of taxa representative of the various phases. The silhouettes were obtained from http://phylopic.org/, and from left to right are *Scleromochlus* (Jaime Headden, modified by T. contemporary avian thermoregulation is the notion that the pronounced reductions in T_b of which some groups are capable (see Section 45.4.4) represent a plesiomorphic (i.e., ancestral) trait. According to this argument, the facultative reductions in metabolic rate and consequent low T_{bs} that occur during hibernation and torpor represent a temporary abandonment of the maintenance of high, constant T_b and amount to a physiological reversion toward the ancestral ectothermic state.

45.3 Models of avian thermoregulation

45.3.1 Overall heat balance

Transfers of thermal energy between a bird and its environment occur via four physical processes: radiation, convection, conduction, and evaporation, and the total heat content (Q) of a bird depends on the sum of heat gain and heat loss, such that

$$\frac{dQ}{dt} = Q_{rad} + Q_{conv} + Q_{cond} + Q_{evap} + Q_{metab}$$

where Q_{rad} is radiative heat flux, Q_{conv} is convective heat flux, Q_{cond} is conductive heat flux, Q_{evap} is evaporative heat loss, and Q_{metab} is metabolic heat production. The radiative, convective, and conductive terms can each be positive or negative (i.e., comprise net heat gain or loss), whereas evaporation always involves heat loss and MHP always involves heat gain. The factors determining each term and the ways in which birds can modify these heat fluxes via behavioral adjustments are considered in more detail in Sections 45.5 and 45.6 below.

45.3.2 Avian endothermic homeothermy

Our current understanding of avian thermoregulation largely has its roots in work undertaken by Per Scholander, Laurence Irving, and their collaborators in the late 1940s, who proposed a model for the relationships between T_b, RMR, insulation, and air temperature (T_{air}) that became known as the Scholander–Irving model. The original formulation of the model (Scholander et al., 1950) did not explicitly include an upper limit to resting MHP (i.e., summit metabolism) nor thermoregulation at T_{air} above the thermoneutral zone (TNZ) (Figure 45.2), but these aspects became clear during subsequent work, such as Dawson's (1954) study of thermoregulation in towhees at high T_{air}. The Scholander–Irving model referred to T_{air} because it was developed for metabolic rates of animals placed in darkened chambers; applying this model to free-ranging birds under natural conditions requires replacing T_{air} with an integrated measure of environmental temperature, such as operative temperature (T_e) (Bakken, 1976; Robinson et al., 1976).

In the Scholander–Irving model (Figure 45.2), RMR (i.e., metabolic rate of a resting bird, in the absence of heat produced as a by-product of activity or digestion) is minimal within the TNZ, the range of T_{air} over which heat production associated with baseline metabolic costs of body maintenance is adequate to balance heat lost to a bird's surroundings. The metabolic rate in the TNZ is referred to as basal metabolic rate (BMR) if measured during the rest phase of the circadian cycle (see Section 45.6.1). The lower boundary of the TNZ is the lower critical limit of thermoneutrality (T_{lc}), and at $T_{air} < T_{lc}$, MHP increases approximately linearly to balance heat loss to the environment, providing the basis for the regulation of a stable T_b even at low T_{air}. Avian T_{lc} varies from 30 to 35°C in small species in tropical habitats down to $T_{air} \approx 0$°C in larger, high-latitude species such as glaucous gulls (*Larus hyperboreus*; Scholander et al., 1950) and snowy owls (*Bubo scandiacus*; Gessaman, 1972).

Below the T_{lc}, the relationship between metabolic rate and T_{air} is described by a linear function $RMR = C_{total} \cdot A_b(T_b - T_{air})$, where RMR = resting metabolic rate (Watts, W) and C_{total} = total thermal conductance in W/m^2°C and A_b is surface area in m^2 (although conductance is frequently expressed as whole-animal values in W/°C or similar units). The original formulation of the Scholander–Irving model implicitly assumed that conductance is minimized (and hence, insulation is maximized) at all $T_{air} < T_{lc}$, yielding the prediction of a linear increase in RMR with decreasing T_{air}. Any postural adjustments such as ptiloerection that occur at lower T_{air} may thus result in changes to the slope of RMR versus T_{air}. A key prediction of the Scholander–Irving model, arising from the assumption that conductance is minimized at all $T_{air} < T_{lc}$, is that extrapolating the RMR versus T_{air} line will see RMR reaching zero at a T_{air} value identical to normothermic T_b. The upper limit to increases in resting MHP and hence cold tolerance is determined by summit metabolism, the maximum RMR achievable via shivering and nonshivering pathways.

The upper boundary of the TNZ is the upper critical limit of thermoneutrality (T_{uc}). Although characterized by RMR remaining at a constant, minimal value from the T_{lc} up to the T_{uc}, and often seen as a sort of physiological steady state, the TNZ is in fact a range of T_{air} values over which many physiological changes are occurring. Thermal conductance, which is theoretically minimal at the T_{lc}, increases with T_{air} within the TNZ. T_b typically begins to increase at some T_{air} within the TNZ, and the same is usually true for evaporative water loss (EWL). The latter point has long been recognized, primarily in the poultry science literature, in the concept of the zone of least thermoregulatory effort, defined as the range of T_{air} bounded at the lower end by the T_{lc} and at the upper end by the inflection T_{air} at which EWL starts to increase (Etches et al., 2008, Figure 45.2).

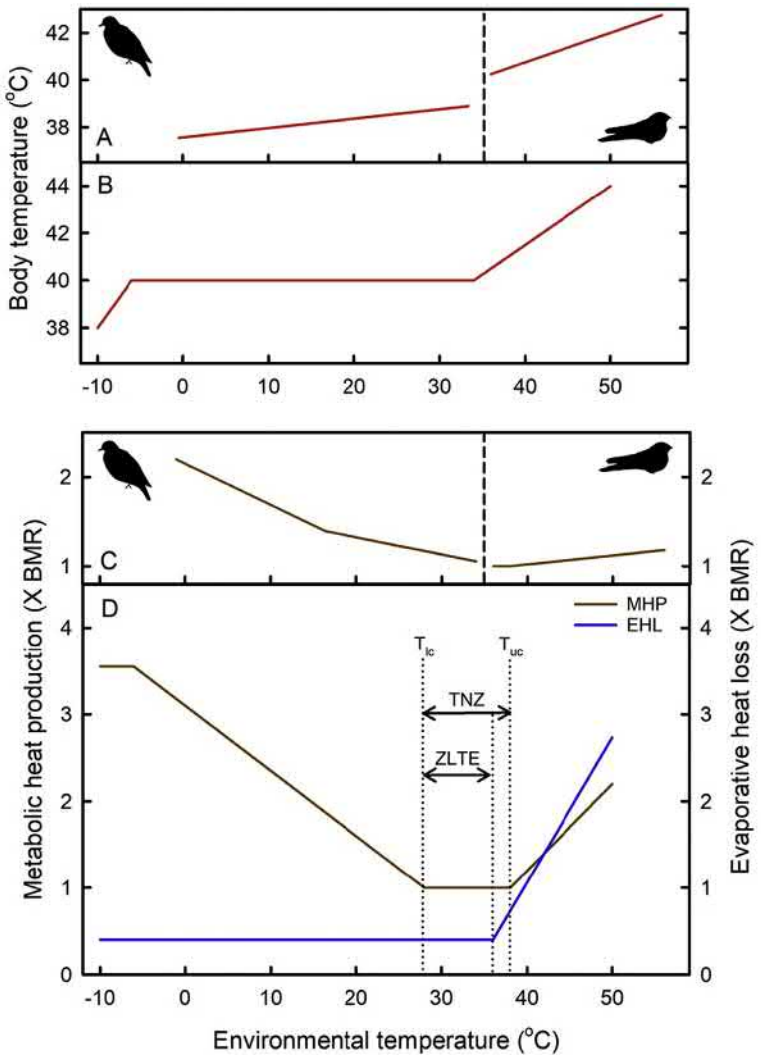

FIGURE 45.2 A general model of the relationships between body temperature (T_b; red lines in panels A and B) and resting metabolic rate and evaporative heat dissipation (panel C and D) in birds. The model, based largely on the Scholander–Irving model, is illustrated in panels (B) and (D), with both metabolic heat production (MHP) and evaporative heat loss (EHL) expressed as multiples of basal metabolic rate (BMR). In panel (D), the lower and upper critical limits of thermoneutrality (T_{lc} and T_{uc}, respectively) that bound the thermoneutral zone (TNZ) are shown by *vertical dotted lines*. Also shown is the zone of least thermoregulatory effort (ZLTE), a concept often used in poultry science literature but rarely in comparative physiology literature. Panels (A) and (C) illustrate deviations from the general model, as reported in African green pigeons (*Treron calvus*, data from Noakes et al., 2013; left of the *vertical dashed line*) and a nightjar (right of the *vertical dashed line*). The silhouettes were obtained from http://phylopic.org/: fruit-dove (L. Shyamal) and nightjar (Ferran Sayol). They are reproduced here under a Creative Commons License (https://creativecommons.org/licenses/by/3.0/).

The T_{uc} is the T_{air} above which the energetic cost of heat dissipation pathways such as panting results in an approximately linear increase in RMR (Figure 45.2D). At $T_{air} > T_{uc}$, the primary physiological process is an increase in evaporative heat dissipation to balance environmental heat gains and MHP, thereby maintaining T_b below lethal limits. Because heat dissipation increases more rapidly with T_{air} than does MHP, ratios of evaporative heat loss (EHL) to MHP increase from EHL/MHP < 1 when $T_b > T_{air}$ to EHL/MHP $= 1$ when $T_b = T_{air}$ and EHL/MHP > 1 at higher T_{air}, providing the physical basis for maintaining T_b below T_{air}.

45.3.3 Deviations from the Scholander–Irving model

Although thermoregulation in most birds investigated to date generally conforms to this model (Figure 45.2), this is not always the case. An example is provided by the African green pigeon (*Treron calvus*), in which normothermic T_b

was atypically variable for a 220-g bird, no TNZ was evident, and T_b gradually decreased with T_{air} (Noakes et al., 2013, Figure 45.2A). In addition, recent work on evaporative cooling in nightjars reveals that some species apparently lack a T_{uc} entirely, with negligible metabolic costs of gular flutter (see Section 45.6.3) resulting in RMR remaining close to minimal levels even at $T_{air} = 50–55°C$ (O'Connor et al., 2017, Figure 45.2C). In highly social taxa, patterns of thermoregulation may depend on the number of individuals roosting communally. In white-backed mousebirds (*Colius colius*), T_b decreased during the course of a night, with the cooling rate negatively related to the number of individuals in a group (McKechnie and Lovegrove, 2001a). In this species, communal roosting is apparently a prerequisite for the defense of an approximately constant rest-phase T_b.

45.3.4 Thermal conductance

Thermal conductance is the rate of total heat transfer between an object and its immediate surroundings per unit surface area per 1°C difference in temperature (IUPS, 2001). Under typical laboratory conditions, total thermal conductance of a bird (C_{total}, W/m^2°C) is quantified as follows:

$$C_{total} = \frac{RMR}{(T_b - T_{air})A_b}$$

where RMR is resting metabolic rate in W, T_b and T_{air} are in °C, and A_b is surface area in m^2. In the absence of empirical measurements of A_b, this variable can be predicted allometrically (Walsberg and King, 1978). Because C_{total} includes EHL, it is sometimes referred to as wet thermal conductance (C_{wet}) (e.g., Schleucher and Withers, 2001). It is also often expressed in the literature as total rather than surface area–specific values. To evaluate the heat transfer properties of birds without the evaporative component, the dry heat transfer coefficient (C, W/m^2°C) is calculated as follows:

$$C = \frac{RMR - EHL}{(T_b - T_{air})A_b}$$

where EHL is evaporative heat loss (W). In general, C is minimal at $T_{air} < T_{lc}$ (although postural adjustments at low T_{air} may reduce it further), increases in the TNZ, and appears to continue increasing at $T_{air} > T_b$ (Tieleman and Williams, 1999).

Within an individual bird, C_{total} and C are ~40% higher during the active phase compared to when roosting (Aschoff, 1981; Schleucher and Withers, 2001). The rest-phase reduction is achieved by increasing plumage depth by ptiloerection and postural changes. Birds roosting in cold environments typically adopt postures as close as possible to that of a sphere by hunching the neck, tucking the beak or head under scapular feathers, and squatting so that the unfeathered legs and feet are drawn into the feather layer. Roosting toucans, for instance, tuck their huge beaks into the feathers between their wings while orientating their tail feathers vertically above their backs, a posture thought to minimize heat loss while roosting (Tattersall et al., 2009).

At an interspecific level, C_{total} and C scale with M_b. Schleucher and Withers (2001) compiled rest-phase conductance data for 257 species and reported a scaling relationship for C_{wet} expressed as mass-specific oxygen consumption ($\dot{V}_{O_2}$ in mL O_2 g^{-1} h^{-1}°C^{-1}) as a function of M_b (g):

$$\log_{10} C_{wet} = -0.477 \log_{10} M_b - 0.163$$

45.4 Body temperature

Although birds are considered endothermic homeotherms that regulate an approximately constant T_b, the known range of avian T_b spans more than 40°C, from values below 5°C during torpor or hibernation to values above 45°C during heat exposure (Table 45.1). This section synthesizes the available information on avian T_b; for convenience, patterns of T_b are treated in a trichotomous fashion as normothermic, hyperthermic (increases above normothermic values), or hypothermic (decreases below normothermic values).

45.4.1 Measurement of body temperature

Historically, most T_b measurements involved thermocouple probes inserted cloacally, subcutaneously, or into tissues such as breast muscles (Dawson, 1954; Randall, 1943). Thermocouples have also been widely used for skin temperature (T_{skin}) measurements or inserted into structures such as the cornea (Pinshow et al., 1982). Cloacal thermocouple measurements remain widely used in laboratory studies of both nondomesticated (e.g., Smit and McKechnie, 2010; Tieleman et al., 2002) and domesticated birds (Arad and Marder, 1982; Marder, 1973).

Remote measurement of T_{skin} via temperature-sensitive VHF transmitters has proven invaluable for studies of thermoregulation in free-ranging birds (Brigham, 1992; Romano et al., 2019; Smit et al., 2011). However, T_{skin} can differ from core T_b by several degrees, particularly during cold weather, and even transmitters in close contact with birds' skin are affected by factors such as solar radiation. Thus, T_{skin} measurements are generally feasible only in studies where comparatively large changes in T_b are anticipated, such as during torpor, and where gradients between skin and core T_b can be experimentally determined (e.g., Brigham, 1992; McKechnie et al., 2007a).

TABLE 45.1 Body temperature (T_b) variation among avian orders in minimum hypothermic values (Min. T_b) during heterothermy, normothermic rest- and active-phase values, and maximum hyperthermic (Max. T_b) values during acute heat exposure. The latter are not lethal values but rather maximum values recorded in individuals exposed to high T_{air} and which fully recovered. Normothermic values followed by ranges in parentheses are rest- or active-phase means reported by Prinzinger et al. (1991). Other sources are listed below the table.

Order	Min. T_b (°C)	Normothermic T_b (°C)		Max. T_b (°C)
		Rest-phase	Active-phase	
Struthioniformes		38.3 (38.0–38.7)	39.3 (38.7–40.1)	
Apterygiformes		38.2 (37.4–39.0)	38.3 (38.1–39.0)	
Casuariiformes		38.6 (37.7–38.9)	38.8 (37.9–39.2)	
Tinamiformes		39.2	40.5	
Galliformes	36.5	38.9 (37.5–40.5)	41.4 (38.2–42.5)	43.6
Domestic fowl		40.5	41.5	45.5–46.2
Anseriformes	35.1	39.0 (38.3–39.5)	41.3 (39.8–43.0)	
Caprimulgiformes	4.3–18.5	37.9 (35.0–39.5)	39.7 (37.0–42.4)	40.7–43.7
Apodiformes				
Apodidae	10.7–20.1	38.6	40.0 (38.6–41.8)	44.7
Trochilidae	3.3–32	38.1 (35.2–39.5)	40.3 (35.6–44.6)	
Cuculiformes	<25–33		41.3 (39.9–42.3)	43.9
Columbiformes	24.8–35	38.6 (37.7–39.9)	40.9 (38.3–43.3)	41.9–44.7
Pterocliformes			39.0–39.4	43.2–43.6
Gruiformes		37.5	40.4 (39.1–41.4)	
Podicipediformes		38.9 (38.5–39.3)	39.5 (38.5–40.2)	
Charadriiformes		38.5 (35.2–39.5)	40.9 (38.3–42.4)	44.3
Gaviiformes		39.2 (35.0–39.5)	39.3 (39.0–39.6)	
Sphenisciformes		37.8 (35.0–39.0)	38.2 (37.0–39.0)	
Procellariiformes		38.3 (37.0–39.6)	39.4 (37.5–41.0)	
Ciconiiformes		39.3 (38.7–39.6)	40.5 (39.5–42.3)	
Pelecaniformes		37.9 (37.1–38.9)	40.6 (39.0–42.7)	
Cathartiformes	34			
Accipitriformes	35.3			
Strigiformes	29–35.5	38.7 (38.0–39.8)	40.2 (38.6–41.2)	42.9–44.2
Coliiformes	18.2–26	38.2 (35.6–39.0)	39.5 (38.0–41.5)	44.1
Coraciiformes	26–28.6	39.2	40.0 (40.0–40.7)	43.5
Piciformes		37.9–39.1	41.8 (39.0–43.0)	44.4
Falconiformes	31–38.3	39.0 (37.9–40.3)		44
Psittaciformes		37.9 (37.7–38.1)	41.3 (41.0–41.5)	43.4–44.1
Passeriformes	24–37.6	38.5 (36–40.8)	41.0 (39–44.1)	43–48.0

Minimum T_b: Brigham (1992), Butler and Woakes (2001), Hohtola et al. (1991), Koskimies (1948), Lane et al. (2004), Morrison (1962), Ramsey (1970), Wolf et al. (2020), Ohmart and Lasiewski (1971), B. Smit et al. (unpublished data), Bahat et al. (1998), Cheke (1971), Clemens (1989), Cooper et al. (2008), Graf et al. (1999), McKechnie and Lovegrove (2001a,b). Normothermic rest-phase T_b: Kemp et al. (2017), Lund et al. (2020), Prinzinger et al. (1991). Normothermic active-phase T_b: Prinzinger et al. (1991), Smit et al. (2008), McKechnie et al. (2016), Czenze et al. (2020). Maximum T_b: Czenze et al. (2020), Freeman et al. (2020), Kemp and McKechnie (2019), McKechnie et al. (2017), McKechnie et al. (2016), McWhorter et al. (2018), O'Connor et al. (2018), O'Connor et al. (2017), Smit et al. (2008), Smith et al. (2015), Smith et al. (2017), Talbot et al. (2018), Talbot et al. (2017), Weathers (1997), Whitfield et al. (2015), Arad and Marder (1982), Randall (1943), Czenze et al. (2020).

Devices surgically implanted into the abdominal cavities of birds are often the most feasible option for monitoring T_b, with transponders, transmitters, and data loggers all routinely used in avian thermoregulation studies. Remote measurement of the T_b of small birds using implanted temperature-sensitive transmitters dates back at least 50 years (Coulombe, 1970; Southwick, 1973), and subsequent technological advances resulting in smaller, more powerful transmitters have ensured that this approach remains widely used (e.g., Thompson et al., 2018). Constraints of this technique include the attenuation of transmitted signals by using helical rather than whip antennae, the fact that the implanted transmitter is surrounded by avian tissues, and the signal drift that has been reported for some transmitters (Cunningham et al., 2017; Williams et al., 2009).

A similar approach involves implanted data loggers that record T_b at user-specified intervals, and such devices have yielded valuable insights into avian thermoregulation in free-ranging individuals of species ranging from migratory geese to small desert passerines (Butler and Woakes, 2001; Smit et al., 2013). A nascent technology that holds much promise is loggers that can download data to a nearby base station (e.g., Tattersall et al., 2016), or use Bluetooth technology to connect to nearby devices such as smartphones (e.g., HOBO TidbiT MX loggers, Onset Computer Corporation, Bourne, MA).

Infrared thermography is another extremely useful tool for studying heat exchange between birds and their environments [see McCafferty (2013) and Yahav and Giloh (2012) for reviews of applications]. Over the last decade, this technique has provided novel insights into the role of the avian beak as a controllable heat radiator (Tattersall et al., 2009, 2018). Infrared thermography also has considerable potential for monitoring animal welfare, including remote detection of chronic inflammation and stress-induced hyperthermia in poultry (McCafferty, 2013).

45.4.2 Normothermic body temperature

Avian resting T_b is characterized by a circadian rhythm, whereby T_b during the rest phase (i.e., the period of inactivity) is lower than T_b during the active phase (daytime for diurnal species). This circadian rhythm is entrained to photoperiod and regulated by inputs from the eyes and pineal body to the suprachiasmatic nuclei (SCN) of the hypothalamus, with the hormone melatonin being the major signaling molecule involved (see Section 45.7.3). The mean ± SD rest-phase T_b for 202 species spanning most avian orders is 38.5 ± 1.0°C and the mean active-phase T_b for 724 species is 41.0 ± 1.3°C (Prinzinger et al., 1991). However, the amplitude of circadian rhythms of T_b (R_T) decreases with increasing M_b. Aschoff (1982) analyzed the scaling of circadian cycles of avian T_b and found that the amplitude is best described as $R_T = 10.856M_b^{-0.396}$ for nonpasserines and $R_T = 4.182M_b^{-0.125}$ for passerines. The data analyzed by Aschoff (1982) primarily involved species from north-temperate latitudes and more recent studies suggest that R_T for species from subtropical latitudes may be higher (Kemp et al., 2017; McKechnie and Smit, 2010).

Whether avian normothermic T_b scales with M_b is less clear. Prinzinger et al. (1991) concluded that T_b decreases with increasing M_b, particularly during the active phase, and that there is no phylogenetic variation after M_b is taken into account. A more recent analysis that did not distinguish between active- and rest-phase T_b values, but which controlled for phylogenetic relatedness, reported a marginally nonsignificant negative relationship between avian T_b and M_b, but also found evidence that the scaling of T_b may vary among orders (Clarke and Rothery, 2008). One group of birds well known for low T_b is the ratites (kiwis, emus, ostriches, and rheas), which typically have T_b equivalent to ~ 3°C below typical avian values (Clarke and Rothery, 2008; McNab, 1966).

Like many physiological traits, avian T_b exhibits phenotypic flexibility, and can be adjusted as a component of acclimation or acclimatization. Active- or rest-phase T_b varies seasonally in some species (Rintamaki et al., 1983; Swanson and Weinacht, 1997), but may also change over even shorter time scales. Studies of white-browed sparrow-weavers (*Plocepasser mahali*) in the Kalahari Desert of southern Africa have revealed that active-phase T_b (and hence R_T) can vary between conspecific populations in a manner correlated with small differences in climate and moreover can also change within a population between dry and wetter periods (Smit et al., 2013).

45.4.3 Hyperthermic body temperature

Avian T_b may increase far above normothermic levels under conditions of heat exposure or intense exercise. For instance, seven of nine species held during midsummer in large outdoor flight aviaries in the Kalahari Desert exhibited maximum $T_b > 44$°C (and in three species, > 45°C, Thompson et al., 2018), and the T_b of breeding marsh tits (*Poecile palustris*) provisioning nests in southern Sweden sometimes exceeded 45°C during warm weather (Nilsson and Nord, 2018). Under resting conditions, avian T_b typically starts increasing above the normothermic setpoint at T_{air} between 35 and 40°C, above which it increases linearly to maximum values that are usually 2−5°C above normothermic values.

Lethal avian T_b values, typically between 46 and 47°C, have been reported for both domesticated and nondomesticated species (Arad and Marder, 1982; Dawson, 1954; Randall, 1943). Avian maximum T_b values equivalent to the critical thermal maximum (CT_{max}), usually taken as the T_b at which the capacity for coordinated locomotion

ceases, typically fall between 44 and 45°C among desert passerines (McKechnie et al., 2017; Smith et al., 2017; Whitfield et al., 2015). A mean value of 45.7°C and individual T_b values as high as 47.0°C have been reported in the variable seedeater (*Sporophila aurita*), a small passerine inhabiting humid tropical lowlands (Weathers, 1997). Recently, a new upper limit for avian T_b was documented in red-billed queleas (*Quelea quelea*); the mean maximum T_b for 20 birds was 48.0°C, with a highest individual value of 49.1°C (Freeman et al., 2020). Among poultry, maximum T_b values from which most individuals recovered fully have been reported as 45.5−46.2°C (Arad and Marder, 1982; Randall, 1943). The extent to which T_b increases above normothermic values varies across taxa, with passerines exhibiting more pronounced facultative hyperthermia than other orders (Gerson et al., 2019).

Whereas maximum T_b for most taxa is restricted to a relatively narrow range of values in the mid-40s, the maximum T_{air} values birds can tolerate vary widely. Passerines from the arid zones of the American southwest, southern Africa, and the interior of Australia tolerated T_{air} of 46−54°C before T_b reached CT_{max} (McKechnie et al., 2017; Smith et al., 2017; Whitfield et al., 2015), but columbids and caprimulgids tolerated T_{air} approaching and sometimes exceeding 60°C (McKechnie et al., 2016; O'Connor et al., 2017; Smith et al., 2015; Talbot et al., 2017). The large variation among taxa in heat tolerance limits appears to arise from differences in the relative efficiency of the major avenues whereby birds dissipate heat evaporatively (see Section 45.5.4).

Like normothermic values, avian heat tolerance and T_b during acute heat exposure may vary within species and exhibit phenotypic plasticity. Heat-acclimated rock doves (*Columba livia*) maintained lower T_b during acute heat exposure compared to individuals acclimated to room temperature (Marder and Arieli, 1988), and a similar result was reported for white-winged doves (*Zenaida asiatica*; McKechnie and Wolf, 2004b). In some cases, intraspecific variation in heat tolerance is correlated with climate: a population of white-browed sparrow-weavers (*P. mahali*) inhabiting a hot, arid site tolerated significantly higher T_{air} during summer than conspecifics from cooler, mesic sites (Noakes et al., 2016).

Avian thermoregulation is characterized by the maintenance of brain temperature (T_{brain}) below core T_b, reflecting the high thermal sensitivity of brain tissue. Gradients between T_b and T_{brain} range from 0.1 to >2.0°C (Bech and Midtgård, 1981; Kilgore et al., 1976), and may reach values as high as 3.5°C in flying pigeons (Pinshow et al., 1982). The major mechanism involved in avian brain cooling is the rete opthalmicum, a network of blood vessels providing a countercurrent heat exchanger that cools arterial blood before reaching the brain (Midtgård, 1983; Porter and Witmer, 2016). The presence of a rete opthalmicum does not, however, appear to be prerequisite for brain cooling; T_b−T_{brain} gradients averaging 0.73°C occur in the calliope hummingbird (*Selasphorus calliope*) even though it lacks this structure (Burgoon et al., 1987).

45.4.3.1 Fever

Regulated hyperthermic responses associated with the activation of the innate immune system are widespread among vertebrates. Avian febrile responses have typically been investigated using lipopolysaccharide (a cellular component of gram-negative bacteria that mimics bacterial infection) to experimentally induce an immune response, with both the peak T_b and duration of fever being dose-dependent (Gray et al., 2013). Muramyl dipeptide, a cellular component of gram-positive bacteria, appears not to trigger avian febrile responses (Koutsos and Klasing, 2001; Marais et al., 2011), whereas the viral mimic polyinosinic:polycytidylic acid triggers fever in some species (Marais et al., 2011) but not others (Coon et al., 2011). The magnitude of hyperthermia during avian febrile responses is typically 1−2°C (occasionally as high as ~3°C) and varies with factors such as environmental temperature and prior exposure to pathogens (Gray et al., 2013). Fever magnitude tends to be greater when environmental temperature is above the TNZ, suggesting that fever-inducing infections could contribute substantially to avian mortality during heat waves (Gray et al., 2013).

Avian toll-like receptors (TLRs), found on the cell membranes of immune cells and which recognize pathogen cell surface molecules, differ to those of mammals. Whereas seven avian TLR genes are shared with mammals and/or fish, there are an additional three TLR genes apparently unique to birds (Temperley et al., 2008). The molecules that mediate the febrile response following TLR recognition of pathogens appear to be broadly comparable among birds and mammals, with prostaglandins, nitric oxide, and cytokines including interleukin-1β (IL-1β) and interleukin-6 (IL-6) involved. However, there are several key differences. First, the roles of IL-1β and IL-6 seem to differ in birds compared to mammals. Second, whereas prostaglandin E_2 is the major mediator of mammalian febrile responses, another prostaglandin appears to play the equivalent role in birds (Gray et al., 2013). As is the case in mammals, glucocorticoids appear to play an important role in modulating avian fever (Gray et al., 2013).

45.4.4 Hypothermic body temperature

The costs of endothermic homeothermy rapidly increase at low environmental temperatures. Some birds do indeed defend T_b at normothermic levels even at extremely low T_{air}, often relying on behaviors such as communal roosting, constructing insulated roost nests, or caching of food to avoid mismatches between energy supply and demand.

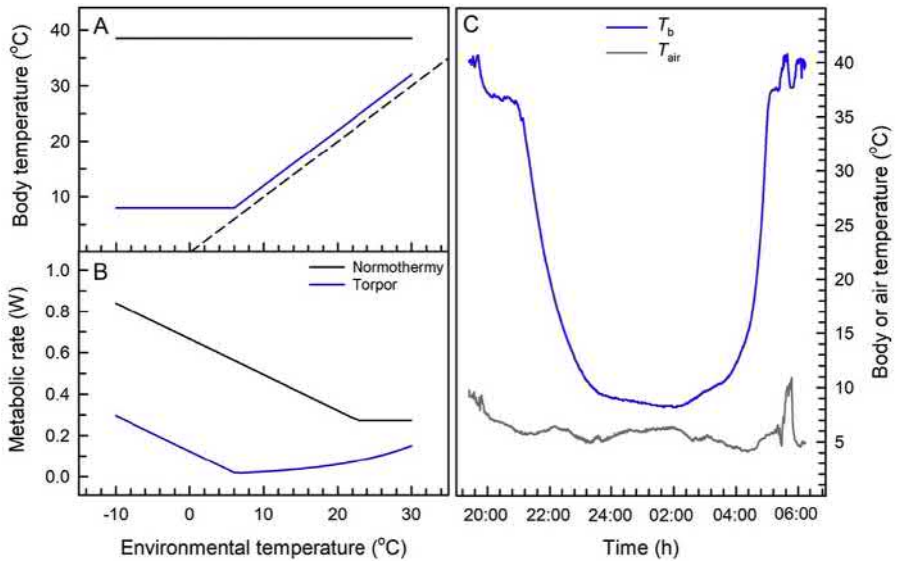

FIGURE 45.3 Avian torpor involves large reductions in metabolic rate and the resetting of body temperature (T_b) to a reduced setpoint. Panels (A) and (B) show the relationships between air temperature (T_{air}) and T_b (A) and metabolic rate (B) during normothermy (*black line*) and torpor (*blue line*) in a hypothetical 22-g bird with normothermic $T_b = 38.5°C$ and torpor setpoint $T_b = 8°C$. Note that at $T_{air} > 6°C$, thermoregulation is essentially ectothermic, with T_b remaining slightly above T_{air} (*dashed line* in panel A indicates equality) and metabolic rate decreasing in a temperature-dependent manner ($Q_{10} = 2.5$ assumed). At $T_{air} < 6°C$, thermoregulation follows the same pattern as during normothermy, with a setpoint T_b defended by linear increases in metabolic rate (panel B). Panel C is an overnight trace of T_b (blue line) and T_{air} (grey line) during a torpor bout in a giant hummingbird (*Patagona gigas*) held in captivity overnight in March 2015 at an elevation of 3800 m above sea level in the Peruvian Andes (Wolf et al., 2020).

Many others, however, show heterothermy involving regulated, reversible reductions in metabolic rate during which T_b may decrease far below normothermic levels (Figure 45.3). Distinguishing between normothermic circadian rhythms of avian T_b and facultative hypothermia is often not straightforward. Several approaches to distinguishing hypothermic T_b from normothermic T_b have been proposed, including the use of threshold T_b values (Barclay et al., 2001; Brigham et al., 2011), statistical approaches based on an assumption that normothermic T_b is normally distributed (McKechnie et al., 2007a), and, increasingly, arguments that avian T_b should be seen as a continuum between normothermy and hypothermia rather than viewed as discrete categories (Boyles et al., 2011a,b). One counterargument to the latter view concerns the fact that some studies have revealed that small differences in T_b can be associated with very different physiological states (Merola-Zwartjes and Ligon, 2000).

Facultative reductions in T_b vary in magnitude from 1-2°C below normothermic values to deep torpor with T_b reductions of >30°C, resulting in minimum $T_b \leq 5°C$. Shallow reductions in rest-phase T_b to 30°C or higher are typical of many passerines overwintering at high latitudes (Andreasson et al., 2019; Chaplin, 1976; Reinertsen and Haftorn, 1986) and are also often reported in response to food deprivation in laboratory studies (McKechnie and Lovegrove, 2003; Noakes et al., 2013; Rashotte et al., 1995). Reductions in T_b to 20−30°C are also taxonomically widespread, with minimum T_b in this range reported for columbids, coraciiformes, and a number of passerine families (Table 45.1). In contrast, the capacity to enter deep torpor and reduce T_b by > 20°C below normothermic levels appears to be restricted to a number of nonpasserine taxa, most notably hummingbirds, swifts, mousebirds, and nightjars and allies (McKechnie and Lovegrove, 2002; Schleucher, 2004).

The most pronounced reductions in avian T_b, to values $\leq 5°C$, occur in the common poorwill (*Phalaenoptilus nuttallii*), the only known avian hibernator (Jaeger, 1948; Woods et al., 2019) and in hummingbirds that inhabit high elevations (Calder and Booser, 1973; Carpenter, 1974; Pearson, 1953). Recently, a minimal cloacal T_b of just 3.3°C has been documented in a black metaltail (*Metallura phoebe*) at 3800 m above sea level in the Peruvian Andes (Wolf et al., 2020).

45.5 Avenues of heat transfer and behavioral modifications

45.5.1 Radiation

Radiative heat fluxes can vary from substantial heat losses (e.g., when roosting under a clear sky on a winter's night) to very rapid heat gains (e.g., foraging from an exposed

perch on a cloudless summer's day). Radiative heat transfer is estimated as follows:

$$Q_{rad} = \varepsilon\sigma A_b\left(T_s^4 - T_a^4\right)$$

where ε is combined emissivity, σ is the Stephan–Boltzmann constant, A_b is surface area in m^2, and T_s and T_a are surface and ambient temperatures in °K. The major avenue of radiative heat gain for free-ranging birds is solar irradiance, which at lower latitudes can exceed 1100 W/m^2 at midday when the sun is directly overhead. Approximately 42% of solar irradiance occurs in visible wavelengths (400–700 nm) and 49% as infrared (>700 nm).

Rates of solar heat gain depend on posture and surface area exposed to the sun, as well as plumage color. In still air or at low wind speeds, 10–40% of solar irradiance striking the outer surface of the plumage is absorbed across the skin as heat depending on irradiance levels (e.g., Wolf and Walsberg, 1996; Wolf et al., 2000). Interactions between pelage color and absorption of solar irradiance in visible wavelengths are not always intuitive, and at higher wind speeds, the solar heat gain associated with dark, heavily pigmented plumage can be lower than that of white plumage because of the interception of photons closer to the outside surface of heavily pigmented plumages (Wolf and Walsberg, 2000). Evidence has recently emerged for adaptive variation in plumage reflectance in near-infrared wavelengths (Medina et al., 2018).

The effect of solar radiation on environmental temperature experienced by a bird can be substantial. At midday in the Sonoran Desert when $T_{air} = 40°C$, an 11-g verdin (*Auriparus flaviceps*) shifting from a shaded site to a sunlit one experiences $T_e = 52°C$ (Wolf and Walsberg, 1996). Average midday T_e experienced by hoopoe larks (*Alaemon alaudipes*) and a female rufous-cheeked nightjar (*Caprimulgus rufigena*) nesting in exposed sites were 50.8 and 51.4°C, respectively (O'Connor et al., 2018; Tieleman et al., 2008). Under cool conditions, sun-basking can greatly enhance solar heat gain and reduce MHP requirements for thermoregulation. Greater roadrunners (*Geococcyx californianus*) and mousebirds (Coliiformes) substantially reduce metabolic costs of thermoregulation by orientating their dorsal or ventral surfaces, respectively, toward the sun and ptiloerecting their feathers so that solar irradiance is absorbed directly by their dark, heavily melanized skin (Dean and Williams, 1999; Ohmart and Lasiewski, 1971).

Under hot conditions, behavioral alterations of solar heat loads primarily involve retreating to shaded microsites to minimize heat gain. A recent comparative study of heat dissipation behavior in arid-zone bird communities on three continents revealed that T_{air} values at which 50% of observed individuals occupy shaded microsites average 30.2–31.4°C across species (Pattinson et al., 2020). There is also considerable interspecific variation, with more active species (e.g., gleaners) retreating to shade at lower T_{air} compared to less active species (e.g., sit-and-wait foragers; Pattinson et al., 2020). Many desert birds nest in sites completely exposed to the sun, apparently to avoid higher predation risk in shaded sites under vegetation (Tieleman et al., 2008), and shade their eggs by crouching above the nest with their backs orientated toward the sun and partially ptiloerecting their dorsal feathers to reduce solar heat gain and enhance convective heat loss and EHL (Grant, 1982). Birds may also seek shelter in burrows. In the Arabian Desert, several species of larks use burrows excavated by a large lizard (*Uromastyx aegypticus,* Williams et al., 1999) and in the Kalahari Desert, southern pied babblers (*Turdoides bicolor*) sometimes use the entrances of aardvark (*Orycteropus afer*) burrows as thermal refugia on very hot days (A.R. Bourne, personal observation).

45.5.2 Convection

Convective heat transfer occurs via free (or natural) convection driven by temperature and density gradients or forced convection driven by movement of air or water. Heat loss by forced convection increases linearly with wind speed or, in some cases, the square root of wind speed (Goldstein, 1983; Wolf and Walsberg, 1996; Wolf et al., 2000), with the slope of this relationship depending on both M_b and the gradient between T_b and T_{air}. Goldstein (1983) found that the slope (in $W/\sqrt{m/s}$) of avian RMR as a function of wind speed at any T_{air} below thermoneutrality can be estimated as follows:

$$\text{Slope} = 0.0092 M_b^{0.66} \Delta T^{0.32}$$

where M_b is body mass in g and $\Delta T = T_{lc} - T_{air}$ in °C.

The ~24-fold higher thermal conductivity of water compared to air means that convective heat loss occurs much more rapidly in aquatic and marine birds. For species that dive below the surface to forage [Emperor penguins (*Aptenodytes forsteri*) may dive to depths > 500 m], convective heat loss is further increased through plumage compression by hydrostatic pressure. In a heat balance model that assumed heat produced as a by-product of activity substitutes for thermoregulatory thermogenesis, depth had the greatest effect on heat loss, with net heat flux in Magellanic penguins (*Spheniscus magellanicus*) swimming at 2.1 m/s in 11°C water varying from ~0 W at the surface to a loss of ~80 W at depths of 40–50 m (Ciancio et al., 2016). Penguins respond to these rapid rates of heat loss when diving by means of peripheral vasoconstriction as well as regional heterothermy; lower abdominal temperatures of king penguins (*Aptenodytes patagonicus*) may be as low as 11°C during sustained deep diving (Handrich et al., 1997).

Roosting birds that remain normothermic employ a number of behavioral pathways to reduce nocturnal heat loss, including seeking protected microsites and postural adjustments such as facing into the wind to minimize disruption of the boundary layer provided by the plumage. Roosting in tree cavities is one way to substantially reduce nocturnal energy demands; the temperatures inside cavities occupied by acorn woodpeckers (*Melanerpes formicivorus*) were sometimes ~10°C above outside T_{air} (Weathers et al., 1990). Many species construct insulated nests and/or use the nests of other species for roosting. In the arid zone of southern Africa, sociable weavers (*Philetairus socius*) construct huge nests containing dozens of individual chambers, the internal temperatures of which may be as much as 23°C above outside T_a when occupied (White et al., 1975).

Another behavior many birds use to reduce overnight energy requirements is communal roosting, which has evolved in several avian lineages (Beauchamp, 1999) and may involve linear roosting huddles with a row of individuals tightly pressed against each other along the length of branch (e.g., long-tailed tit *Aegithalos caudatus*, Hatchwell et al., 2009) or approximately spherical clusters (e.g., mousebirds). The energy savings achieved in this way can be as high as 20–50% (Chaplin, 1982; McKechnie and Lovegrove, 2001b). Some species roost communally within insulated nests resulting in even more greater energy savings; chestnut-crowned babblers (*Pomatostomus ruficeps*) roosting in groups of seven or more individuals did not increase RMR above basal levels even when outside $T_{air} = 5$°C (Chappell et al., 2016).

45.5.3 Conduction

Conductive heat loss can be important for thermoregulation in very hot weather; Bedouin fowls respond to very high T_{air} by moving to shaded microsites, scratching away the top layer of sand, and lying prone with the ventral surfaces and legs in contact with the cooler, subsurface soil (Marder, 1973). Similar behavior occurs in desert birds such as the red lark (*Calendulauda burra*), a nondrinking species inhabiting hot, arid habitats; as T_{air} approaches T_b, the larks retreat to shaded microsites under shrubs and rest with their bellies in contact with cool sand below the surface layer (Kemp and McKechnie, 2019).

For emperor penguins breeding in the Antarctic winter, uninsulated feet are potentially a source of rapid heat loss. In addition to having the smallest feet relative to M_b of any penguin, pronounced vasoconstriction and a countercurrent heat exchanger that allows birds to maintain tissue temperatures in the distal part of the foot at ~0°C, and a characteristic resting posture with the distal parts of the feet lifted off the surface is thought to reduce conductive heat loss to the frozen substrate (Goldsmith and Sladen, 1961; Le Maho, 1977).

45.5.4 Evaporation

The evaporation of water is an endothermic reaction which, at a temperature of 40°C, uses 2.406 kJ/g H_2O (Tracy et al., 2010). EHL is thus an inevitable component of avian heat balance, but also provides the only mechanism whereby a bird can defend T_b below environmental temperature in hot environments. Although rates of EWL from a bird are primarily determined by physical factors, specifically the vapor pressure deficit arising from the temperature and humidity of surrounding air, both baseline ("insensible") evaporation (Eto et al., 2017) and thermoregulatory increases in total evaporative water loss (TEWL) (see below), are under physiological control.

TEWL (i.e., the sum of respiratory and cutaneous evaporation) measured under laboratory conditions is approximately constant at T_{air} below thermoneutrality. Baseline TEWL at thermoneutral or lower T_{air} scales allometrically with M_b, and is consistently lower in birds inhabiting arid habitats. William's (1996) analysis of TEWL at $T_{air} = 25$°C among 89 species indicated that in arid-zone birds TEWL (mL/day) $= 0.176M_b^{0.750}$, whereas in species from mesic habitats TEWL (mL/day) $= 0.365M_b^{0.661}$, equivalent to a difference of 56% for 25-g birds and 38% for 100-g birds.

When environmental temperature approaches or exceeds T_b, TEWL increases above baseline levels, with the resultant increases in Q_{evap} providing the basis for maintaining T_b below lethal limits. Under very hot conditions, most birds can increase TEWL to rates equivalent to 5–15 × baseline values, with the ratio of maximum TEWL during acute heat exposure to minimum thermoneutral TEWL referred to as evaporative scope. Authors have variously modeled the relationship between T_{air} and TEWL at $T_{air} > T_{uc}$ as an exponential curve, second-order polynomial curve, or as a segmented linear model (i.e., a "broken-stick" relationship characterized by two different linear relationships either side of an inflection T_{air}; Figure 45.2).

Heat tolerance limits, the maximum T_{air} values birds can tolerate during acute heat exposure, depend on both evaporative scope and the increase in Q_{metab} at $T_{air} > T_{uc}$. Heat tolerance limits of passerines are typically 48–52°C (McKechnie et al., 2017; Smith et al., 2017; Whitfield et al., 2015), whereas some desert doves and nightjars can tolerate $T_a \geq 60$°C using cutaneous evaporation or gular flutter (see Section 45.5.4). Recently, variation in evaporative scope among desert passerines was shown to be functionally linked to drinking behavior, with regularly drinking species capable of larger increases in Q_{evap} than nondrinkers (Czenze et al., 2020).

45.5.4.1 Respiratory evaporative water loss

The rate of EHL via respiration (Q_{evap_r}) is determined by the volume of air exhaled per unit time, the temperature of

exhaled air (generally assumed to be fully saturated with water vapor, but see Withers et al., 1981), the humidity of inhaled air, and the latent heat of vaporization in the expired air, such that Q_{evap_r} (W) is calculated as follows:

$$Q_{evap\_r} = \left[\dot{V}\left(\rho_{ex} - \frac{\Phi_a \rho_{in}}{100}\right)\lambda\right]/60$$

where $\dot{V}$ is respiratory minute volume (L/min), ρ_{ex} and ρ_{in} are the saturated water contents (g H_2O L^{-1}) of exhaled and inhaled air at their respective temperatures, Φ_a is the relative humidity (%) of inhaled air, and λ is the latent heat of vaporization for exhaled air (J/g).

The nasal cavities of birds, like those of mammals, have cartilaginous projections known as respiratory turbinates, which potentially act as countercurrent heat exchangers that raise the temperature of inhaled air to near T_b and saturate it with water vapor. On exhalation, the turbinates cool air exhaled through the nasal cavity to well below T_b, resulting in water recovery via condensation and greatly reducing EWL (Schmidt-Nielsen et al., 1970). Early and some, but not all, recent investigations support the notion of countercurrent heat exchange being the primary determinant of the temperature of exhaled air (e.g., Berger et al., 1971; Geist, 2000; Murrish, 1973). However, two species of larks showed reductions in respiratory evaporative water loss (REWL) much smaller than expected, leading the authors to suggest an alternate hypothesis, that the temperature of exhaled air is determined instead by the temperature of the uninsulated bill and surrounding tissue (Tieleman et al., 1999).

In most avian taxa investigated to date, increases in REWL provide the major avenue for evaporative cooling under hot conditions or during activity. The two major avenues of avian respiratory evaporative cooling are gular flutter and panting, with the relative importance of these two mechanisms varying among taxa. Many nonpasserines use a combination of panting and gular flutter, but gular flutter appears to be absent in some orders, including parrots and passerines.

45.5.4.1.1 Panting

Panting (or thermal tachypnea) occurs in response to increasing T_b and involves changes in respiratory frequency (f_{resp}), tidal volume (V_T), and thus respiratory minute volume (total volume of air passing through respiratory system per minute). Panting responses are broadly divisible into Type I and Type II (Figure 45.4). Type I panting is the primary mode of panting induced by small increases in T_b and involves increases in f_{resp} accompanied by decreases in V_T, which result in three- to sixfold increases in respiratory

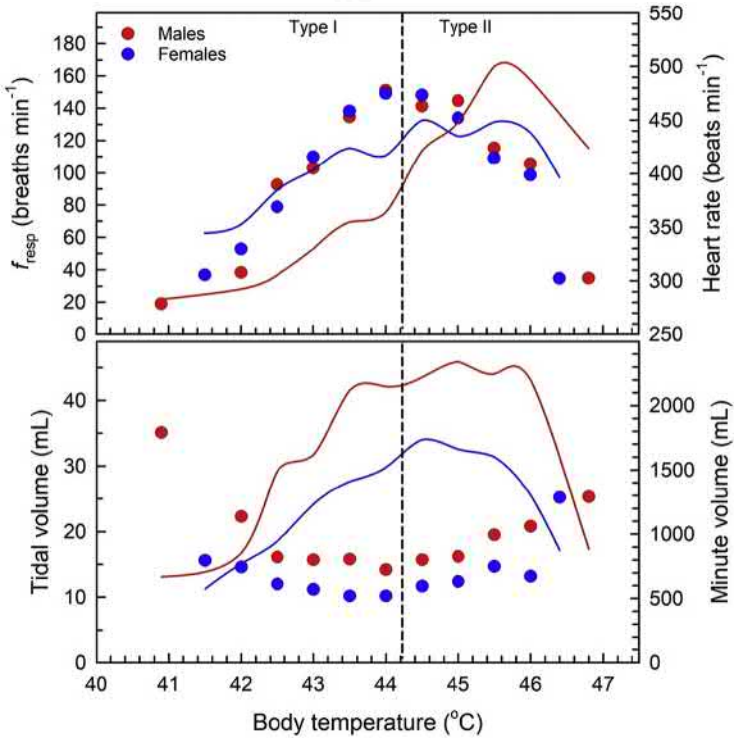

FIGURE 45.4 Relationships between body temperature (T_b) and respiratory frequency (f_{resp}; *filled circles*, upper panel), heart rate (*lines*, upper panel), tidal volume (*filled circles*, lower panel), and respiratory minute volume (*lines*, lower panel) in heat-stressed white leghorn chickens (data from Frankel et al., 1962). The *dashed vertical line* shows the approximate transition from Type I panting characterized by increases in f_{resp} and decreases in tidal volume to Type II panting associated with severe hyperthermia approaching lethal T_b during which f_{resp} decreases.

minute volume (Richards, 1970). Type II panting, on the other hand, is associated with severe heat exposure and T_b approaching lethal levels. Type II panting occurs after maximum f_{resp} of Type I panting has been reached, and involves decreases in f_{resp} and increases in V_T. Respiratory minute volume during Type II panting may increase slightly above the maximum reached during Type I panting.

Type I panting can involve gradual increases in f_{resp} with increasing T_b, the pattern that predominates in passerines, some quail, cormorants, and mousebirds (Lasiewski, 1972). In other taxa, including ostriches, roadrunners, columbids, guineafowl and pelicans, f_{resp} increases in an abrupt, step-wise fashion (Lasiewski, 1972; Nassar et al., 2001). Both resting f_{resp} and maximum f_{resp} during panting show negative scaling with M_b, with exponents varying among taxa between -0.25 and -0.35 and f_{resp} typically increasing to $\sim 16 \times$ resting levels during panting (Calder and King, 1974).

The large increases in respiratory minute volume that occur during panting have the potential to affect blood CO_2 and acid–base balance by leading to hypocapnia and alkalosis. Significant reductions in blood CO_2 and increases in pH have been reported in several studies, but are often attributable to stress associated with experimental conditions or the induction of Type II panting (Bech and Johansen, 1980; Marder and Arad, 1989). In general, birds can avoid alkalosis during Type I panting because reductions in V_T often result in increased ventilation largely confined to the respiratory dead space, whereas there is little change to ventilation of the parabronchi (Bech and Johansen, 1980). These authors argued for three general categories of avian panting response. The first is the aforementioned confinement of increased ventilation to the respiratory dead space, the second is the compound ventilation described in pigeons by Ramirez and Bernstein (1976) involving the superimposition of rapid, shallow panting on slower, deeper parabronchial ventilation, and the third is a pattern described in flamingos where bouts of panting are interspersed by brief, deeper "flush-out" breathing (Bech et al., 1979).

A long-standing question concerning respiratory evaporative cooling in species where f_{resp} during Type I panting shows a step-wise increase above resting levels is whether panting f_{resp} matches the resonant frequencies of respiratory systems, which would minimize the metabolic costs of panting (Bartholomew et al., 1968; Crawford and Kampe, 1971; Weathers, 1972). Although panting in several species, including ostriches, apparently does not occur at resonant frequencies (Schmidt-Nielsen et al., 1969), it does appear to do so in helmeted guineafowl *Numida meleagris* (Nassar et al., 2001). The authors of the latter study showed that panting f_{resp} during rest (6.67 Hz) as well as both step frequency (6.73 Hz) and f_{resp} (6.71 Hz) during treadmill locomotion did not differ significantly from the resonant frequency of the respiratory system (7.12 Hz), and argued that locomotory/respiratory entrainment at resonant frequencies of respiratory systems has evolved in both birds and mammals.

During panting, the majority of evaporation occurs in the upper respiratory tract (Lasiewski and Snyder, 1969; Menuam and Richards, 1975). In domestic fowls, surface temperatures (T_s) of the abdominal, thoracic, and clavicular air sacs did not differ from cloacal T_b, whereas those throughout the trachea and nasal and buccal regions were significantly (up to 2.3°C) lower than cloacal T_b, confirming that evaporation was largely confined to these regions (Menuam and Richards, 1975). There is, however, evidence for significant evaporation in the postthoracic and interclavicular air sacs of ostriches (Schmidt-Nielsen et al., 1969).

45.5.4.1.2 Gular flutter

Gular flutter involves rapid pulsation of the hyoid apparatus and thus the gular membranes at frequencies varying from 176 to >1000 cycles min^{-1} and may accompany panting either at frequencies synchronized with panting or independent of panting frequency (Lasiewski, 1972). The frequency of gular flutter tends to be synchronized with that of panting in quails, roadrunners, columbids, and owls, but is independent of panting in groups including pelicans, cormorants, mousebirds, and nightjars (Lasiewski, 1972). In birds belonging to the latter category, gular flutter frequencies may greatly exceed those of panting. In double-crested cormorants (*Phalacrocorax auritus*), for example, maximum panting f_{resp} was ~ 60 breaths min^{-1} when T_b exceeded 44°C, whereas the corresponding rate of gular flutter was ~ 700 min^{-1} (Bartholomew et al., 1968).

Early arguments that gular flutter provides the basis for extremely efficient evaporative cooling among caprimulgids (Dawson and Fisher, 1969; Lasiewski, 1969) have been confirmed by more recent studies, with rufous-cheeked nightjars (*C. rufigena*) achieving ratios of evaporative heat loss to metabolic heat production (EHL/MHP) > 5 (O'Connor et al., 2017). Unlike panting, gular flutter is sometimes associated with no discernible increase in MHP and some caprimulgids show virtually no evidence of an upper boundary to their TNZ (Figure 45.5).

The absence of gular flutter, most notably among passerines, constrains evaporative cooling capacity to levels well below those achievable by some nonpasserine taxa. Maximum EHL/MHP among passerines varies from 1.2–2.4 (Czenze et al., 2020; McKechnie et al., 2017), whereas several caprimulgids achieve EHL/MHP > 4 (O'Connor et al., 2017; Talbot et al., 2017). Parrots, which also lack gular flutter, augment REWL using lingual flutter,

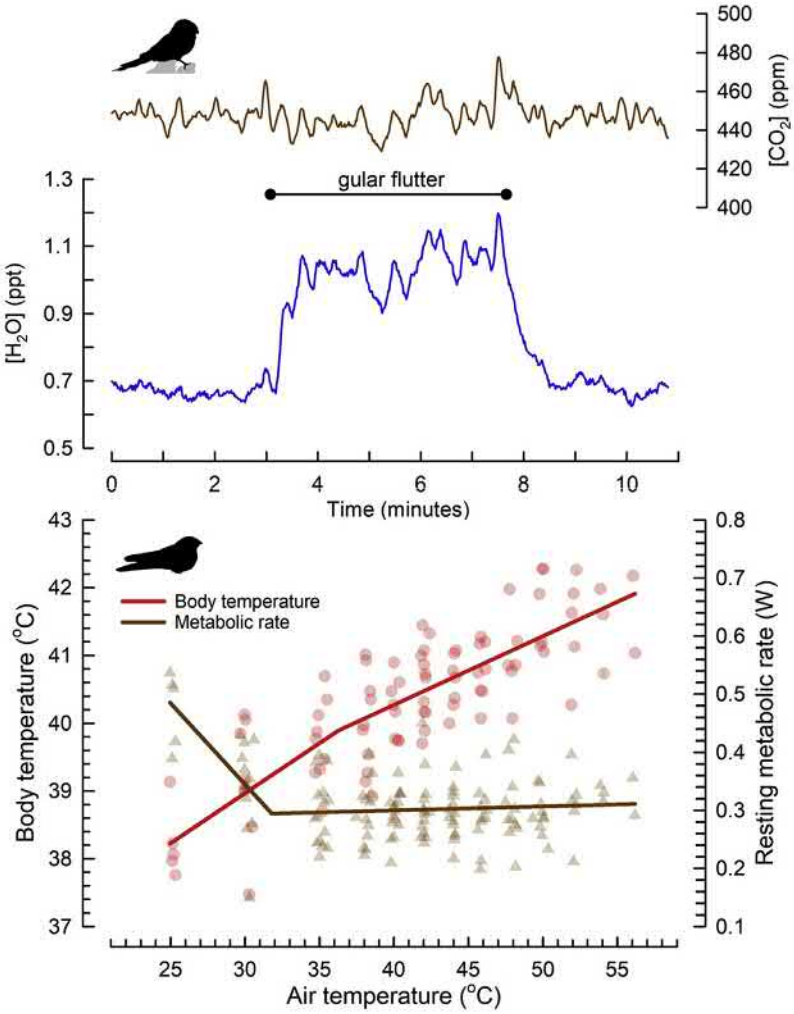

FIGURE 45.5 In nightjars and allies, gular flutter provides the basis for extremely efficient evaporative cooling at little metabolic cost. The upper panel shows a ~10-minute trace of the concentrations of H_2O vapor (*blue line*) and CO_2 (*brown line*) during measurements of evaporative water loss (EWL) and resting metabolic rate (RMR) in an Australian owlet-nightjar (*Aegotheles cristatus*) before, during, and after a bout of gular flutter (redrawn from Talbot et al., 2017). Note the large increase in EWL associated with gular flutter but lack of any discernible concomitant increase in RMR. The lower panel shows the relationships between air temperature (T_{air}) and body temperature (T_b) and RMR in a rufous-cheeked nightjar (*Caprimulgus rufigena*; data from O'Connor et al., 2017). Whereas T_b increases by 2.2°C between $T_{air} = 35$°C and $T_{air} = 55$°C, there is virtually no associated increase in RMR. The silhouettes were obtained from http://phylopic.org/: *Aegotheles* (Christopher Watson and T. Michael Keesey) and nightjar (Ferran Sayol). vertical movements of the tongue at frequencies synchronized with panting (Weathers and Caccamise, 1975, 1978). In galahs (*Eolophus roseicapilla*) and mulga parrots (*Psephotellus varius*), the onset of panting is not necessarily associated with significant increases in RMR, likely reflecting the contribution of lingual flutter to enhancing evaporative cooling efficiency (McWhorter et al., 2018).

45.5.4.2 Cutaneous evaporative water loss

The rate at which birds lose water via evaporation across the skin is a function of the temperature and humidity of surrounding air, as well as the skin's resistance to water vapor diffusion, with cutaneous EHL (Q_{evap_c}) in W/m^2 calculated as follows:

$$Q_{evap\_c} = h_e\left(\frac{\Phi_{skin}}{100}P_{ws} - \frac{\Phi_a}{100}P_{wa}\right)\lambda$$

where h_e is the evaporative heat transfer coefficient (g/s m^2 kPa), Φ_{skin} and Φ_a are the relative humidities at the skin surface and of the air (%), and P_{ws} and P_{wa} are the saturation vapor pressures (kPa) at T_{skin} and T_{air}, respectively, and λ is the latent heat of vaporization at T_{skin} (J/g). If measurements of CEWL are available, whole-body skin resistance to vapor diffusion (r_v, in s/m) can be calculated as follows:

$$r_v = \frac{\rho'_{vs} - \rho_{va}}{\dot{E}}$$

where ρ'_{vs} is saturation vapor density at T_{skin} (g/m^3), ρ_{va} is vapor density of air (g/m^3), and $\dot{E}$ is CEWL in g/m^2 s (Webster et al., 1985).

The extent to which the skin acts as a barrier to EWL is primarily determined by the ultrastructure and lipid composition of the stratum corneum (Menon et al., 1988, 1989, 1996). The avian stratum corneum differs from that of mammals by containing substantial quantities of cerebrosides, although evidence has recently emerged for convergent evolution whereby the skin of bats' wings also has large cerebroside content (Ben-Hamo et al., 2016).

One of the factors contributing to reduced TEWL in desert birds (Tieleman and Williams, 2000; Tieleman et al., 2003a; Williams, 1996) appears to be reduced permeability of the skin to water vapor, and recent work by J.B. Williams and colleagues has revealed how the lipid composition of lamellar layers in the extracellular matrix of the avian stratum corneum is correlated with adaptive variation in CEWL. The stratum corneum of larks from desert habitats contains higher proportions of ceramides and lower proportions of free fatty acids (Haugen et al., 2003), and CEWL is negatively correlated with percentage cerebroside and ceramide I content and positively correlated with triacylglyceride content (Champagne et al., 2012).

Habitat-correlated differences in CEWL at moderate T_{air} may also occur at an intraspecific level. House sparrows (*Passer domesticus*) inhabiting a desert habitat had CEWL ~26% lower than conspecifics in a mesic environment (Muñoz-Garcia and Williams, 2005). Although stratum corneum lipid composition differed substantially between the two populations, rates of CEWL across nonliving skin did not differ, leading these authors to argue that skin water proofing interacts with biological control processes. Several studies have demonstrated phenotypic flexibility in CEWL, including short-term thermal acclimation in hoopoe larks (Tieleman and Williams, 2002) and acclimation to ambient humidity in house sparrows (Muñoz-Garcia et al., 2008). In these studies, the direction of changes in CEWL was consistent with the hypothesis that the function of these adjustments is water conservation in warm, dry conditions.

The skin also plays an important role in evaporative cooling during heat exposure. Avian skin lacks sweat glands and many early workers considered CEWL to contribute little to evaporative cooling, panting thought to be the major pathway for elevated TEWL at T_{air} approaching or exceeding T_b (Dawson, 1954; Dawson and Schmidt-Nielsen, 1964). By the 1970s, however, there was evidence that CEWL is important for thermoregulation in some taxa (Bernstein, 1971; Lasiewski et al., 1971), and subsequent work revealed large cutaneous components to evaporative cooling in columbids (Marder and Arieli, 1988; Webster and Bernstein, 1987; Webster and King, 1987; Withers and Williams, 1990). Rapid cutaneous evaporative heat dissipation among Columbiformes appears to provide the basis for heat tolerance exceeding that of most taxa (McKechnie et al., 2016; Smith et al., 2015).
