The partitioning of columbids' EHL into respiratory and cutaneous avenues also exhibits phenotypic flexibility, with evidence for increases in CEWL over time scales of minutes in response to experimentally reduced REWL (Hoffman and Walsberg, 1999) and weeks as a component of thermal acclimation to hot environments (McKechnie and Wolf, 2004b). Increases in CEWL as a component of thermal acclimation in columbids arise from both ultrastructural changes in the skin (Peltonen et al., 1998) and microvascular adjustments (Ophir et al., 2003). Experimental inhibition or stimulation of adrenergic receptors altered arterial and venous blood flow in heat-acclimated rock doves, leading to increases in capillary hydrostatic pressure thought to cause elevated water outflow from skin capillary beds and concomitant increases in CEWL (Ophir et al., 2003).

45.5.4.3 Other avenues of evaporative cooling

EHL from the corneas contributes to the maintenance of T_{brain} below core T_b (Bernstein et al., 1979; Pinshow et al., 1982). The ocular circulation appears to represent a second source of cooled venous blood to the rete opthalmicum, augmenting cooler blood flowing from capillaries adjacent to the moist membranes of the buccopharyngeal cavity (Pinshow et al., 1982). Another site proposed to represent a significant component of avian TEWL is the cloaca. Cloacal evaporation was estimated to represent 21% of TEWL at $T_{air} = 42°C$ in Inca doves (*Columbina inca*) but just 6.4% in common quail (*Coturnix coturnix*), raising the possibility that, in some birds, regulated cloacal cooling is an important component of thermoregulation during heat exposure (Hoffman et al., 2007). Finally, in southern ground-hornbills (*Bucorvus leadbeateri*) experiencing high T_{air}, dilute fluid originating from the nares runs in grooves along the length of the beak (Kemp and Kemp, 1980). Recently, ground-hornbills were observed wiping their beaks on their dorsal feathers in an apparent effort to spread this fluid over a larger area, and thermal images suggest that the consequent evaporative cooling may contribute significantly to heat loss from the beak's surface (Janse van Vuuren et al., 2020).

45.5.5 Heat dissipation challenges in commercial poultry production

Domesticated birds, most notably chickens (*Gallus domesticus*) and turkeys (*Meleagris gallopavo*), have experienced strong artificial selection for rapid growth and

minimization of the time required to reach slaughter M_b (in the case of broilers) or high egg production (laying hens). The time required for chicken broilers to reach a slaughter M_b of 1.8 kg decreased from 90 days in the 1940s to <40 days by the end of the 20th century (Konarzewski et al., 2000). The active- and rest-phase normothermic T_b of chickens are typically 41.5 and 40.5°C, respectively (Etches et al., 2008), whereas the T_{uc} is 24−27°C (Czarick and Fairchild, 2008).

For poultry raised in large-scale commercial facilities, thermoregulatory challenges primarily relate to the dissipation of metabolic heat loads associated with rapid tissue synthesis. Panting is the primary avenue of EHL in poultry, with REWL accounting for 75% of TEWL at $T_{air} = 40$°C in chickens (Richards, 1976). The T_{air} associated with the onset of panting in poultry varies with humidity and may be as low as $T_{air} = 29$°C (reviewed by Etches et al., 2008). In contrast to the limited evidence for significant respiratory alkalosis during Type I panting in nondomesticated birds, some authors have reported increases in blood pH in poultry (e.g., Kohne and Jones, 1975; Raup and Bottje, 1990; Teeter et al., 1985). A widely used management strategy to counteract respiratory alkalosis in poultry involves dietary supplements such as sodium bicarbonate, ammonium chloride (Teeter et al., 1985), or potassium chloride (Ahmad et al., 2008).

The value of using poultry breeds from hot, arid climates to understand the upper limits to heat tolerance and evaporative cooling capacity has been demonstrated by the work of J. Marder and colleagues on Bedouin fowls, in which T_b increases from normothermic values of ~41°C at $T_{air} = 25$−30°C to hyperthermic values of ~43°C at $T_{air} = 48$°C (Marder, 1973). Rates of EWL at $T_{air} = 48$°C are equivalent to ~525% of corresponding values at $T_{air} = 30$°C. Modest increases of only ~9% in RMR over this increase in T_{air}, accompanied by no significant changes in heart rate (Marder, 1973), reveal efficient evaporative cooling in this breed which is significantly more heat resistant than commercial breeds (Arad and Marder, 1982).

Poultry species exhibit phenotypic plasticity in heat tolerance. Most work in this field has focused on developmental plasticity in response to heat exposure by embryos or hatchlings (see Section 45.8.2). However, responses to heat also involve short-term acclimation of older birds. Lott (1991), for example, showed that broilers exposed to $T_{air} = 35$°C at 30−40 days of age drank significantly more water and maintained lower T_b during acute heat exposure compared to nonacclimated individuals. A key aspect of thermoregulation in the heat for commercial poultry is heat produced via the heat increment of feeding (HIF), with removal of feed prior to heat exposure increasing survival (McCormick et al., 1979).

Heat dissipation by commercial poultry is typically enhanced by designing houses for enhanced natural ventilation or power ventilation to augment heat loss via forced convection, typically with wind speeds of 2−3 m/s (reviewed by Czarick and Fairchild, 2008). In addition to increasing convective heat loss, evaporative cooling can be enhanced via the use of fogging systems, sprinkler systems, or evaporative cooling pads that reduce incurrent T_{air} to a house by forcing air over wet surfaces (Czarick and Fairchild, 2008). The efficacy of evaporative cooling systems is strongly dependent on prevailing relative humidity. Another approach to artificially enhancing heat dissipation involves cool roosts, where birds have access to perches consisting of metal pipes within which chilled water is circulated (Okelo et al., 2003).

45.6 Metabolic heat production

The capacity of birds to produce heat through endogenous metabolic thermogenesis in the absence of activity provides the basis for avian homeothermic endothermy. For a resting, inactive bird defending a normothermic setpoint T_b, the lower and upper boundaries of metabolic thermogenesis are BMR and summit metabolism, respectively. This section provides an overview of basal and cold-induced thermoregulatory metabolism in the context of their contributions to avian heat balance. First, however, it is worth considering how metabolic heat generated during activity and feeding interacts with endogenous thermoregulatory MHP.

During activity at environmental temperatures below thermoneutrality, heat produced as a by-product of activity may contribute to heat balance, although the extent to which it does so depends on taxonomy, M_b, and environmental temperature (Humphries and Careau, 2011). In a metaanalysis of 51 studies, 28 of 32 species showed evidence for activity-thermoregulatory heat substitution, with an average magnitude of substitution of 57% (Humphries and Careau, 2011). These authors demonstrated that substitution is more likely in larger birds at T_e approaching T_{lc}, although some studies of small passerines found the extent of substitution increased with decreasing T_{air} (Paladino and King, 1984; Pohl and West, 1973).

Another source of MHP is the HIF (or specific dynamic action) associated with the digestion and absorption of ingested food. Evidence for substitution of HIF for thermoregulatory metabolic thermogenesis has been variable among studies (reviewed by Marsh and Dawson, 1989a). A series of experimental investigations of rock doves revealed a major thermoregulatory role for HIF in species that store food in their crops, and which can hence temporally separate HIF from ingestion (Geran and Rashotte, 1997; Hohtola et al., 1998; Rashotte et al., 1997). Pigeons fasted before the onset of the rest phase relied almost entirely on shivering for nocturnal thermoregulation, whereas individuals fed various quantities of food late in the active

phase maintained higher rest-phase T_b but reduced shivering, indicating that HIF contributed substantially to rest-phase thermogenic defense of T_b (Rashotte et al., 1999). In other cases, however, HIF appears to be of minimal thermoregulatory importance, particularly if the temperature of prey is far below T_b (Lovvorn, 2007).

45.6.1 Basal metabolic rate

Basal metabolic rate is the minimal normothermic rate of MHP measured under conditions that avoid any increments associated with digestion, activity, thermoregulation, growth, or reproduction. Caution is needed in evaluating published avian BMR measurements, for several reasons. First, some reported BMR measurements were (a) not conducted under the conditions required to elicit BMR or (b) conducted under unspecified conditions (McKechnie and Wolf, 2004a). Second, steady-state measurements lasting >6 h are typically required for RMR to reach minimum levels, i.e., BMR (Page et al., 2011). Third, there is evidence from domestic fowl (Misson, 1974) and budgerigars (Jacobs and McKechnie, 2014) that birds may require habituation to metabolic chambers before minimal metabolic rates are achieved.

This variable has a long history of use in comparative analyses of avian energetics (Lasiewski and Dawson, 1967; Londoño et al., 2015; Riddle et al., 1932), and BMR remains widely used for testing hypotheses concerning physiological adaptation to biotic and abiotic factors (Londoño et al., 2015; Noakes et al., 2013; Tieleman and Williams, 2000; White et al., 2007). The approximate range of avian BMR is from 0.07 W in 3-g hummingbirds to 63 W in the 93-kg common ostrich (*Struthio camelus*; Londoño et al., 2015; Withers, 1983). The number of species for which BMR measurements exist, particularly in the tropics, has increased substantially in the last decade, thanks in large measure to two studies that contributed data for 66 species in Vietnam (Bushuev et al., 2017) and a remarkable 253 species in Peru (Londoño et al., 2015).

A bird's BMR represents the sum of maintenance energy requirements of its organs and tissues, with the largest component comprising the metabolic costs of the liver, brain, kidneys, heart, and other organs (Daan et al., 1990; Suarez and Darveau, 2005; Wang et al., 2001). At the interspecific level, residual BMR was predicted by the residual combined mass of the heart and kidneys (Daan et al., 1990) and by the gut, liver, kidney, and breast muscle (Chappell et al., 1999). Lower BMR among tropical species compared to their higher-latitude counterparts has also been ascribed to proportionately smaller organs, including heart, liver, pancreas, kidneys, flight muscles, ovaries, and testes (Wiersma et al., 2012).

The largest component of variation in avian BMR is attributable to M_b. A phylogenetically corrected analysis of BMR in 488 species, with a balanced representation of tropical and temperate-latitude species, yielded the following equations predicting BMR (W) from M_b in g (Londoño et al., 2015):

$$\text{Non-passerines (excluding Apodiformes): BMR} = 0.021M_b^{0.724}$$

$$\text{Apodiformes: BMR} = 0.067M_b^{0.450}$$

$$\text{Passeriformes: BMR} = 0.045M_b^{0.627}$$

The processes underlying patterns of metabolic scaling are the subject of long-standing and ongoing debate (Darveau et al., 2002; Kleiber, 1932; Rubner, 1883; West et al., 1999). The scaling of avian BMR shows variability at both interspecific and intraspecific levels. Scaling exponents differ between wild-caught and captive-raised birds (McKechnie et al., 2006). A number of studies have revealed intraspecific slopes steeper than interspecific slopes; for instance, Kvist and Lindström (2001) reported interspecific slopes of 0.62−0.74, but intraspecific slopes of 0.93−4.21 for migratory waders.

Prior to the 1990s, it was widely accepted that passerine BMR is significantly higher than that of nonpasserines (e.g., Lasiewski and Dawson, 1967; Zar, 1968, but see also Prinzinger and Hänssler, 1980). The development of comparative methods that accounted for phylogenetic nonindependence of physiological traits (Felsenstein, 1985), however, led to the view that the higher BMR of extant passerines did not arise from selection for elevated BMR, but simply represented phylogenetic inertia and descent from a common ancestor (McKechnie and Wolf, 2004a; Reynolds and Lee, 1996). Londoño et al.'s (2015) analysis, based on a recent and well-supported avian phylogeny (Hackett et al., 2008), revealed that the BMR of passerines is indeed significantly higher than that of nonpasserines by ~12%.

After M_b and phylogenetic inertia have been taken into account, BMR is correlated with several environmental variables, in particular temperature. Among 90 species from absolute latitudes ranging from 60 degrees to the equator, BMR increased with decreasing average T_{air}, but was not related to primary productivity (White et al., 2007). Avian BMR has also been linked to diet type (McNab, 1988), although a more recent analysis of BMR in 19 neotropical passerines revealed no direct effects of diet composition on M_b-independent BMR (Sabat et al., 2010). In black-faced sheathbills (*Chionis minor*) on the subantarctic Marion Island, BMR was 35% higher in a population

with year-round access to resource-rich foraging areas compared to a population that foraged in areas poorer in resources (McClennand et al., 2016). Another broad factor affecting avian BMR is insularity; several studies have reported that the BMR of columbids whose distribution is restricted to islands is lower than that of continental species (McNab, 2000; Noakes et al., 2013).

Although sometimes viewed as a static, species-specific trait, BMR shows considerable phenotypic flexibility. Reversible, within-individual adjustments in BMR typically occur in one of three contexts: seasonal acclimatization, short-term thermal acclimation, and migration (reviewed by McKechnie, 2008; McKechnie and Swanson, 2010). Seasonal changes have long been recognized as an important component of acclimatization, particularly among nonmigratory species in temperate latitudes with long, cold winters (Pohl and West, 1973; Swanson, 2010; Weathers and Caccamise, 1978). Species occupying latitudes >35 degrees generally increase BMR in winter, sometimes by as much as 60%, whereas species from lower latitudes may exhibit winter increases or decreases (McKechnie et al., 2015). Studies tracking metabolic patterns over time have revealed that BMR is adjusted over periods of days to weeks in response to environmental temperature (Swanson and Olmstead, 1999). Moreover, acclimatization may vary substantially in direction and magnitude across years; in a desert population of white-browed sparrow-weavers (*P. mahali*), over a 4-year period BMR in winter varied from 20% lower to 68% higher than summer values (Noakes and McKechnie, 2020).

During acclimation of captive populations, BMR typically increases with decreasing T_{air} (Gelineo, 1964; McKechnie et al., 2007b). However, the magnitude of increases may vary substantially; among four species of lark, differences in BMR between conspecifics acclimated to $T_{air} = 15°C$ or $T_{air} = 35°C$ ranged from 5 to 29% (Tieleman et al., 2003b). Large changes in BMR may be associated with cyclical changes in body composition and physiology during migration. The BMR of great knots (*Calidris tenuirostris*) decreased by 42−46% during the course of migration between northwestern Australia and southern China (Battley et al., 2001), and Swanson and Dean (1999) found that BMR of yellow-rumped warblers (*Dendroica coronata*) was 31% higher during the northward spring migration compared to southward autumn migration. These changes can be very rapid; several studies have reported changes in BMR of >20% within 2−6 days (Klaassen and Biebach, 1994; Lindström et al., 1999).

The processes underlying phenotypic flexibility in BMR primarily involve changes in organ mass and/or metabolic intensity (Swanson, 2010). Changes in the masses of the digestive tract appear to be one major source of variation, with increases in BMR in cold-acclimated and -acclimatized birds thought to reflect the greater support costs of the larger digestive tracts required to process greater quantities of food during periods of elevated energy requirements (Vézina et al., 2006; Williams and Tieleman, 2000), as well as larger pectoral muscles for shivering thermogenesis (Vézina et al., 2017). In addition, the metabolic intensity of tissues is up or downregulated via changes in several key enzymes involved in aerobic metabolism (Swanson, 2010; Vézina et al., 2017).

45.6.2 Resting metabolic thermogenesis and cold tolerance

The capacity of avian tissues to produce heat in the absence of activity provides the basis for remarkable feats of cold tolerance; winter-acclimatized snowy owls can briefly tolerate T_{air} as low as −93°C (Gessaman, 1972). In a resting bird, MHP for thermoregulation primarily arises from shivering (Hohtola, 1982; Marsh and Dawson, 1989b) fueled by lipids (McWilliams et al., 2004). The large pectoral muscles often represent the primary source of shivering thermogenesis but leg muscles may also contribute substantially, particularly in young birds (Carey et al., 1989; Dietz et al., 1997).

Nonshivering thermogenesis (NST) also contributes to avian MHP (Barre et al., 1985; Bicudo et al., 2002), although birds lack brown adipose tissue and associated uncoupling protein 1(UCP1)−mediated NST similar to that of mammals (Emre et al., 2007). Avian NST primarily involves the 1a isoform of sarcoplasmic reticulum Ca^{2+}-ATPase (SERCA1a) in fast-twitch muscle fibers (Dumonteil et al., 1993). Upregulated SERCA1a expression and ryanodine receptors (Ca^{2+} channels on the sarcoplasmic reticulum) have been documented in cold-acclimated birds (e.g., Dumonteil et al., 1995). The extent to which sarcolipin, a key peptide involved in mammalian muscle NST, contributes to avian muscle NST remains unclear (Cheviron and Swanson, 2017; Nowack et al., 2017), with some recent evidence suggesting that sarcolipin-mediated NST could in fact hinder avian thermoregulation at very low T_a (Stager and Cheviron, 2020). In addition to SERCA, the existence of avian homologs to UCP1, including HmUCP, a homolog identified in the pectoral muscles of hummingbirds, suggests a second source of avian NST (Bicudo et al., 2002; Vianna et al., 2001). A UCP homolog (avUCP) identified in the skeletal muscle of chickens (Raimbault et al., 2001) has been implicated in thermogenesis, a notion supported by positive associations between avUCP mRNA expression and the HIF in domestic fowls and increases in its expression following cold acclimation or glucagon treatment (Li et al., 2013; Raimbault et al., 2001). However, the presumed mitochondrial uncoupling role of avUCP remains controversial (Walter and Seebacher, 2009).

Avian M_{sum} (also sometimes referred to as peak cold-induced metabolic rate) represents maximal thermogenic capacity and is typically measured in a helox (21% O_2, 79% He) atmosphere. The use of helox greatly increases rates of heat loss compared to those in air, obviating the need to expose birds to very low T_{air} values with the attendant risks of freezing injury. Among birds investigated to date, ratios of M_{sum}/BMR (metabolic expansibility, ME) are typically 3–9 (Noakes and McKechnie, 2020; Swanson, 2010), and M_{sum} is well below maximal exercise-induced metabolic rate (MMR). In birds from tropical Central America, M_{sum} averaged 4.52 × BMR and MMR averaged 6.44 × BMR (Wiersma et al., 2007). An analysis of data for 44 predominantly north-temperate species (Swanson and Garland, 2009) revealed a best-fit model for M_{sum} (expressed in mL O_2 min^{-1}) as a function of M_b (g) of:

$$\log_{10} M_{sum} = 0.626 \log_{10} M_b - 0.080$$

There is considerable phylogenetic variation in M_{sum} (Swanson and Garland, 2009), including ~74% higher M_{sum} in oscine passerines compared to suboscines. Swanson and Bozinovic (2011) argued this greater metabolic capacity of oscines has contributed to the dominance of this clade on all continents except South America. These two studies also revealed M_{sum} is correlated with the average winter T_{air} experienced by a species, confirming the functional link between maximum resting MHP and cold tolerance. Observations that low-latitude species have lower M_{sum} than their temperate-zone counterparts are consistent with the notion of a functional link with cold tolerance. Wiersma et al. (2007) reported M_{sum} 34% lower among tropical compared to temperate-latitude species and presented the following scaling relationships for M_{sum} (W) as a function of M_b (g):

$$\text{Tropical (19 species)}: \log_{10} M_{sum} = 0.814 \log_{10} M_b - 0.975$$

$$\text{Temperate (21 summer - acclimatized species)}: \log_{10} M_{sum} = 0.699 \log_{10} M_b - 0.654$$

Like BMR, M_{sum} exhibits considerable phenotypic flexibility, with seasonal acclimatization typically associated with increases of 25–50% among species from temperate latitudes (Swanson, 2010). Adjustments occur over shorter time scales in response to changing thermoregulatory demands. In black-capped chickadees (*Poecile atricapillus*) and dark-eyed juncos (*Junco hyemalis*), average T_{air} during 14–30 days preceding measurements was the strongest predictor of M_{sum}, whereas in American tree sparrows (*Spizelloides arborea*), average T_{air} over the preceding 0–5 days emerged as the best predictor (Swanson and Olmstead, 1999). The mechanisms underlying short-term within-individual variation in M_{sum} include changes in flight muscle size and hematocrit. An experimental manipulation of pectoral muscle size achieved by clipping half the flight feathers of black-capped chickadees revealed, upon subsequent recapture, increases in pectoral muscle size, hematocrit, and M_{sum} (Petit and Vézina, 2014). In addition to metabolic capacity responding to short-term fluctuations in winter temperature, fuel stores are also modulated: the fat reserves of snow buntings (*Plectrophenax nivalis*) respond to daily changes in T_{air} and snowfall (Laplante et al., 2019).

Seasonal adjustments in M_{sum} are not restricted to species from highly seasonal environments at high latitudes. In seven Central American species, M_{sum} was 13–35% lower in winter compared to summer (Wells and Schaeffer, 2012). In white-browed sparrow-weavers in an arid habitat at a latitude of 27°S, seasonal patterns varied from no significant change to M_{sum} 38% lower in winter, whereas cooccurring scaly feathered weavers (*Sporopipes squamifrons*) showed no seasonal changes (Noakes and McKechnie, 2020). In these species, BMR and M_{sum} were related to food availability but not minimum T_{air}, results supporting the idea that global patterns of seasonal metabolic adjustments represent a continuum driven by trade-offs between energy conservation and cold tolerance (Smit and McKechnie, 2010).

45.6.3 Metabolic costs of evaporative cooling

Another source of metabolic heat with profound thermoregulatory implications is increases in RMR during evaporative heat dissipation. The metabolic costs of evaporative cooling are highest among taxa that rely on panting, most notably passerines, in which gular flutter seems to be absent entirely. Above the TNZ, RMR increases 5- to 10-fold more rapidly in passerines than in similarly sized columbids, reflecting the latter's efficient cutaneous cooling (McKechnie et al., 2021). These authors found, based on analysis of data for 30 arid-zone passerines and six columbids, that RMR slopes at $T_{air} > T_{uc}$ (W/°C) for these two groups can be predicted from M_b (g) as follows:

$$\text{Passerines}: \log_{10}\text{Slope} = 0.856 \log_{10} M_b - 2.897$$

$$\text{Columbids}: \log_{10}\text{Slope} = 1.379 \log_{10} M_b - 4.446$$

The most exceptional taxon in terms of efficient evaporative cooling is the nightjars and allies. Because many members of this nocturnal taxon roost in exposed, sunlit microsites during the day, early workers realized they must possess an extremely effective cooling mechanism (Cowles and Dawson, 1951), and subsequent work reinforced this conclusion (Dawson and Fisher, 1969; Lasiewski, 1969). More recently, data for several species have revealed very small increases in RMR with T_{air} over the 45–60°C range (O'Connor et al., 2017; Talbot et al., 2017).

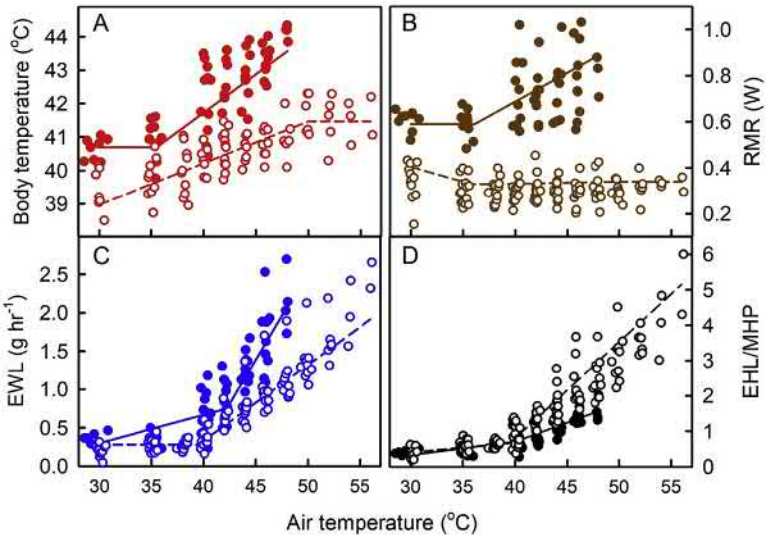

FIGURE 45.6 Interactions between body temperature (A), resting metabolic rate (RMR, B), evaporative water loss (EWL, C), and the ratio of evaporative heat loss to metabolic heat production (EHL/MHP, D) differ substantially among similarly sized (~53g) birds depending on the primary mode of evaporative cooling. Australian chestnut-crowned babblers (*Pomatostomus ruficeps*; filled symbols, solid regression lines) are passerines and rely on panting. They exhibit rapid increases in RMR (B) above an obvious upper critical limit of thermoneutrality (T_{uc}), with their body temperature (T_b) approaching 44°C (A) at a maximum tolerable air temperature (T_{air}) of 48°C and a maximum EHL/MHP of 1.6 (D). Rufous-cheeked nightjars (*Caprimulgus rufigena*; clear symbols, dashed regression lines) from southern Africa achieve similar maximum EWL (C) but make extensive use of gular flutter. In the nightjars, no T_{uc} is evident (B) and RMR remains at minimal levels even at T_{air} in the mid-50s, providing the basis for EHL/MHP > 5 (D) and T_b generally remaining below 42°C (A). Data for babblers and nightjars are from McKechnie et al. (2017) and O'Connor et al. (2017), respectively.

In rufous-cheeked nightjars, RMR at $T_{air} = 55°C$ was just 5% higher than minimum values at $T_{air} = 35°C$ (Figure 45.6).

The relationship between RMR and T_{air} in rufous-cheeked nightjars is all the more remarkable for the concomitant 2.2°C increase in T_b. This increase in T_b would be expected to cause a 17−28% increase in RMR on account of the temperature dependence of biological processes, for which Q_{10} is typically 2−3. The absence of temperature effects on avian RMR during heat exposure was reported by Weathers (1981), who noted $Q_{10} \approx 1$ in several species where T_b increased within the TNZ and temperature effects on RMR could thus be evaluated. The possibility that metabolic suppression (i.e., facultative hypometabolism) may be a component of avian thermoregulation in the heat is deserving of further investigation, and is receiving attention in small tropical mammals (Lovegrove et al., 2014; Reher et al., 2018).

45.7 Physiological control of thermoregulation

Our understanding of the neuronal thermostat underlying endothermic homeothermy in birds and mammals is rooted in the model for setpoint thermoregulation proposed by Hammel (1965). Defense of a T_b setpoint is achieved by the integration in the hypothalamus of afferent inputs from diverse thermoreceptors in the central and peripheral nervous systems and an array of efferent neuronal and endocrine responses that modulate physiological and behavioral pathways of heat gain or loss. The integration center resides primarily in the preoptic anterior hypothalamus (POAH), although an additional integration site involved in thermoregulatory responses to heat is a panting center located in the dorsal midbrain, electrical stimulation of which results in the increases in f_{resp} and decreases in V_T characteristic of Type I panting (Richards, 1971).

45.7.1 Thermoception

The network of neuronal cells providing inputs to the POAH includes thermoreceptors in the brain, spinal cord, deep tissues, and the peripheral regions spanning the skin, beak, and tongue. Unlike the case in mammals, the spinal cord is the most important site for avian thermoception. In most, but not all, species investigated to date, the spinal cord is a region of high thermosensitivity and localized heating induces rapid panting responses in species including domestic fowl (Avery and Richards, 1983). The thoracic region of the spinal cord typically exhibits greater thermosensitivity than the cervical region (Østnes and Bech, 1992; Rautenberg, 1969). Temperature transduction

also appears to involve molecular-level processes in neurons that lack thermosensory function (Simon, 2000).

A number of studies quantifying cold sensitivity in response to experimental manipulation of temperature in different regions of the central nervous system (CNS) have revealed that inputs from thermoreceptors outside the CNS comprise a major component of afferent input to the avian POAH (Mercer and Simon, 1984; Simon et al., 1981). Peripheral thermoreceptors in the skin and other tissues also play a significant role, with localized heating or cooling of feathered skin regions resulting in thermoregulatory responses (Necker, 1977). During acute cold exposure, the role of inputs from skin thermoreceptors of pigeons appears to exceed that of internal thermoreceptors (Østnes and Bech, 1998). In pigeons trained to wear masks so that inspired T_{air} could be varied without changing T_{air} of the birds' surroundings, changes in MHP suggested peripheral thermoception in the head (Bech et al., 1988). Skin thermoreceptors in regions such as the brood patch are thought to be vital for the regulation of egg temperature during incubation (Rautenberg, 1986).

A key group of molecules involved in transducing information about the temperature of a bird's surroundings are temperature-sensitive transient receptor potential (thermoTRP) channels, which are involved in both nociception and thermoception (Patapoutian et al., 2003). ThermoTRP channels are phylogenetically widespread among animals but show substantial functional diversity. For instance, TRPA1 channels appear to be heat sensitive in amphibians, reptiles, and birds, but cold sensitive or nontemperature sensitive in mammals (Yamamoto et al., 2016). An investigation of the role of TRPM8 channels in cold sensitivity in chicken dorsal root ganglion neurons suggested considerable functional overlap with mammalian TRPM8 channels, but also revealed large populations of TRPM8-independent cold-sensitive neurons (Yamamoto et al., 2016).

45.7.2 Neuronal integration

The basis for regulation of avian T_b around a setpoint involves proportional responses triggered by the firing rates of populations of warm-sensitive (i.e., firing rate positively related to T_b), cold-sensitive (i.e., firing rate negatively related to T_b), and temperature-insensitive neurons (reviewed by Boulant, 2006), with greater proportions of warm-sensitive neurons compared to cold-sensitive ones (Boulant and Dean, 1986; Simon, 2000). These neurons provide the basis for fine control of T_b, with even small deviations from the setpoint resulting in adjustments of heat loss or heat gain. Thermal control appears to involve at least two levels of regulation. One involves fine control based on differences in firing rates between cold- and warm-sensitive neurons. A second, less graded level of regulation arises from temperature guardian neurons, first described in the POAH of Muscovy ducklings (*Cairina moschata*) and which alter firing rates when T_b crosses specific lower and upper thresholds of 36.1 and 42.3°C, respectively (Basta et al., 1997).

In addition to integrating thermoreceptor inputs, the POAH also processes neuronal input related to osmotic variables. Damage to the POAH causes disruptions to both thermoregulation and osmoregulation and water balance (e.g., Kuznetsov and Kazakov, 2000). Numerous neuroactive molecules are involved in integration in the POAH and thermoregulatory effector responses are altered by a variety of experimental manipulations. Injections of norepinephrine, 5-hydroxytryptamine, or acetylcholine result in suppression of shivering thermogenesis in pigeons and domestic fowl (Hillman et al., 1980; Hohtola et al., 1989) and often result in hypothermia in the former species (Hissa, 1988). Other neuroactive molecules that play a role in thermoregulatory integration in the POAH include prostaglandins (Hissa et al., 1980; Nistico and Marley, 1976), arginine vasotocin and angiotensin II (Hassinen et al., 1994).

45.7.3 Efferent outputs

Outputs from the POAH effect an array of physiological and behavioral responses, modulated by neuronal or endocrine signaling. These include behavioral responses such as wing-drooping in domestic fowl (Lepkovsky et al., 1968). Elevated MHP primarily involves increases in thyroxine secretion by the thyroid gland and the subsequent synthesis of triiodothyronin (T_3), the primary thermogenesis-stimulating hormone, via deiodinase enzymes in tissues (Silvestri et al., 2005). The major effect of elevated T_3 is to stimulate metabolism in muscle and major organs including the kidney and liver. In addition to being the main stimulus for shivering and probably NST, T_3 also influences BMR. In black-legged kittiwakes (*Rissa tridactyla*), plasma T_3 concentrations were correlated with both whole-animal and mass-specific BMR (Welcker et al., 2013).

Another key neuroendocrine process involved in avian thermoregulation is the secretion of melatonin, which occurs in response to photoreceptor inputs integrated in pacemakers that include the hypothalamic SCN, pineal gland, and the retinae. The entrainment of avian circadian rhythms, with light levels representing the primary *Zeitgeber*, is functionally linked to elevated melatonin secretion during the rest phase. Melatonin synthesis by gastrointestinal cells has been suggested to be involved in adjusting T_b in response of restricted food availability (Saarela et al., 1999).

45.7.4 Circulatory adjustments of heat transfer

Regulation of blood flow to and from specific tissues is a critical component of avian thermoregulation. Reductions in heat loss across the skin occur through vasoconstriction of cutaneous capillary beds and directing blood flow through venae comitantes and retia, circulatory structures that promote heat transfer from warm arterial blood to cooler venous blood (Midtgård, 1989a). Arteriovenous anastomoses (AVAs) consist of low-resistance circuits that facilitate increases in peripheral blood flow and permit rapid heat loss. In domestic fowl, AVA blood flow occurs mainly in unfeathered skin and increases from 17% of total blood flow under cold conditions to 83% under hot conditions (Wolfenson, 1983). The density of AVA is a phenotypically flexible trait, with significantly higher AVA density in the nasal mucosa of heat-acclimated chickens compared to controls (Midtgård, 1989b).

Vasodilation is usually a component of circulatory responses to high T_e, serving to increase rates of heat loss, but may also be important in the prevention of freezing injury for species in which peripheral tissues are maintained at temperatures just above freezing. In swimming mallard ducks, metabolic rate increased rapidly when water temperature decreased below 0°C, reflecting vasodilation in the ducks' feet and associated increases in heat loss (Kilgore and Schmidt-Nielsen, 1975).

Birds can dissipate significant quantities of heat via vasodilation of the microvasculature of the beak (Hagan and Heath, 1980) and changes in the beak T_s of Toco toucans (*Ramphastos toco*) revealed this species' massive beak functions as a controllable heat radiator that can account for up to 100% of total heat loss (Tattersall et al., 2009). Finely controlled heat loss arising from adjustments to blood flow to the beak has been demonstrated in taxa including Darwin's finches (Tattersall et al., 2018), hornbills (van de Ven et al., 2016), and ground-hornbills (Janse van Vuuren et al., 2020), as well as the casques of cassowaries (Eastick et al., 2019).

Heat dissipation via the beak typically involves T_s increasing abruptly above some threshold T_{air}, creating a gradient for heat loss that diminishes as T_{air} approaches T_b. In southern ground-hornbills, the threshold T_{air} is approximately 20°C (Figure 45.7). Modulation of heat loss across the beak surface also appears to be a component of avian responses to perceived food scarcity. Great tits (*Parus major*) habituated to a feeder during winter immediately reduced beak T_s in response to food restriction, evidently as a preemptive measure to reduce the probability of a mismatch between energy supply and demand (Winder et al., 2020).

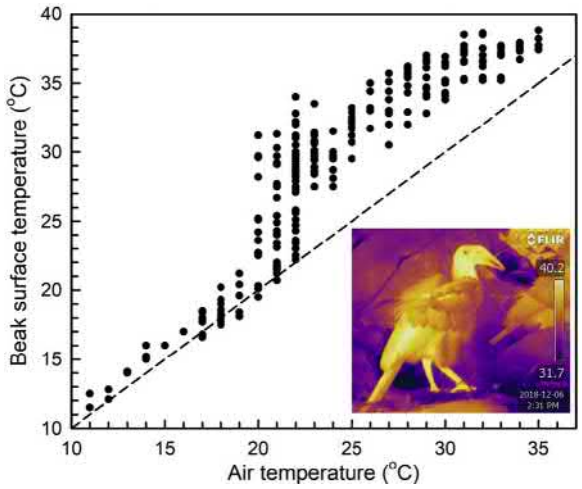

FIGURE 45.7 Beak surface temperature in southern ground-hornbills (*Bucorvus leadbeateri*) tracks air temperature (T_{air}) when $T_{air} < 20°C$, but then rapidly increases to values 6–10°C above T_{air} under warmer conditions, creating a gradient for nonevaporative heat loss. *Redrawn from Janse van Vuuren et al. (2020).*

45.8 Development of thermoregulation

Avian embryos make the transition to endothermy either before or after hatching, with the ontogenetic trajectory of endothermy involving many of the same fundamental steps that occurred during the evolution of endothermy: the acquisition of metabolic machinery to produce heat on demand, the development of a neuronal thermostat enabling the defense of a T_b setpoint, and the development of circulatory and respiratory systems suitable for transporting oxygen and nutrients to cells at the rates required to sustain metabolic rates substantially higher than those of ectotherms (Price and Dzialowski, 2018).

45.8.1 The altricial–precocial spectrum

The thermoregulatory status of hatchlings varies greatly depending on where they fall along the continuum from altriciality to precociality (Figure 45.8). The hatchlings of precocial taxa, such as Galliformes (including the domestic fowl), Anseriformes, Charadriiformes, Otidiformes, and Pteroclidiformes, hatch with down and are capable of maintaining an approximately constant T_b over a range of T_e. At the opposite end of the continuum, altricial hatchlings of orders such as Columbiformes, Cuculiformes, and Passeriformes lack any meaningful capacity for thermoregulatory heat production and are wholly dependent on external heat sources, typically the incubating parent.

As soon as the constraints on ventilation imposed by the eggshell are removed by hatching (Sirsat and

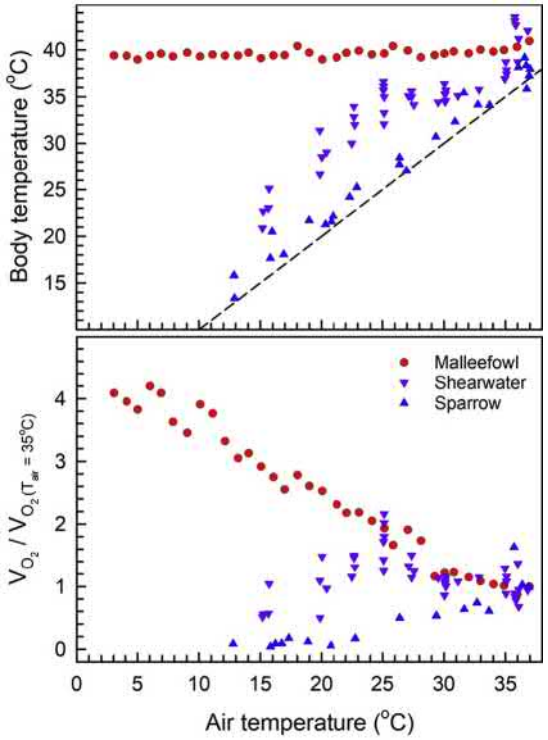

FIGURE 45.8 Thermoregulation in avian neonates represents a continuum from ectothermy in altricial species to endothermic homeothermy in precocial species, illustrated here by relationships between air temperature (T_{air}) and body temperature (T_b, upper panel) and oxygen consumption ($\dot{V}_{O_2}$, lower panel) for altricial vesper sparrows (*Pooecetes gramineus*), semiprecocial wedge-tailed shearwaters (*Ardenna pacifica*) and precocial malleefowl (*Leipoa ocellata*). In the shearwater neonates, T_b is regulated at a setpoint of ~35°C when T_{air} is between approximately 25°C and 35°C by means of increasing MHP, but declines at lower T_{air}. To account for interspecific differences in body mass, oxygen consumption (V_{O_2}) for each species is expressed as a fraction of average $\dot{V}_{O_2}$ calculated over $T_{air} = 32.5–37.5$°C. Data for sparrows, shearwaters, and malleefowl are from Dawson and Evans (1960), Mathiu et al. (1992) and Booth (1984), respectively.

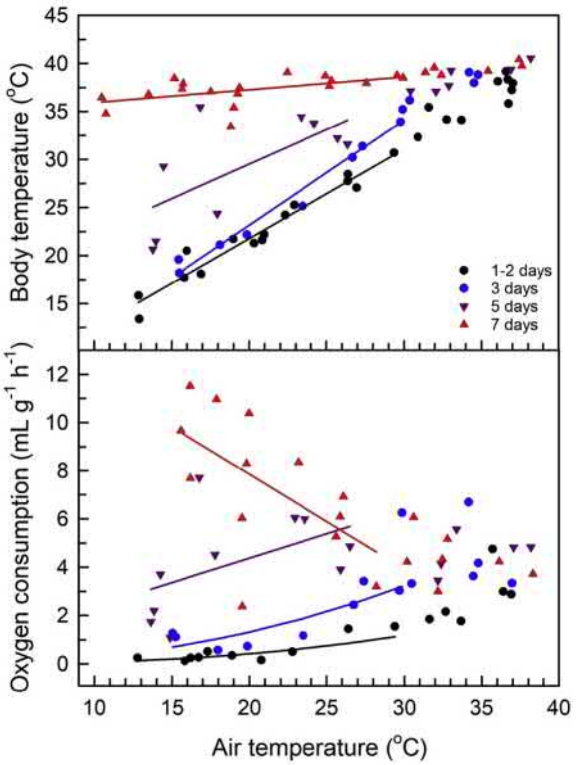

FIGURE 45.9 Development of endothermy in the altricial nestlings of vesper sparrows (*Pooecetes gramineus*), showing how the relationships between air temperature (T_{air}) and oxygen consumption (lower panel) and body temperature (upper panel) change within 7 days of hatching. The *solid lines* are regressions fitted to data at $T_{air} < 30$°C to illustrate the progressive development of endothermic homeothermy. *Data from Dawson and Evans (1960).*

Dzialowski, 2016), the neonates of precocial species show similar patterns of thermoregulation as adults, with thermogenesis compensating for heat loss at T_e below the TNZ. The thigh muscles appear to provide the major source of metabolic thermogenesis early in development, and the percentage of total M_b they represent increases rapidly immediately prior to hatching in Pekin ducks (*Anas platyrhynchos domestica*), whereas the relative mass of the heart increases more gradually (Price and Dzialowski, 2018). The metabolic intensity of cardiac and skeletal muscles also peaks at the time of hatching.

In contrast, the neonates of altricial species are fully ectothermic and develop endothermy posthatching, a process requiring from a few days up to 3 weeks (Figure 45.9). The pectoral muscles are the major sites for shivering thermogenesis and grow rapidly. In red-winged blackbirds (*Agelaius phoeniceus*), complete endothermy is attained around day 10 posthatching, associated with rapid increases in the relative mass of pectoral muscles (Olson, 2001; Sirsat et al., 2016). The growth of the pectoral muscles is accompanied by increases in activities of enzymes such as citrate synthase and pyruvate kinase and the rate of mitochondrial oxidative phosphorylation (Choi et al., 1993; Sirsat et al., 2016). The attainment of endothermy is also influenced by the number of nestlings and their collective thermal inertia; endothermy occurred earlier in blue tit (*Cyanistes caeruleus*) nestlings in experimentally reduced broods compared to control and enlarged broods (Andreasson et al., 2016).

Another functional difference between altricial and precocial species concerns the timing of the development of the thermostat provided by the neuronal integration center in the POAH. Functioning warm- and cold-sensitive neurons are evident up to a week before hatching in Muscovy duck embryos (Tzschentke and Basta, 2000) and thermoregulatory increases in MHP in malleefowl embryos 3 days before hatching imply a fully functional POAH (Booth, 1987). The neonates of many species solicit brooding behavior by means of vocalizations, which may be distinct

from food-soliciting calls. In American white pelicans (*Pelecanus erythrorhynchos*), both embryos and neonates use specific calls to solicit parental brooding (Evans, 1992), with the temperature dependence of these vocalizations shifting in parallel with the progressive development of the capacity for shivering thermogenesis during the first 2 weeks of posthatching development (Evans, 1994).

Thermoregulation during breeding may also involve heterothermy by adults or endothermic nestlings. Incubating female broad-tailed hummingbirds (*Selasphorus platycercus*) occasionally enter deep torpor while incubating eggs, with egg temperature as low as 6.5°C (Calder and Booser, 1973). After attaining endothermy at 5 days posthatching, fork-tailed storm petrel (*Oceanodroma furcata*) chicks in nesting burrows on Alaska's Barren Islands respond to extended periods without food provisioning by entering torpor, during which T_b was as low as 10.6°C (Boersma, 1986).

45.8.2 Developmental plasticity of thermoregulation

The thermal environment experienced by avian embryos can have profound effects on thermoregulation later in life. Not surprisingly, the species in which developmental plasticity of thermoregulation has received most attention is the domestic fowl, with a variety of egg thermal manipulations used to maximize commercial production. These manipulations, which typically involve exposing embryos to repeated transient increases or decreases in incubation temperature (T_{inc}), largely mimic the changes in temperature experienced by the embryos of wild species in which parental nest attendance is intermittent.

Most thermal manipulations employed in poultry production focus on the period during the middle third of incubation when the hypothalamus–thyroid–pituitary–adrenal (HTPA) axis is formed and thermal conditions are most likely to influence the development of thermoregulatory function (Yahav et al., 2009). For example, broiler embryos exposed to $T_{inc} = 39.5$°C and 65% relative humidity for 12 h/day between embryonic days E7 and E16 exhibited significantly lower eggshell temperatures, heart rates, and $\dot{V}_{O_2}$ after E18 compared to embryos incubated under control conditions of constant $T_{inc} = 37.8$°C and 56% relative humidity (Piestun et al., 2009). Posthatching, chicks from the experimental treatment had significantly lower T_b and levels of circulating thyroid hormones (Piestun et al., 2008). Responses to thermal manipulation during the period of hypothalamic development often differ from those associated with continuous thermal manipulation throughout incubation.

Changes in embryo thermal physiology induced by thermal manipulation may involve trade-offs between growth and heat production. Zebra finch embryos regularly cooled to 20°C showed lower mass and yolk reserves on E12, as well as higher mass-specific metabolic rates compared to embryos incubated at constant $T_{inc} = 37.5$°C, revealing that the efficiency of converting macronutrients contained in the egg into embryo tissue was reduced (Olson et al., 2006). The effects of periodic cooling on embryo growth appeared to be stronger in tissues such as muscles and organs compared to the skeleton (Olson et al., 2008).

An intriguing new mechanism for developmental plasticity in avian heat tolerance was reported by Mariette and Buchanan (2016). Incubating female zebra finches were observed vocalizing during periods of $T_{air} > 26$°C within 5 days of hatching and experimental playback of these heat-associated calls to eggs in artificial incubators resulted in long-term phenotypic effects. Finches exposed to the heat-associated call as embryos showed differences in begging and growth trajectories as nestlings, as well as in reproductive success and thermal preferences as adults, compared to individuals exposed to control playback of adult contact calls (Mariette and Buchanan, 2016).

Thermal acclimation soon after hatching can also significantly affect thermoregulatory performance in adults. Heat or cold acclimation during the first week posthatching significantly affects subsequent tolerance of high or low T_{air} at 6–7 weeks in chickens (Shinder et al., 2002; Yahav and Hurwitz, 1996). Far less is known about developmental plasticity in response to posthatching thermal acclimation among nestlings of wild birds, but Andreasson et al. (2018) found evidence for fitness benefits of exposure of 8- to 12-day old blue tit nestlings to high nest temperatures. Nestlings were able to maintain T_b below lethal levels even when nest temperature exceeded 50°C, and nestlings from heated nest boxes appeared to show higher annual survival and recruitment into the breeding population as adults compared to control nestlings from unheated nest boxes (Andreasson et al., 2018). Much remains to be learned about developmental plasticity in thermoregulation among wild birds. Nord and Giroud (2020) raise the interesting possibility that in altricial species, in which formation of the HTPA axis occurs during the week following hatching, posthatching thermal conditions may exert a greater influence on developmental plasticity than prehatching conditions, and vice versa for precocial species in which HTPA axis formation occurs earlier in development.

45.9 Avian thermoregulation and global heating

The thermal landscapes in which birds regulate their T_b are rapidly changing as a consequence of anthropogenic greenhouse gas emissions. In the absence of meaningful emission reductions, global average T_s is projected to

increase by ~4°C over the course of the 21st century (IPCC, 2014). The frequency, intensity, and duration of heatwaves are anticipated to increase, and some hot, arid regions are already showing more rapid heating than anticipated (van Wilgen et al., 2016). Climate change affects birds in a multitude of ways, and this section considers only direct impacts on thermoregulation.

The most obvious direct impacts of higher T_{air} are apparent in birds inhabiting hot, arid regions, where extreme heat events have occasionally caused catastrophic mortality involving vast numbers of individuals (e.g., Finlayson, 1932). More recently, smaller-scale mortality events have revealed the potential for heatwaves to rapidly cause severe declines in populations of threatened species (Saunders et al., 2011). Avian mortality by lethal hyperthermia (T_{air} exceeding species-specific heat tolerance limits) or lethal dehydration (cumulative TEWL exceeding dehydration tolerance) is predicted to occur more frequently and over larger areas under future climates, particularly in the arid zones of North America and Australia (Albright et al., 2017; Conradie et al., 2020).

Physiological constraints on maintaining T_b at sublethal levels during hot weather also create a host of trade-offs involving foraging and thermoregulatory behaviors. High T_{air} may result in reduced foraging efficiency by forcing birds to spend more time in shaded microsites or engaged in panting, with progressive loss of M_b during periods of sustained hot weather (du Plessis et al., 2012; van de Ven et al., 2019). Temperature-driven reductions in adult foraging efficiency during the nesting period may have severe negative impacts for breeding success through increased likelihood of nest abandonment, decreases in fledgling size and M_b, or increases in nest predation risk by extending the nestling period (Cunningham et al., 2013; Sharpe et al., 2019; van de Ven et al., 2019). Such trade-offs are not, however, limited to hot desert habitats; seabirds breeding at high latitudes can experience greater nestling mortality on days when $T_{air} > 14$°C forces adults to leave nests to engage in thermoregulatory behaviors such as bathing (Oswald et al., 2008).

Higher average air temperatures and more frequent and extreme heatwaves also have far-reaching impacts for domesticated birds and food production. In addition to compounding heat management challenges for commercial production, climate change is emerging as a significant threat to small-scale, subsistence poultry production systems and thus to food security and human well-being in low-income countries where rural communities rely heavily on poultry as a source of protein (Nyoni et al., 2018). In developing African countries, for example, free-ranging village chickens experience natural temperature cycles and depend on foraging to meet the nutritional requirements for survival, growth, and reproduction (Sonaiya, 2007; Yusuf et al., 2014). Domestic fowls in rural subsistence production systems in hot regions may be expected to be subject to fitness costs of hot weather similar to those observed in nondomesticated birds, and thus global heating has the potential to severely impact production and food security.

Chapter 46

Flight

Charles M. Bishop[1] and Christopher G. Guglielmo[2]

[1]School of Natural Sciences, Bangor University, Bangor, Gwynedd, United Kingdom; [2]Department of Biology, Advanced Facility for Avian Research, Western University, London, ON, Canada

46.1 Introduction

Birds typically fly between 29 and 83 km/h, with larger species generally flying faster than smaller ones (Alerstam et al., 2007). Although flapping flight is the most energy-intensive form of vertebrate locomotion, these high air speeds result in a lower cost of transport per unit distance than for terrestrial travel (Tucker, 1970; Schmidt-Nielsen, 1972; Butler, 1991), which enables birds to undertake large foraging trips (Jouventin and Weimerskirch, 1990) and long-distance seasonal migrations (Gill et al., 2009; Klaassen et al., 2011), more easily than any other group of animals. Thus, around 20% of the approximately 10,000 avian species are migratory (Sekercioglu, 2007; Kirby et al., 2008), although this is strongly influenced by breeding latitude. Almost all polar species move to lower altitudes during their winter periods, while the majority of tropical species are resident all year round. In more temperate latitudes, this is closer to 50%, despite the added problem of the birds initially carrying a relatively large amount of fuel (Alerstam and Lindström, 1990; Hedenström and Alerstam, 1992; Witter and Cuthill, 1993).

The critical factor for flight is to obtain sufficient airflow around the wings (to generate lift and thrust) and this is most challenging during take-off and slow flight. Hence, the general relationship between flight cost and speed is a U shape, with the cost of developing lift dominating at slow speeds and that of fighting drag forces dominating at high speeds (Pennycuick, 1968; Rayner, 1993; Alexander, 1997; Klein Heerenbrink et al., 2015). The large forces required from the avian flight muscles under powered take-off are relatively brief and much of it can be developed utilizing anaerobic muscle metabolism (George and Berger, 1966; Bishop and Butler, 1995). At one end of the spectrum, a few species and families of birds have evolved flight musculature that is specialized for these "burst" episodes of wing flapping, such as a number of species of Galliformes (Pheasants and Quail) and Tinamiformes (Tinamou), which they utilize to escape terrestrial predators, or to roost in trees. However, these birds are unable to sustain such activity for more than a few tens of seconds, and may be rendered incapable of flying at all after repeated bursts of activity (Marden, 1994). At the other end of the spectrum, the most aerial avian species may not touch down on land for many days, e.g., Godwits (Gill et al., 2009), or even for many months in the case of Swifts (Liechti et al., 2013; Hedenström et al., 2016).

In between these two extremes of aerial ability are birds that exhibit a range of different body masses (M_b) , adaptive wing morphology, and flight styles, which relate to the aeroecology of the species (Kunz et al., 2008). Relatively large-winged birds, like Condors (Williams et al., 2020), Frigatebirds (Weimerskirch et al., 2016), and Albatrosses (Sato et al., 2009; Richardson, 2011), may not flap their wings for many minutes at a time but remain airborne by soaring in thermals or through wind shear; or gliding over waves and mountain ridges; or other deflecting surfaces. Such behavior may reduce the cost of flight to a small fraction of the energy required for flapping flight, during both foraging and migratory journeys (Bevan et al., 1995a; Sakamoto et al., 2013; Duriez et al., 2014). Some intermediate-sized seabirds (e.g., Manx Shearwater, *Puffinus puffinus*) may regularly oscillate between flapping and gliding, with relatively short duty cycles of typically less than 5 s duration (Spivey et al., 2014). The flap-to-glide ratio of the Shearwater varies with the prevailing wind conditions, and largely determines the aerodynamic power output (P_o) of the bird. A variety of other species also display flap-gliding behavior, while generally smaller terrestrial passerines (from Woodpeckers and to Finches) employ the more extreme flight "gait" of flap-bounding (Tobalske and Dial, 1994; Tobalske et al., 2009). A number of hypotheses have been postulated to explain the possible advantages of these flapping gaits. Ideas vary from those that focus on aerodynamic consequences, e.g., that bounding may assist in generating higher horizonal velocities (Wang et al., 2018), to those that consider

Sturkie's Avian Physiology. https://doi.org/10.1016/B978-0-12-819770-7.00012-8

it primarily as a physiological constraint related to flight muscle activation and the optimal cost of producing work efficiently (Rayner, 1985a; Usherwood, 2016).

Efficient "oxidative" or "aerobic" muscle metabolism of fuel substrates is a prerequisite for sustained powered flapping flight, and results in adaptive selection on respiratory and cardiovascular functional capacity, and the fiber composition of the flight muscles. Relative heart size typically varies twofold among avian families and up to 10-fold between Hummingbirds and Tinamous (Hartman, 1961), which reflects the evolutionary selection for aerobic flight power (Bishop, 1997; Nespolo et al., 2018). Relative aerobic capacity also scales negatively with M_b, resulting in larger birds investing in anaerobic muscle fibers (George and Berger, 1966) primarily for use during take-off. Consequently, this most likely accounts for a restricted range of sustainable speeds in larger birds, reflecting the U-shaped power/velocity relationship (Bishop and Butler, 1995; Bishop, 1997). At the same time, individual birds have to regulate body temperature (T_b) during exercise to within an acceptable range (Parr et al., 2019a,b) while also controlling evaporative water loss in the face of the large amount of heat that is generated by the intense muscular activity (Torre-Bueno, 1978b; Engel et al., 2006b).

The energy cost of spring migration may be so high as to influence the subsequent energy dynamics of reproduction (Bromley and Jarvis, 1993). The postbreeding autumn migration follows a period of relatively sedentary behaviors such as incubation, brooding, and molt for the adults, during which there is evidence, for some species at least, that the main flight muscles atrophy (Mainguy and Thomas, 1985; Piersma, 1988; Bishop et al., 1996; Portugal et al., 2009). In addition, the energy and time taken for birds to molt and replace their flight feathers may be a major consideration in regulating the length of the breeding season and, even, the maximum size of flying birds (Rohwer et al., 2009). Thus, for postbreeding and postmolting adults, as well as for the season's fledglings, the flight muscles and supporting systems have to achieve an adequate level of aerobic fitness and functionality in preparation for the forthcoming migratory flights (Bishop et al., 1995, 1996). Some long flights may force birds to tackle a variety of different environmental challenges, such as crossing featureless deserts (Schmaljohann et al., 2007) and oceans (Butler et al., 1998; Shaffer et al., 2006; Gill et al., 2009), negotiating high mountains (Hawkes et al., 2011) and dealing with changes in weather conditions (Safi et al., 2013). All such challenges may affect a bird's overall energy budget and require individuals to make strategic decisions that could trade off considerations of time versus energy optimization (Efrat et al., 2019). Those species of birds that occasionally fly at high altitudes during their migration also have the combined problems of engaging in this energetically costly activity in a severely hypoxic and cold environment and at a reduced air density (Liechti and Schaller, 1999; Bishop et al., 2015).

This chapter will focus primarily on the following: the energetics of bird flight, including long distance migration; the function, physiology, and biochemistry of the flight muscles, including physical fitness in preparation for migration; deposition of fuel stores in preparation for migration and fuel use during migratory flight; respiratory and cardiovascular adjustments associated with flight, including temperature control and water loss; and the special case of flight at high altitudes. To begin with, however, there is a short introduction to the significance of animal size and scale.

46.2 Scaling effects of body size

It is important to be able to assess the significance of a particular characteristic, or adaptation, and compare it with those of other individuals and/or species, even though these other animals may vary greatly in size. The study of the consequences of changes morphological design or physiological and behavioral functions in relation to M_b is called scaling (Schmidt Nielsen, 1984), and it is frequently used in comparative biology. If two bodies are the same shape, or "geometrically similar," but of different volume (V) and mass (assuming constant tissue density, so that V and M_b are mathematically interchangeable), then their various body characteristics, such as lengths and areas, are directly proportional to their difference in M_b, and these individuals are said to scale isometrically with regard to each other. Thus, if we consider two cubes of different size, then each side will have a length (L), and the area (A) will be proportional to the length squared ($A \propto L^2$), while the mass will be proportional to the length cubed ($M \propto L^3$). From the perspective of mass, we can show that area will be proportional to mass to the two-thirds power ($A \propto M^{2/3}$ or $M_b^{0.67}$) and length will be proportional to mass to the one-third power ($L \propto M^{1/3}$ or $M_b^{0.33}$). Because M_b is a relatively easy variable to measure in most animals and one which represents the large size range seen in animals, it is most frequently used as the independent variable in scaling.

Pennycuick (1982) studied the flight and morphometric parameters of 11 species of Procellariiformes (e.g., petrels and albatrosses), ranging from 0.03 to 9 kg, and found that wing span (b) scaled in proportion to $M_b^{0.37}$ (Figure 46.1A) and wing area (S) in proportion to $M_b^{0.627}$ (Figure 46.1B). These results indicate that there is a slight tendency for larger birds to have relatively longer wings and smaller wing areas. This change of shape can be more easily demonstrated if the two measurements are combined by calculating the dimensionless variable called aspect ratio (Λ), which is the wing span divided by the mean wing width (or chord) and is equivalent to b^2/S. Figure 46.1C shows that Λ scales in proportion to $M_b^{0.116}$ and is highly significantly

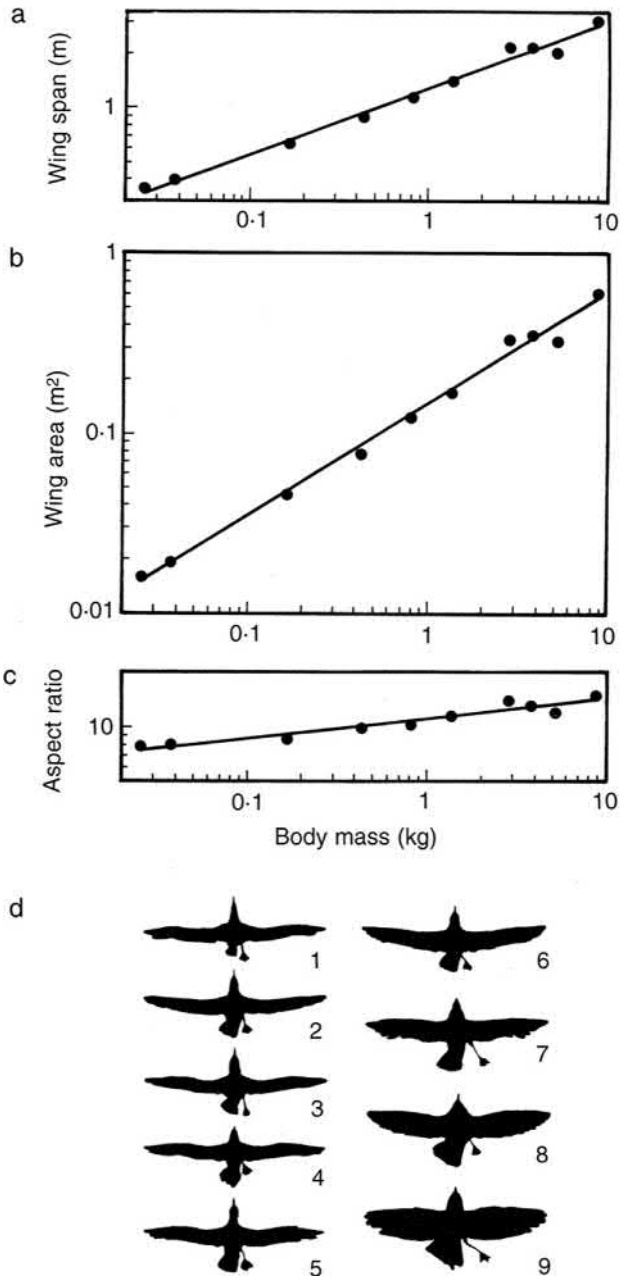

FIGURE 46.1 (A) Wing span, *S;* (B) Wing area, *A;* (C) Aspect ratio of 11 species of Procellariiform birds, plotted against body mass. (D) Wing tracings from nine of these species, with the smaller species enlarged such that all have the same wing span. 1, wandering albatross *Diomedea exulans*; 2, black-browed albatross *Diomedea melanophris*; 3, grey-headed albatross *Diomedea chysostoma*; 4, light-mantled sooty albatross *Phoebetria palpebrata*; 5, giant petrel *Macronectes* sp.; 6, white-chinned petrel *Procellaria aequinoctialis*; 7, cape pigeon *Daption capensis*; 8, dove prion *Pachyptila desolata*; 9,Wilson's storm petrel *Oceanites oceanicus*. The wing span of the largest species, *Diomedea exulans*, is 3.03 m and that of the smallest, *Oceanites oceanicus*, is 0.393 m. *(C) From C. J. Pennycuick (1992). (D) From Pennycuick (1982).*

different from the expected isometric value of $M_b^{0.0}$. Thus, this feature of birds scales allometrically with M_b. Similarly, we can easily visualize this change (Figure 46.1D) if the outlines of each species are displayed so that they all have the same wing span (Pennycuick, 1992).

Such analyses can also be used to test predictions regarding the scaling of animal energetics. Thus, the surface area of endothermic vertebrates should reflect the rate at which heat will be lost to the environment and, consequently, the metabolic rate (MR) required to replace this lost heat. Until recently, most studies of vertebrates had shown that basal metabolic rate (BMR) actually scales allometrically, at around $M_b^{0.72-0.75}$, i.e., slightly greater than predicted from the surface area law. However, at least with respect to the analysis of MR in birds and mammals, the scaling exponent has become quite a controversial subject, with some authors suggesting that there is no rigid scaling exponent and that it varies with a number of counfounding variables, such as relative exercise intensity (Koteja, 1987; Bishop, 1999; Glazier, 2008; White et al., 2009) or T_b (White et al., 2007; Gillooly and Allen, 2007). Other studies have suggested that it may also vary between taxonomic groupings or with ecological adaptations (White et al., 2007).

Despite these difficulties, scaling analysis has been used to address a wide variety of issues in biology (Schmidt-Nielsen, 1984), and the scaling of metabolic and biomechanical parameters associated with bird flight will be considered throughout this chapter.

46.3 Energetics of bird flight

One of the most useful physiological variables is the rate at which a bird expends chemical energy (i.e., power input (*P*i)) during flight. The *P*i of both resting and exercising animals are important considerations in many ecological and physiological studies of animal behavior and evolution, particularly as the metabolic power consumed by an organism is ultimately what determines how much food must be obtained from the environment. During locomotion, the chemical energy available from the catabolism of the various fuel molecules must be transformed by the myofibrillar proteins of the flight muscles into the mechanical *P*o required to fly, while the remainder is released as heat. The exact quantity of *P*o produced from a given *P*i will depend on the efficiency with which the muscles can convert the chemical energy into mechanical power. Some of the "waste" heat produced may be used to regulate T_b, but much is almost invariably "lost" to the environment.

The SI unit of mechanical *P*o is the watt (W) which is equivalent to 1 J per second. An estimate of metabolic *P*i can be obtained by converting the rate of oxygen consumption ($\dot{V}_{O_2}$, mL/s) to W. However, this conversion of $\dot{V}_{O_2}$ to *P*i depends on the metabolic substrate; for metabolism of pure carbohydrate, with a respiratory

quotient (RQ) of 1, 1 mL O_2/s = 21.1 W, whereas for pure fat metabolism (with an RQ of 0.71), 1 mL O_2/s = 19.6 W (Lusk, 1919; Brobeck and Dubois, 1980). Pure protein metabolism in birds would yield an RQ of 0.74 and 1 mL O_2/s = 18.4 W Schmidt-Nielsen, 1997. During short-duration exercise, it is likely that carbohydrate oxidation will be favored; for example, short hovering flights during foraging in hummingbirds (Suarez et al., 1990) and soon after take-off in pigeons (Butler et al., 1977), but during longer bouts of exercise, it is likely that fat oxidation will become dominant (Rothe et al., 1987). However, this may be influenced by the feeding regime and by the season well-fed and summer birds start at a higher RQ and take longer to reach an RQ of approximately 0.7 (Nachtigall, 1995). Thus, if RQ is unknown, a compromise for an RQ of 0.8 of 1 mL O_2/s = 20.1 W is often used for calculations of *P*i during aerobic activity (Schmidt- Nielsen, 1997).

In practice, it is not easy to obtain accurate experimental data from a bird during flight, either in a wind tunnel or the wild, and no single experimental method can adequately give all of the necessary information required for a full analysis of the physiological responses to flight. Thus, various techniques are used to study the biology of flight, some of which are discussed below, primarily with respect to the estimation of *P*i and *P*o during flight.

46.3.1 Techniques used to study the mechanical power output required for flight

46.3.1.1 Aerodynamic and biomechanical models

The use of aerodynamic and biomechanical models provides a theoretical framework for understanding the physiological adaptations and energetics of birds and the likely constraints acting on different species. It is theoretically possible to estimate the *P*i of a particular bird, using estimates for *P*o based on aerodynamic models (Rayner, 1979; Pennycuick, 1989; Klein Heerenbrink et al., 2015; Chin and Lentink, 2016; Deetjen et al., 2020), provided the efficiency by which the flight muscles are able to transduce chemical energy into mechanical energy is known or can be estimated. However, while Pennycuick (2008) has assumed that flight muscle efficiency is around 23% for all bird species, other authors have pointed out that the overall efficiency appears to scale positively with increasing M_b for many types of invertebrate and vertebrate locomotion, including flight (Alexander, 2005; Bishop, 2005; Askew et al., 2010). Under ideal uniform conditions, the *P*o required for different modes of flight is primarily determined by the overall mass, wing kinematics, and detailed morphology of the bird under investigation (Pennycuick, 1968). The actual energetic costs incurred in the wild are influenced by many additional effects induced by the prevailing environmental conditions, such as wind strength and direction, local air thermals and deflected currents from nearby surfaces, or air density, humidity, and temperature (Pennycuick, 1989, 2008).

As aerodynamic theory predicts that *P*o and, therefore, *P*i should vary with flight speed in a U-shaped fashion (Figure 46.2), then there is an intermediate speed at which *P*o and *P*i should be at a minimum (U_{min}) and at which the bird should fly in order to maximize its flying time. However, this is not the speed at which the bird should fly in order to maximize the distance flown for a given amount of fuel consumption (i.e., the speed at which the energy cost of transport is lowest). This is the maximum range speed (U_{mr}, Figure 46.2) and the speed at which a long-distance migrant might be expected to fly to optimize fuel use (Pennycuick, 1969; Alerstam and Lindström, 1990). Thus, Hedenström and Alerstam (1995) contend that birds should adapt their flight speed differently when migrating, or transporting food, compared with when they are foraging, and this will depend on whether the bird is time or energy limited (Hedenström, 2008).

The interspecies scaling of the biomechanical power required to hold the wings out and to support the mass of the body during gliding flight is discussed by Pennycuick (1989). Given the limited amount of data available, he tentatively concludes that the power required should scale with respect to Mb between $M_b^{0.67}$ and $M_b^{0.83}$, i.e., that the power required is approximately a fixed multiple of the aerobic BMR in birds of different mass. This is consistent with the limited amount of data on the cost of gliding in birds (see below).

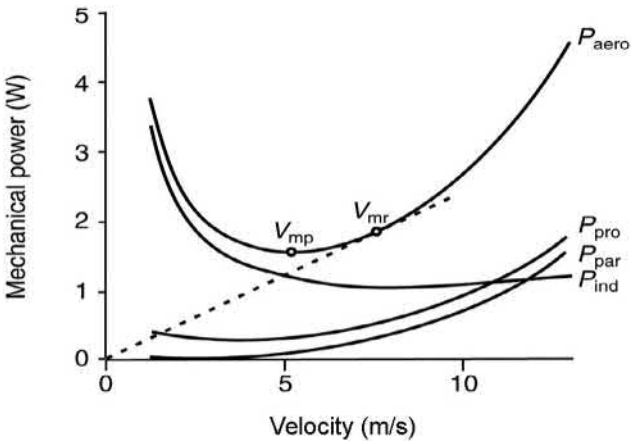

FIGURE 46.2 Calculated mechanical power output (*Paero* or *Ptot*) and its separate components (induced power, *P*ind; parasite power, *P*par; profile power, *P*pro) for the European kestrel *Falco tinnunculus* (mass 0.21 kg) flying at different speeds. Also shown are the minimum power speed (*U*min) and maximum range speed (*U*mr). *Based on Rayner (1999).*

Pennycuick (1968, 1969, 1989) has also discussed the factors which may limit the flapping flight performance of different species of birds. He hypothesizes that, for geometrically similar birds, the *P*o required for flight should scale proportional to $M_b^{1.17}$ and predicts that the *P*o available from the flight muscles should scale proportional to $M_b^{0.67}$. As the mass of the flight muscles appears to scale in direct proportion to M_b (Greenewalt, 1962; Marden, 1987; Rayner, 1988; Bishop and Butler, 1995), this results in larger birds exhibiting a reduced flight performance in terms of rate of climb, speed of take-off, ability to hover, and so on. In addition, as the maximum heart rate of both birds and mammals scale negatively with M_b, maximum sustained flight performance will also be limited by the negative scaling of maximum cardiac output (Bishop and Butler (1995); Bishop, 1997; Bishop and Spivey, 2013). Given that the M_b scaling exponents for the aerodynamic *P*o required and the sustainable metabolic *P*i available appear to be so different, there should be a clear upper limit to the size of birds which can perform flapping flight, and this would appear to be at approximately 12–20 kg (Pennycuick, 1968; Sato et al., 2009). The range of flight performance of any particular bird will depend on the detailed relationship between the U-shaped power/velocity curve and the maximum *P*o available from the flight muscles and cardiovascular system (Bishop and Butler, 1995). Thus, two categories of maximum power (P_{max}) are distinguished by Pennycuick (1968): (1) absolute P_{max}, which recruits the combined aerobic (sustained) and anaerobic (burst) capacity of the flight muscles, and (2) maximum sustainable power (P_{ms}), which only includes the aerobic capacity of the muscles and is ultimately limited by the rate of delivery of oxygen and related metabolites through the cardiorespiratory system (Figure 46.3). In the most aerobic species, e.g., hummingbirds, both P_{ms} and P_{max} may lie above the power required for hovering (Figure 46.3B), so that these birds can hover aerobically (Chai and Dudley, 1995). At the other end of the spectrum, Tinamous and many species of Pheasant have such small hearts that they cannot truly sustain any form flight (Bishop, 1997). Larger soaring specialists, such as Vultures and Condors (Figure 46.3C and D), appear to have a threshold for both P_{ms} and P_{max} that lies fairly close to the minimum power required for flapping flight, thus providing only very limited support for take-off and sustained powered performance (Duriez et al., 2014; Williams et al., 2020). The majority of bird species lie between these two extremes, with birds such as pigeons (Figure 46.3A), possessing a P_{max} sufficient to hover for brief periods using anaerobic metabolism and a P_{ms} sufficient for fast forward flight. More recent aerodynamic modeling (Klein Heerenbrink et al., 2015) suggests that the U-shaped relationship may be more skewed toward the slower speeds, so that sustaining slower speeds may be energetically more demanding than higher speeds when plotted symmetrically around the U_{min}, although ultimately drag at sufficiently high speeds will predominate.

46.3.1.2 Air flow visualization and direct force measurements

Although the mathematical models for estimating aerodynamic *P*o have been available for many years, it is only very recently that developments in technology have enabled

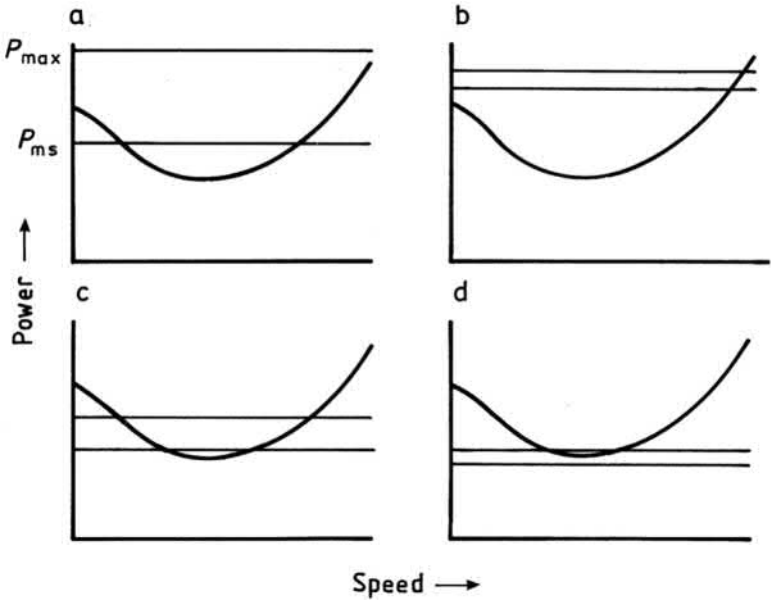

FIGURE 46.3 Power curves (see Figure 1) for (A) pigeon, *Columba livia*, (B) humming bird, *spp*., (C) white-backed vulture, *Gyps africanus*, and (D) California condor, *Gymnogyps californianus* (not to scale). The upper horizontal line represents maximum power available (*P*max), the lower line represents the maximum sustainable power (*P*ms). *Based on Pennycuick (1968).*

measurements to be made that could attempt to test the accuracy of the models by obtaining measurements of the aerodynamic forces produced by the wings. Some ingenious early experiments enabled the wake of a pigeon (*Columba livia*), jackdaw (*Corvus monedula*), and European kestrel (*Falco tinnunculus*) to be visualized, as they flew slowly during short indoor flights through a cloud of neutrally buoyant helium bubbles (Spedding, 1986; Spedding et al., 1984, 1987). The data obtained generally supported the hypothesis (Rayner, 1979) that the wake is composed of a chain of small vortex rings during slow flights (indicating that the upstroke is aerodynamically relatively inactive), but consisted of a pair of continuous, undulating trailing vortices during slightly faster speeds (indicating that the upstroke of the wing was aerodynamically active). Using wingbeat kinematics to infer lift production, Tobalske and Dial (1996) concluded that black-billed magpies (*Pica pica*) use a vortex-ring gait at all speeds, whereas pigeons use a vortex-ring gait at 6–8 m/s, a transitional gait at 10 m/s, and a continuous-vortex gait at higher speeds.

More recent work, utilizing sophisticated particle image velocimetry (PIV) equipment to monitor the wake of birds flying in wind tunnels (e.g., Thrush Nightingales *Luscinia luscinia*, Spedding et al., 2003), has indicated that, in reality, the results for most flight speeds indicate a more complex and somewhat intermediate set of wakes, with strong and continuous wing tip vortices and, at least in the case of swifts (*Apus apus*), additional vortices shed at the root (or base) of the wing (Henningsson et al., 2011). Once again, hummingbirds demonstrate their unusual aerodynamic approach, with a bound circulation that is not shed as a vortex at the end of the wingbeat but persists, so that there is a near-continuous production of lift throughout the wing cycle (Warrick et al., 2009). As a result, some 25% of the weight support is generated by the aerodynamically "active" upstroke of the wing during hovering (Warrick et al., 2012, Figure 46.4). While some other birds may hover for very limited periods, they retract the wing on the upstroke so that it almost folds up while sweeping close to the body and is, therefore, aerodynamically "inactive." To compensate for this, the pied flycatcher (*Ficedula hypoleuca*) can produce 23% of its weight support from a combination of its body and tail surfaces (Muijres et al., 2012a). An important new technique developed for bats (von Busse et al., 2014) and birds (Johansson et al., 2018) uses PIV to estimate the rate of kinetic energy imparted to the wake as a direct measurement of *P*o. Provided the cross-section of the wake can be accurately captured, this method allows measurements of *P*o across a range of speeds for the generation of power curves (Hedh et al., 2020). Comparisons of the wake structures of birds and bats (Figure 46.5) show that birds have a higher aerodynamic efficiency (including a high lift-to-drag ratio) than bats and this might contribute to the observation that birds tend to migrate more frequently and over longer distances than bats (Muijres et al., 2012b).

The first empirical attempt to measure directly the biomechanical force produced by the muscles of a bird during flight used a calibrated strain gauge, recording from the humerus of a starling (*Sturnus vulgaris*) and a pigeon (*C. livia*), and yielded estimates for the biomechanical *P*o generated by the pectoralis muscle (Biewener et al., 1992; Dial and Biewener, 1993). A more complete series of measurements were achieved with black-billed magpies (*Pica hudsonia*), with flight speeds ranging from 0 to 14 m/s (Dial et al., 1997), followed by further studies on cockatiels (*Nymphicus hollandicus*) and turtle doves (*Streptopelia risoria*) over the next few years (Tobalske et al., 2003) and finally hummingbirds (Warrick et al., 2012). For the magpie,

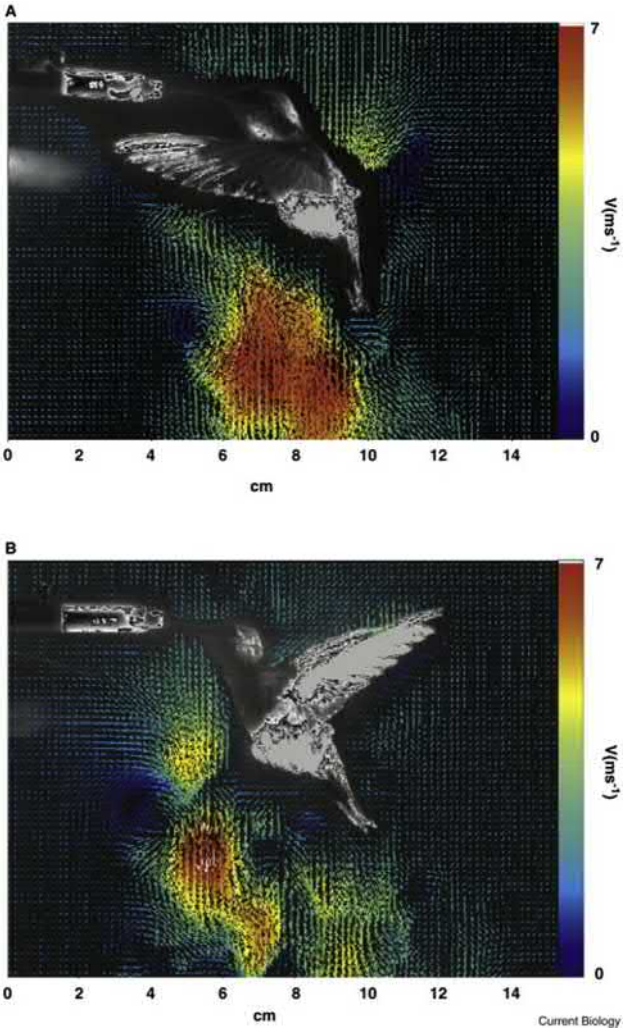

FIGURE 46.4 Flow field beneath a hovering hummingbird at the end of downstroke (A) and the end of upstroke (B) illustrating the relative strengths of the momentum jet at the end of each half-cycle. The momentum jet produced by the downstroke is normally two or more times that produced by the upstroke. *From Warrick et al. (2012).*

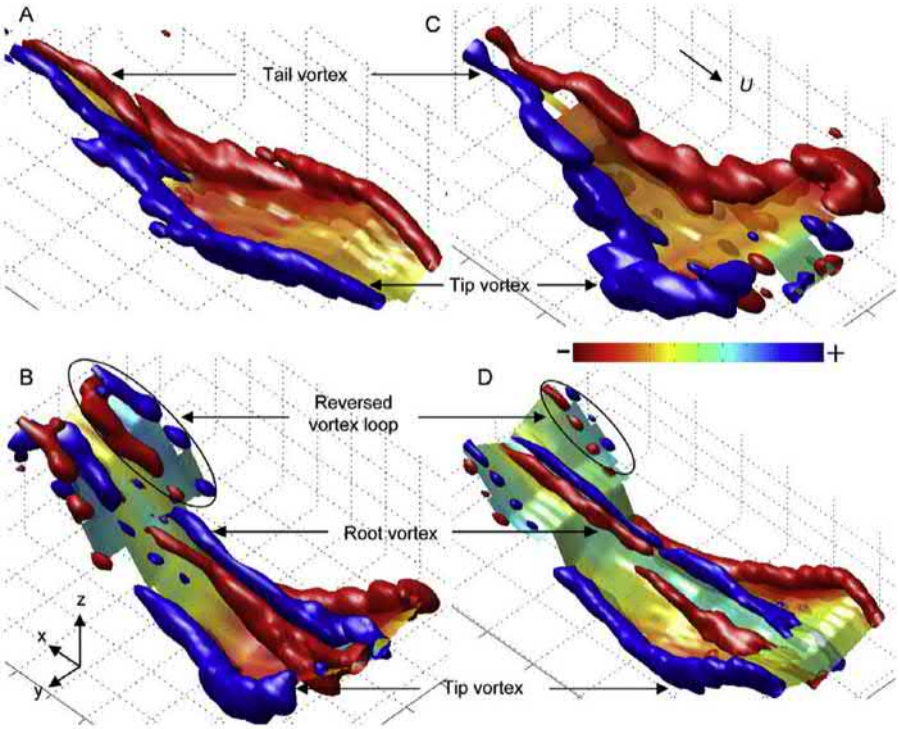

FIGURE 46.5 Reconstruction of the wake topology of a single flap cycle of two species of bird (A and C) and two species of bat (B and D) flying at 7 m/s. (A) pied flycatcher *Ficedula hypoleuca*, (B) Pallas' long-tongued bat, *Glossophaga soricina*, (C) blackcap *Sylvia atricapilla*, and (D) lesser long-nosed bat *Leptonycteris yerbabuenae*. The color-coded surface shows downwash (see color bar) as the animals fly from right to left. Bats produce root vortex at the base of the wing during the downstroke but have a slightly active upstroke that produces a reversed vortex loop due to generating thrust but negative lift. Birds have a largely inactive upstroke by retracting the wings toward the body and leaving a visible tail vortex. *From Muijres et al. (2012b).*

only hovering resulted in a significantly higher value of *P*o, compared with speeds of 2−14 m/s, yielding a so-called L-shaped curve. However, for the cockatiel, dove, and hummingbirds, changes in biomechanical *P*o during flight showed the occurrence of significant U-shaped power curves with a change in velocity, with pectoralis mass-specific *P*o ranging from 74 to 231 W/kg for the cockatiel (Figure 46.6). These authors point out that considerable flexibility in the precise shape and positioning of the power curve probably exist between avian species, which may have different flight styles and can functionally morph their wings and tail profiles during flight and, thus, affect their relative *P*o (Dial et al., 1997; Tobalske et al., 2003). This is a complex technique and the authors acknowledge that there may have been some limitations in the calibration of the strain gauges, which would have led to an underestimation of the maximal force and *P*o.

Usherwood placed differential pressure sensors along and across the wings of Canada geese, *Branta canadensis*, and pigeons (Usherwood et al., 2003, 2005), in order to measure the net aerodynamic forces acting on the wings of birds during take-off and slow forward flight. This technique was used to determine the lift and drag values for the wings and revealed a muscle mass-specific *P*o of 273 W/kg for the pigeon. This value is much higher than that determined by Tobalske et al. (2003) for cockatiels and doves flying at a similar speed (80 and 150 W/kg muscle) but

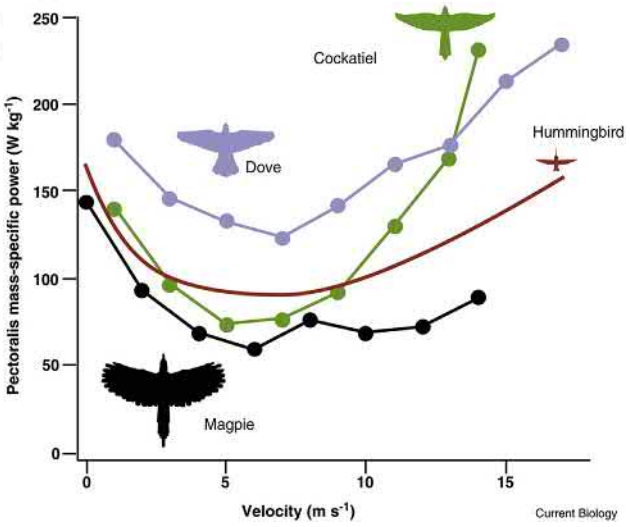

FIGURE 46.6 Comparative mean mass-specific pectoralis muscle power output as a function of flight velocity in cockatiels (*Nymphicus hollandicus*), doves (*Streptopelia risoria*), Black-billed Magpies (*Pica hudsonia*), and combined and smoothed data from Anna's Hummingbird (*Calypte anna*) and Allen's Hummingbird (*Selasphorus sasin*). *From Warrick et al. (2012).*

similar to those recorded during maximum fast flights in the wind tunnel and from the similarly sized American crow (*Corvus brachyrhynchos*) during vertical flight (Jackson and Dial, 2011). Askew and Marsh (2001) developed an in vitro method for measuring muscle force production in the blue-breasted quail (*Coturnix chinensis*), using typical

in vivo length and activity patterns, to record average *P*o of 350 W/kg. Of course, these higher values for in vitro *P*o may not accurately represent sustainable aerobic performance in vivo. A similar approach was taken by Askew and Ellerby (2007) to show that in vitro *P*o from budgerigars (*Melopsittacus undulatus*) and zebra finches (*Taeniopygia guttata*) do follow a classical U-shape.

46.3.2 Techniques used to measure the power input required for flight

46.3.2.1 Mass loss

Some of the earliest measurements of *P*i were estimated from the mass loss recorded during a long, nonstop flight, with the assumption that fat constituted by far, the major part of this loss and that the net loss of water, was negligible (Nisbet et al., 1963). Berger and Hart (1974) criticized this method, as they believed that total water loss may exceed the production of metabolic water, particularly at high environmental temperatures (cf. Nachtigall, 1995), leading to significant dehydration. Another problem with this method is that there is evidence to indicate that migrating birds also catabolize protein (e.g., muscle and intestine) during flight (Piersma and Jukema, 1990; Jenni-Eiermann and Jenni, 1991; Jenni and Jenni-Eiermann, 1998; Battley et al., 2000), and whereas fat has an energy density of 39.3 kJ/g, the value for muscle (which is composed of approximately 70% water) is only 5.4 kJ/g (cf. Schmidt-Nielsen, 1997).

Masman and Klaassen (1987) developed a more complex method of using changes in M_b to estimate flight costs. They studied the energy budgets of trained kestrels (*F. tinnunculus*) performing directional flights in the laboratory. Energy expenditure during flight was calculated by monitoring daily metabolizable energy intake, oxygen consumption and carbon dioxide production during rest, and time spent flying per day. A similar approach was applied to the study of a thrush nightingale (*L. luscinia*) flying for very long periods (seven different 12 h flight sessions) in a wind tunnel (Kvist et al., 1998).

Recently, the mass loss technique has been refined by using quantitative magnetic resonance (QMR) analysis of body composition changes during flight (Guglielmo et al., 2011, 2017; Gerson and Guglielmo, 2011a). In this technique, QMR measurements lasting a few minutes are taken immediately before and after flight, and decreases in fat, lean, and water masses are used to calculate *P*i, the relative contribution of protein to energy, and aspects of water balance. Estimates of *P*i using the QMR method are comparable to those obtained by respirometry and isotopic methods.

46.3.2.2 Doubly labeled water

The most commonly used method to determine the field metabolic rate (FMR) of air-breathing vertebrates is the doubly labeled water (DLW) method, and it has been used extensively with free-ranging birds (Hails, 1979; Ellis, 1984; Tatner and Bryant, 1989). This method was first proposed as a means of determining CO_2 production by Lifson and his coworkers over 40 years ago (Lifson et al., 1949, 1955). It involves the injection of a mixture of ^2H_2O (or ^3H_2O) and $H_2^{18}O$ into the animal, allowing these isotopes to equilibrate with the body water pool(s), taking a body fluid sample after injection and releasing the animal into the field. After a number of days, the animal is recaptured and another body fluid sample is taken. The difference between the rate of loss of the different isotopes is assumed to be equivalent to the rate of CO_2 production ($\dot{V}_{CO_2}$), from which the MR and *P*i of the animal can be estimated. The many assumptions that are made when using this technique have been thoroughly discussed by Nagy (1980), Speakman (1990, 1998).

Although DLW is a relatively simple method to use in the field, it has three major limitations. Perhaps most importantly for field work is the fact that the duration of an experiment is limited by the turnover rate of the ^{18}O; thus, it is necessary to recapture the animal after a sufficient delay following injection of the isotopes to enable a reasonable decline in the enrichment of ^{18}O, but before the enrichment is too low (Nagy, 1983). The second problem is that the technique only gives an average value for energy expenditure between the two sampling points and this is usually over a 24-h daily cycle of activity (Speakman and Racey, 1988). When DLW is used to determine the metabolic cost of a specific activity (e.g., flying), then, as with the M_b method, it is necessary to have accurate information on the duration of the flying period(s). Ideally, the RQ also needs to be known to convert the calculated $\dot{V}_{CO_2}$ to an estimate of $\dot{V}_{O_2}$ and/or *P*i (see above).

Recent validation studies with captive birds exercising at different levels of activity (but not flying) over a period of 72 h have indicated that, provided mean data are used from a number of birds, the DLW method can give estimates of MR that are within a few percent of those measured by respirometry (Nolet et al., 1992; Bevan et al., 1994, 1995a), although they do show a greater variance. The only validation study on a flying bird was that of Ward et al. (2004), in which they used three independent techniques, DLW, mask respirometry, and heat transfer modeling to measure the *P*i of the European starling (*S. vulgaris*) flying in a wind tunnel between 6 and 14 m/s. Heat transfer modeling and mask respirometry yielded

comparable results and a linear increase in *P*i with increasing velocity, but the DLW results had a greatly increased scatter and variance between individual flight measurements. DLW has been used to measure *P*i in other wind tunnel experiments where flight durations were sufficiently long (Kvist et al., 2001; Engel et al., 2006b). The advent of laser spectrometers that measure hydrogen and oxygen isotope ratios in near real time in exhaled breath water makes the DLW more practical for flight and other energetic studies (Mitchell et al., 2015).

46.3.2.3 ^{13}C sodium bicarbonate

Carbon dioxide produced by aerobic metabolism enters the bicarbonate pool until it is reconverted to CO_2 and exhaled at the lungs. Turnover of the bicarbonate pool is rapid, and the flux of CO_2 can be measured by labeling the bicarbonate pool with ^{13}C sodium bicarbonate (NaBi) and measuring the kinetics of $^{13}CO_2$ in exhaled breath. The NaBi method was first developed and applied to birds by Hambly et al. (2002) to measure *P*i of zebra finches (*T. guttata*) flying between perches for 2 min. It was similarly used in a study of European Starlings (*S. vulgaris*) and Palestine Sunbirds (*Nectarinia osea*) (Hambly et al., 2004). The bird is injected with a calibrated ^{13}C NaBi solution and placed in a respirometry chamber with a constant flow of CO_2 free air. Peak enrichment of the bicarbonate pool is reached in a few minutes after which ^{13}C enrichment of the breath CO_2 declines in a log-linear fashion at a rate that is proportional to the rate of CO_2 production at rest, which can be measured simultaneously from excurrent CO_2 concentration and the air flow rate through the chamber. The bird is then quickly removed from the chamber, flown for 1−2 min, and returned to the chamber to measure the postflight ^{13}C enrichment. The rate of CO_2 production in flight is calculated from the rate of decline in ^{13}C enrichment during the flight period, using the calibration obtained during the preflight resting period. The advantage of this technique is that it allows measurements of uninstrumented birds flying for short periods, even at uncomfortable speeds. Recently, the NaBi method was used to measure *P*i of Blackcaps (*Sylvia atricapilla*) flying at speeds between 4 and 12 m/s in a wind tunnel (Hedh et al., 2020).

46.3.2.4 Telemetry and data logging

Much progress has been made in the use of biotelemetry and data logging devices for studying the physiology of free-ranging animals (Cooke et al., 2004; Ropert-Coudert and Wilson, 2005). Any externally mounted object is likely to influence the flight performance of a bird, not only as a result of the added mass but also by increasing the aerodynamic drag of the body (Bowlin et al., 2010). These effects may be minimal for a relatively small transmitter that the bird can preen under its contour feathers (Obrecht et al., 1988). However, in some circumstances, the effects can be quite substantial, particularly for high-performance birds like homing pigeons (Gessaman and Nagy, 1988). Butler and Woakes (1980) overcame the problem of increasing body drag by implanting relatively small (<10 g) radio-transmitters into the abdominal cavity of barnacle geese (*Branta leucopsis*) and were able to record heart rate (mean, 512 beats/min) and respiratory frequency (mean, 99 breaths/min) from two birds (mean mass, 1.6 kg) flying behind an open-topped vehicle. It is now possible to implant data loggers (weighing less than 30 g) that will store basic physiological information (heart rate, T_b, etc.) over periods of many days. The data can then be downloaded after the animal is recaptured (Woakes et al., 1995; Bevan et al., 1995b; Wascher et al., 2009; Bishop et al., 2015).

46.3.2.4.1 Heart rate

Heartbeat frequency (f_H) can be accurately measured and used as a proxy for metabolic energy consumption. Thus, if properly calibrated and validated, and if mean data are used from a number of animals, f_H may be used as an indicator of the rate of oxygen uptake in free-living birds (Butler et al., 2004; Green, 2011). However, the relationships between f_H and $\dot{V}_{O_2}$ that are obtained during walking and running, or during swimming, may not be identical to those obtained when the birds are flying (Gessaman, 1980; Nolet et al., 1992; Ward et al., 2002; Bishop and Spivey, 2013). The study by Ward et al. (2002) is the only report of a direct calibration of heart rate against mask respirometry of a bird flying in a wind tunnel, in which there is a reasonable variation in both the measures of heart rate and the rate of oxygen consumption (Figure 46.7). These results indicate that f_H verses $\dot{V}_{O_2}$ relationships during flight are well described by power equations, with barnacle geese $\dot{V}_{O_2} = 0.0019 f_H^{1.98}$ and bar-headed geese $\dot{V}_{O_2} = 0.0013 f_H^{2.08}$. Thus, the $\dot{V}_{O_2}$ approximates to a quadratic or square law relationship, i.e., $\dot{V}_{O_2} = m\, f_H^{2.0}$ for these birds during flight (their "primary mode" of locomotion—defined as the mode that typically induces maximum $\dot{V}_{O_2}$ for a specific species), while it is closer to a direct linear relationship $\dot{V}_{O_2} = m\, f_H^{1.0}$ during running (i.e., nonprimary mode). The constant (m) is likely a function of both M_b and heart mass (M_h). Thus, it is likely that it is the running relationship that is unusual in these normally volant species, given that geese are not thought to be particularly reliant on running in the wild. This simple square law relationship for geese in flight can be generalized to an interspecies comparison of 24 species of endothermic vertebrates (12 birds and 12 mammals) during their appropriate "primary modes" of locomotion (Bishop and Spivey, 2013), when differences in M_b and M_h are taken

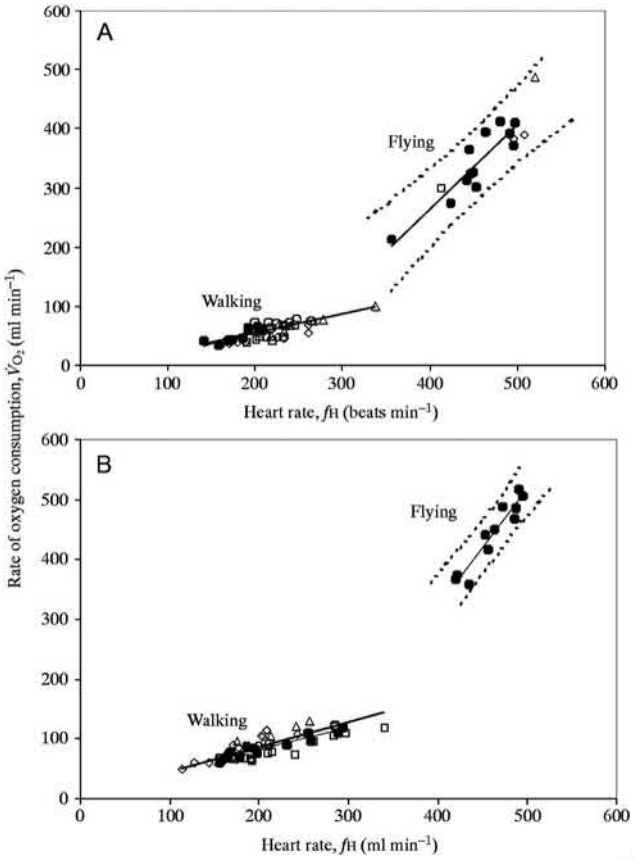

FIGURE 46.7 Linear relationships between mean rate of oxygen consumption *V*o2 and mean heart rate (f_H) of (A) barnacle geese, *Branta leucopsis*, and (B) bar-headed geese, *Anser indicus*, walking on a treadmill and flying in a wind tunnel. The filled circles show data from a single bird of each species from which most data on the relationships between f_H and *V*o2 were obtained during flight (N = 12 flights by barnacle goose B−B and 11 flights by bar-headed goose BH−O). The open symbols show data from other birds. The solid lines show the relationships between f_H and *V*o2 during walking and flight by barnacle goose B−B [walking, $Vo2 = 0.47\,f_H$ - 35.9, $r2 = 0.78$; flight, $Vo2 = 1.42\,f_H$ - 304, $r2 = 0.82$] and bar-headed goose BH−O [walking, $Vo2 = 0.35\,f_H + 12$, $r2 = 0.88$; flight, $Vo2 = 1.97\,f_H - 467.5$, $r2 = 0.90$]. The broken lines show the 95% prediction intervals. *Based on Ward et al. (2002).*

into account. Thus, while some small regulation of cardiac output may be achieved by changes in stroke volume, between rest and exercise modes, for primary modes of locomotion, such changes are relatively small compared to changes in f_H, which range from around 4- to 10-fold (Butler, 1991; Bishop and Butler, 1995).

46.3.2.4.2 Accelerometry

Accelerometers have been mounted on the body of animals to provide high-resolution measures of acceleration (or changes in velocity). During steady-state locomotion, the average acceleration, taken over a sufficient number of limb cycles (or flapping in the case of flight), is equivalent to the "static" component of acceleration due to gravity. The modulus of individual raw acceleration data points minus the mean static acceleration for a given time period gives a measure of the "Dynamic Body Acceleration" or DBA (Qasem et al., 2012). Strictly speaking, DBA should be considered a potential proxy for biomechanical *P*o in the previous section, but it is usually correlated against measures of metabolic *P*i. In multidimensional acceleration studies, summing the data taken from the different axes is called Overall Dynamic Body Acceleration (ODBA), and calculating the vectoral length is termed VeDBA (Wilson et al., 2006; Qasem et al., 2012). Both these measures have been shown to be well correlated with rates of oxygen consumption in human subjects and a number of other mammal and bird species while running on treadmills (Halsey et al., 2011; Wilson et al., 2019).

While no detailed and direct correlation of DBA and rate of oxygen consumption have been conducted on birds during flight, ODBA was shown to increase during ascending and decrease during descending flights by a captive Griffon vulture *Gyps fulvus* (Halsey et al., 2009). Elliott et al., (2013) showed that VeDBA was quite well correlated with the average daily energy expenditure (DEE) of breeding thick-billed murres (*Uria lomvia*), as determined by measurements of DLW. Mean values of DBA are correlated with heart rate for free-flying captive Griffon Vultures (*G. fulvus* and *Gyps himalayensis*) (Duriez et al., 2014) and wild living bar-headed geese (*Anser indicus*) (Bishop et al., 2015) and Great Frigatebird (*Fregata minor*) (Weimerskirch et al., 2016). In addition, Spivey and Bishop (2013) describe a mathematical model to help to interpret data collected by accelerometers mounted on the body of birds during flight. By assuming that the body motion of the bird during steady forward flight approximates to a sinusoidal waveform, they showed that the root mean square of acceleration (aRMS), another form of time averaged DBA (which is closely related to VeDBA), can be naturally derived from the mathematics. The biomechanical power visible to the body-mounted accelerometer can be interpreted in the SI units for mass-specific power ($W = m^2 \times s^{-3}$) by a number of possible terms, including the following:

$$P_{body} \text{ is proportional to } (\text{aRMS})^2 / f_w$$

where f_w is wingbeat frequency (Hz). However, this modeling approach was developed around horizontal flight and only partially accounted for climb power performance in captive Harris's Hawks (*Parabuteo unicinctus*) trained to fly at different flight angles (Van Walsum et al., 2020). Uncertainties regarding the use of accelerometry center around the alignment of the sensor with the axis of movement of the body, variation in the position of the sensor on the body, the fact that the cost of limb movements may be partially "hidden" from a body-mounted sensor, as may

changes in M_b itself, and that rotations of the body not directly linked to movement costs may exaggerate the apparent energy required. However, analysis of body movement and acceleration is already an important technique in assessing animal locomotion and energetics (Wilson et al., 2019).

Measurements of acceleration (especially in conjunction with angular velocity and/or orientation in the Earth's magnetic field) can also be used to determine relative body orientation and kinematics (Wilson et al., 2019). For example, changes in wingbeat frequency (f_w) of foraging European shags (*Phalacrocorax aristotelis*) returning to the nest to feed their chicks were reliably correlated to relative changes in M_b (Sato et al., 2008). f_w was determined for five species of Procellariiformes during take-off and during forward flight Sato et al. (2009). They showed that during take-off the wingbeat frequency was higher and scaled with $M_b^{-0.3}$, while during forward flight it scaled as $M_b^{-0.18}$. By extrapolating these two relationships until they intercepted, it was suggested that the maximum limits to practical soaring flight might be around 41 kg for a bird or pterosaur with a wingspan of around 5.1 m (Figure 46.8).

46.3.2.5 Respirometry

*P*i is most easily estimated by indirect calorimetry, and under laboratory conditions, by directly measuring the $\dot{V}_{O_2}$ of birds flying in a wind tunnel and then converting that to *P*i (see above). The increased use of wind tunnels during the past 50 years has greatly added to our knowledge and understanding of the physiology of birds during flight (Butler and Woakes, 1990; Norberg, 1990). Perhaps the main advantage of being able to use a wind tunnel is that it is possible to make physiological measurements that would be virtually impossible by other means (e.g., repeated blood samples, blood pressure and flow measurements, direct measurements of force production, etc.). However, it must also be borne in mind that, as with almost any other method for studying a living animal, the wind tunnel itself and the measuring equipment required can influence the behavior of the animal flying in it and hence affect the data obtained when compared with those from free flying birds (Butler et al., 1977; Rayner, 1994). For example, gas exchange ($\dot{V}_{O_2}$ and $\dot{V}_{CO_2}$) is usually determined by means of a lightweight mask which covers the beak and nose and through which air is drawn via an attached tube (Tucker, 1968b, 1972; Bernstein et al., 1973; Butler et al., 1977; Gessaman, 1980; Hudson and Bernstein, 1983; Rothe et al., 1987; Ward et al., 2001, 2002; Peters et al., 2005). The mask and tubing will influence the recorded data because of their mass, but more so because of the extra drag that they impose. $\dot{V}_{O_2}$ can also be measured in a similar way for hummingbirds while feeding at artificial flower heads (Wells, 1993a,b; Clark and Dudley, 2010). The only studies

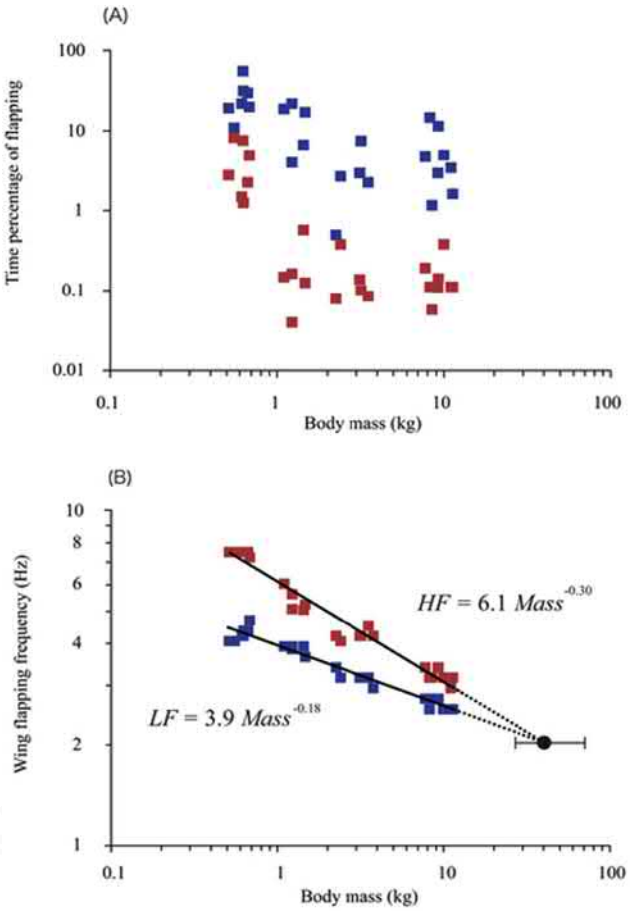

FIGURE 46.8 (A) The relationship between body mass and the percentage of time spent flapping relatively slowly (*blue squares*) and relatively quickly (*red squares*) during the foraging flights of five species of albatrosses and petrels. (B) The relationship between body mass and wingbeat frequency for the same species. Regression lines were calculated for high (*red squares*) and low (*blue squares*) frequencies and extrapolated for larger animals (*dashed lines*). The two lines intersect at a body mass of 41 kg (5.1 m wingspan), with a 95% CI (26–75 kg). *From Sato et al. (2009).*

in which gas exchange has been determined in a wind tunnel without the use of a mask are those by Tucker (1966) and Torre-Bueno and Larochelle (1978), using airtight, closed-circuit wind tunnels and measured the changing concentration of gases in the atmosphere. An aerodynamic analysis by Rayner (1994) suggested that, in closed wind tunnels, the *P*o versus speed curve (see above) will be flatter than that for free flying birds.

46.3.2.6 Modeling of cardiovascular function

Some of the shortcomings of using the aerodynamic models to estimate *P*o and then, subsequently, converting them to estimates of *P*i (by assuming a value for efficiency) could possibly be reduced by devising a model to estimate total *P*i directly. This was highlighted by the studies of Ward et al.

(2001, 2004) who pointed out starlings may not have a constant value of muscle efficiency throughout their speed range and that conversion of *P*o to *P*i was sensitive to the value of efficiency. Bishop and Butler (1995) attempted a modeling approach to estimating *P*i by assuming that the mass of an animal's heart could be used as a basis for estimating cardiac stroke volume and calculating the animal's aerobic capacity. The role of the various components of the cardiovascular system in presenting O_2 to (and removing CO_2 from) the exercising muscles can best be described by a form of Fick's formula for convection:

$$\dot{V}o_2 = f_H \times V_S \times \left(C_aO_2 - C_{\bar{v}}O_2\right)$$

where f_H is heart beat frequency (beats/min); V_S is cardiac stroke volume (mL); and $\left(C_aO_2 - C_{\bar{v}}O_2\right)$ is the difference between the oxygen content in arterial and mixed venous blood (mL of O_2 per mL of blood). In theory, each of these variables can scale independently with respect to M_b such that

$$\left(\dot{V}o_2\right)M_b^{Z} = (f_H)M_b^{w} \times (Vs)M_b^{X} \times \left(C_aO_2 - C_{\bar{v}}O_2\right)M_b^{Y}.$$

There have only been two studies in which all four variables of the Fick equation have been measured in a bird during forward flapping flight (Butler et al., 1977; Peters et al., 2005). Bishop and Butler (1995) substituted each of the values from the Butler et al. (1977) study into the above equation, based on a series of general allometric equations ($y = a.x^b$) for the scaling of f_H, Vs, and $\left(C_aO_2 - C_{\bar{v}}O_2\right)$, respectively. For birds flying close to their minimum power speeds, the individual components of the Fick equation were estimated to scale as follows: $f_H = 574\ M_b^{-0.19}$, $Vs = 3.48\ M_b^{0.96}$, and $\left(C_aO_2 - C_{\bar{v}}O_2\right) = 0.083\ M_b^{0.00}$. The estimated scaling of V_S during flight was based on the assumption that *V*s should be almost directly proportional to the M_h, or $Vs = 0.3\ M_h^{1.05}$, while f_H during flight and M_h may be readily determined experimentally.

Bishop and Butler (1995) concluded that, for birds with a high aerobic capacity (such as pigeons), $\dot{V}_{O_2}$ (mL/min) = $166M_b^{0.77}$, for birds flying close to their minimum power speeds. This compares favorably with the relationship ($\dot{V}_{O_2} = 160\ M_b^{0.74}$) calculated by Butler (1991) and reanalyzed using RMA for seven species of birds during forward flapping flight in a wind tunnel. Bishop (1997) used a similar approach to estimate the maximum $\dot{V}_{O_2}$ of birds during flight, again using M_h as the basis of the calculation, and it would appear that the use of M_h to predict the aerobic capacity of different species of birds may have more general applicability than the use of a general allometric relationship. Bishop and Spivey (2013) did a metaanalysis of data from 12 species of birds and 12 species of mammals that were said to be performing their "primary" modes of locomotion (i.e., running, swimming, or flying, respectively) and concluded that there was an overall allometric trend across all species for $\dot{V}_{O_2}$ to be approximately proportional to heart rate squared (f_H^2). Individuals and different species may vary in how closely they followed this quadratic heart rate exponent, but knowledge of both M_h and M_b gave the best predictive relationship for rate of oxygen consumption (Figure 46.9).

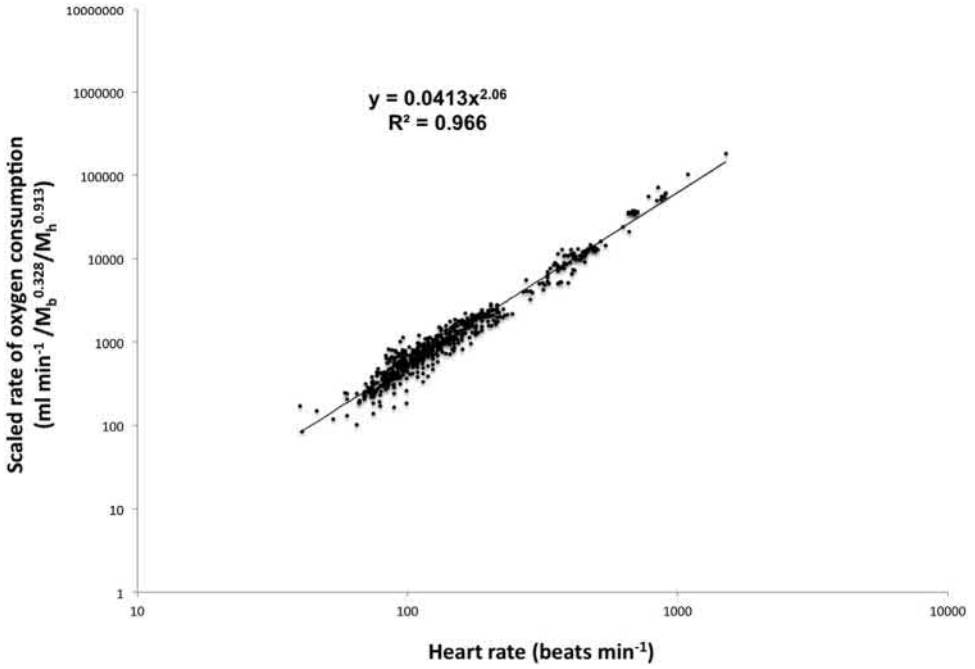

FIGURE 46.9 The relationship between heart rate (beats/min) and the rate of "rescaled" oxygen consumption (mL/min/*M*b0.328/*M*h0.913) for 12 species of birds and 12 species of mammals, after taking into account differences in body mass (*M*b) and heart mass (*M*h) between species. Each species was flying, running, or swimming, depending on what was considered their "primary mode" of locomotion, i.e., the form of locomotion that would yield the highest rate of oxygen consumption. *From Bishop and Spivey (2013).*

46.3.3 Empirical data concerning the power input during flight

An individual flight by a free-ranging bird will include at least one take-off and a period of climbing, probably several maneuvers (turns, short periods of "burst" flying, and changes of gait) as well as various periods of gliding, soaring, bounding, and flapping flight. The power requirements associated with all of these various types of flight will be different and may be provided by either anaerobic or aerobic metabolic pathways or by a combination of the two.

Species belonging to the Galliformes (e.g., pheasants, grouse, and quail) routinely engage in a powerful "burst" type of flight during take-off and short-duration flights. Their muscles use predominantly anaerobic metabolism of intracellular stores of glycogen which leads to the accumulation of lactic acid and a metabolic acidosis, followed rapidly by fatigue. Thus, a large proportion of the total cost of these explosive flights is "repaid" while the bird is resting following the flight (Bishop and Butler, 1995), and an assessment of the true cost of such explosive flights, if based on $\dot{V}_{O_2}$, would have to include the postflight period of recovery. In other words, measurements of $\dot{V}_{O_2}$ can only be used for accurate estimates of Pi if the activity is sustainable for relatively long periods of time (i.e., if the bird is metabolizing aerobically, usually for at least a few minutes).

46.3.3.1 Gliding and soaring flight

In general, BMR decreases as body size increases, while at the same time the speed of flight increases, so it would be expected that larger birds should benefit more than smaller species from the strategic use of gliding. Of course, it should be remembered that, even when gliding, birds can actively adjust the shape and span of their wings, including the sweep angle that they make to the body, in order to adjust air speed and the aerodynamic efficiency of the wing (Rosén and Hedenström, 2001; Lentink et al., 2007). Pennycuick (1997) hypothesized that the cost of holding the wings outstretched when gliding and soaring should scale at around 1.5 times the BMR. In reality, most empirical studies have recorded slightly higher costs for gliding. For herring gulls (*Larus argentatus*) gliding in a wind tunnel, Pi (calculated from measured $\dot{V}_{O_2}$) was 15.3 W/kg, or 2.1x the resting value (Baudinette and Schmidt-Nielsen, 1974).

In the wild, birds such as albatrosses try to maximize the use of soaring and gliding flight, and even in near calm conditions, they only beat their wings occasionally (Alerstam et al., 1993). In a study on black-browed albatrosses (*Diomedea melanophris*), Bevan et al. (1995b) used the f_H method to determine the FMR and salt water switches to determine when the birds were on the water. Interestingly, the average metabolic cost of flying was 6.2 W/kg, which was similar to the cost of birds when resting on the water (5.8 W/kg), approximately 2.0x the predicted BMR but around 2.2x the estimated costs duration incubation. However, the study by Bevan et al. (1995b) illustrates the importance of accurately determining the behavior of the animals under study and the advantages of using methods, such as measuring f_H and/or acceleration, for estimating the metabolic cost of the separate behaviors in combination with the satellite position data. During Section 46.2 of the trip, the albatross covered a distance of 80.1 km in 1.7 h, a mean ground speed of 13.1 m/s. This is very similar to the mean speed of 12.9 m/s that Alerstam et al. (1993) report for a visually tracked black-browed albatross. MR was remarkably low during this period (2.4 W/kg), which is likely to be dominated by soaring and gliding flight, and barely greater than that during incubation (2.2 W/kg). On the other hand, during Section 46.4 of the trip, the straight-line distance traveled was only 6.3 km at a mean ground speed of 1.6 m/s, but the bird exhibited a high MR of 8.8 W/kg. This suggests that the bird was likely foraging within a restricted area and was engaged in some form of relatively strenuous activity.

Similar to the large Procellariiformes, Frigatebirds are renowned for being one of the most aerial of avian species, spending the majority of their time in slow soaring flight, often up to a week without landing (Weimerskirch et al., 2016) while sleeping on the wing, although apparently much less than on land (Rattenborg et al., 2016). They constantly ascend and descend on thermals during the day and night, while looking for infrequent opportunities to feed on flying fish, off the sea surface without landing, or by pursuing other bird species and kleptoparasitizing their prey (Weimerskirch et al., 2003). During their long trips circumnavigating the doldrums of the Indian ocean (Figure 46.10A), the Great Frigatebird (*F. minor*) regularly soars like a vulture, typically circulating up to around 400 m, or occasionally obtaining lift inside the strong updrafts provided by cumulus clouds where they can reach up to 4000 m (Weimerskirch et al., 2016). They then glide slowly down over many kilometers before picking up another thermal and repeating the process for many hours. This rollercoaster flight pattern is achieved with only occasional bouts of wing flapping while soaring and gliding >100 m above sea level and with no access to feeding opportunities, but is then interrupted by periods of flight near the sea surface which consist of a more active and vigorous flight performance. Figure 46.10B shows a 12-h period of tracking of a Great Frigatebird during which the first 3 h are spent low over the sea and these events coincide with heart rates of over 400 beats/min and intense periods of acceleration (Weimerskirch et al., 2016). Interestingly, f_w is very focused around 2.5 Hz, but the DBA is highly variable (indicating strong amplitude modulation of

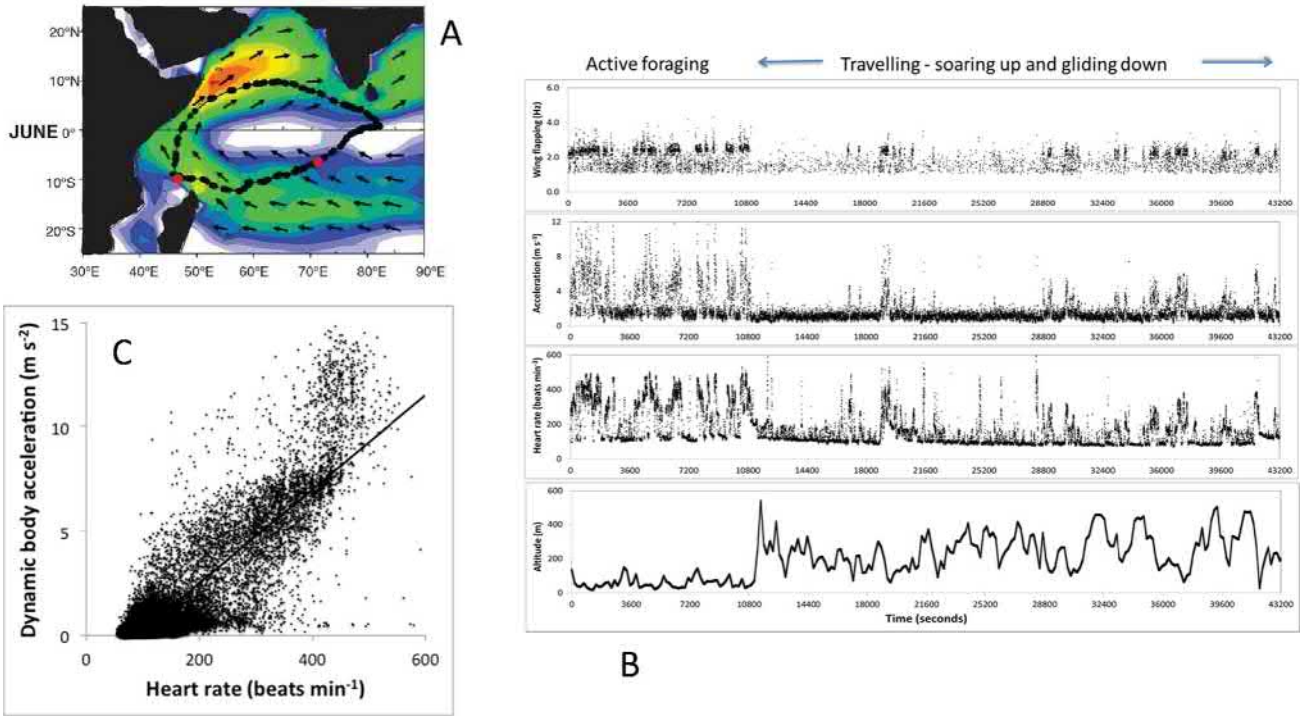

FIGURE 46.10 Tagging data from adult male Frigatebirds: (A) A 24-day clockwise foraging trip from Aldabra Island (Seychelles) in relation to wind strength (color scale – white zero to red >16 m/s) and direction (*arrows*), with a 1 h stop in the Chagos Islands. (B) Changes in wingbeat frequency, dynamic body acceleration, heart rate, and altitude over a 12 h period. (C) Root mean square DBA plotted against heart rate from a single Frigatebird over a 72 h flight. *Modified from Weimerskirch et al. (2016).*

flap effort), while the highest values for DBA (>4 m/s/s) are associated with heart rates of over 400 beats/min but are not well correlated (Figure 46.10C). These appear to represent brief but powerful bouts of flapping where the cardiovascular response is either near its maximum, or the cardiovascular response is too slow, so that the biomechanical effort involved is not reflected by the aerobic capability and where the flight muscle may be recruiting anaerobic fibers for a quick burst of extra flight performance. The final 9 h are spent routinely spiraling and soaring up to between 300 and 600 m, followed by long and shallow gliding descents. Heart rates, values of DBA, and f_w are generally very low throughout this time, even during the ascending flights. Thus, it is only the active feeding phases that are energetically costly and not the long periods of oceanic circumnavigation.

As gliding is thought to be more common in larger species of birds, it has seldom been quantified in smaller species, although some small species of birds, such as the Hirundines (martins and swallows) and the Apodidae (swifts), regularly glide. However, Sapir et al. (2010) showed that, like in the study of Black-browed albatrosses (Bevan et al., 1995b), the heart rate of resting European bee-eaters was similar to that recorded while gliding and soaring, either on migration or at stop-over sites (Figure 46.11). Surprisingly, they suggest that not only was gliding MR only 1.9 times BMR but that the air speed of soaring was sufficiently fast (10.6 m/s) as to make gliding very economic. Assuming that the rate of oxygen consumption is proportional to f_H^2 (Bishop and Spivey, 2013; Figure 46.9), provides a determination that the energy consumed during gliding flight is at least 5 times lower than during flapping flight for the bee-eaters. Swifts (*A. apus*) have been predicted to glide most efficiently at velocities of 8–10 m/s (Lentink et al., 2007), which fits nicely with their behavior of climbing high above the ground and gliding slowly at around 10 m/s while probably sleeping on the wing (Hedenström et al., 2016).

During gliding flight, it is important to minimize body (or parasite) drag and to maintain a high lift-to-drag ratio. Even turning the head from side to side can significantly increase the effective body drag. Indeed, because birds usually have laterally placed eyes with relatively low stereoscopic fields of view, they often prefer to see things either in one eye or the other. In the case of a fast diving peregrine falcon (*Falco peregrinus*), it approaches its prey

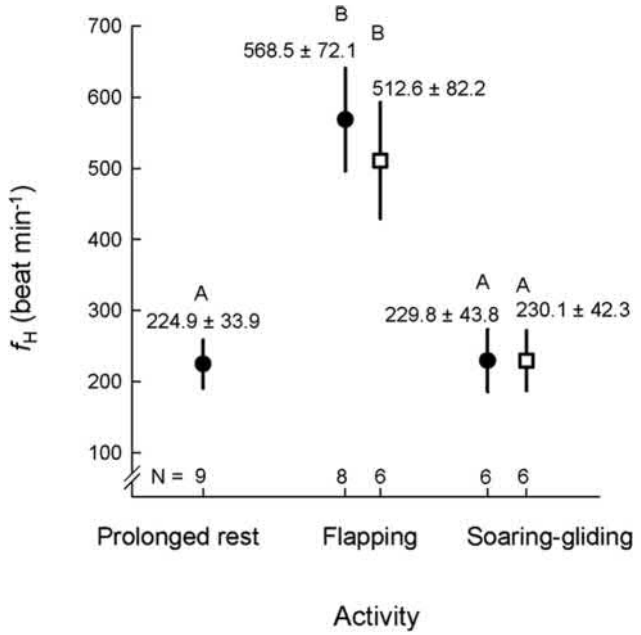

FIGURE 46.11 Heart beat frequency (f_H) of European bee-eaters, *Merops apiaster*, measured in the field in relation to their behavior. The data are presented as the mean ± standard deviation of f_H for bee-eaters resting for prolonged duration or in different flight modes recorded, during stopovers (*filled circles*) and migratory cross-country flights (*open squares*). Different letters above the bars indicate groups that differed statistically. N = number of birds whose f_H was recorded during each activity. *From Sapir et al. (2010).*

by flying along a spiral path so that it can keep its head facing forward on its body (Tucker et al., 2000). Moving the head to one side or the other can increase parasite drag by around 50%.

46.3.3.2 Forward flapping flight

Some of the most comprehensive data we have on the overall energy consumed by the body (*P*i) and the biomechanical power output by the muscles (*P*o) during forward flapping flight are those obtained from birds flying in wind tunnels. In theory, the use of wind tunnels makes it possible to estimate both *P*o and *P*i at different flight speeds, although few studies have done this simultaneously and the details of these relationships appear to vary among species. The majority of studies of *P*i were determined by measuring the rate of oxygen consumption while the birds wore a plastic respirometry mask (Figure 46.12). Results from the laughing gulls, fish crows, and white-necked ravens have shown a J-shaped curve against flight velocity (Tucker, 1972; Bernstein et al., 1973; Hudson and Bernstein, 1983), while the starling, barnacle, and bar-headed goose have a relatively flat "curve" (Ward et al., 2001, 2002). Only the budgerigar (*M. undulatus*), cockatiel, pigeon, and hummingbirds have showed an obvious U-shaped curve for *P*i (Tucker, 1966; Rothe et al., 1987; Bundle et al., 2007; Clark and Dudley, 2010), similar to that predicted by aerodynamic theory for mechanical *P*o (Pennycuick, 1969; Tucker, 1973; Greenewalt, 1975; Rayner, 1979). Arguably, the J-shaped *P*i curves may not be so different from a U-shaped curve, but very low air velocities were not obtained with these species, presumably because the birds were not able/willing to sustain flight for long enough at such speeds. Both budgerigars (Tucker, 1966; Bundle et al., 2007) and cockatiels (Bundle et al., 2007; Morris et al., 2010) show distinct U-shaped *P*i curves, but the slowest speed that they were willing to fly at while wearing a face mask was 5 m/s. However, it seems certain that slower velocities, including hovering, would have increased their aerodynamic flight costs even further. A study of Anna's and Allen's hummingbirds (*Calypte anna* and *Selasphorus sasin*, respectively), flying between 0 and 14 m/s, showed that there was a distinct *P*i minimum at intermediate speeds. Energetic costs during hovering and faster speeds were increased by around 30–40% (Clark and Dudley, 2010), while even relatively slow but backward flights showed a reduction of around 20% over that of hovering (Sapir and Dudley, 2012). The depth of the curve appeared to be slightly increased in birds with higher wing loadings, which was also more typical of males.

Figure 46.13 illustrates an allometric plot of the available data for the minimum *P*i of seven species of birds during forward flapping flight in wind tunnels (Tucker, 1968b, 1972; Bernstein et al., 1973; Butler et al., 1977; Torre Bueno and Larochelle, 1978; Gessaman, 1980; Hudson and Bernstein, 1983) and it demonstrates two interesting features. First, on average, the minimum *P*i (after adjusting for the drag of the mask and tubing, where necessary) of the seven species (mass range, 35–480 g) is 9.2 times the BMR calculated for nonpasserine birds (Prinzinger and Hänssler, 1980), and second, it is 2.2 times greater than the *P*i of mammals of similar mass (up to 900 g) running at their maximum sustainable speed (Pasquis et al., 1970). It can be seen from Figure 46.13 that the minimum MR during flight of the hummingbird, *Colibri coruscans* (Berger, 1985), is close (within 20%) to that predicted from the extrapolated regression line for the other seven species of birds. If the value from the hummingbird data is included in the regression analysis, the equation becomes $48.5M_b^{0.69}$, $r^2 = 0.98$, using least-squares regression analysis. The mean *P*i of a 1.8 kg barnacle goose (*B. leucopsis*) flying in a wind tunnel was 102 W, while that of a 2.8 kg bar-headed goose (*A. indicus*) was 135 W (Ward et al., 2002). These results are reasonably similar to the values of 81 and 113 W obtained for the predicted minimum *P*i, determined from an extrapolation of the allometric equation, $\dot{V}_{O_2} = 160M_b^{0.74}$, derived from the

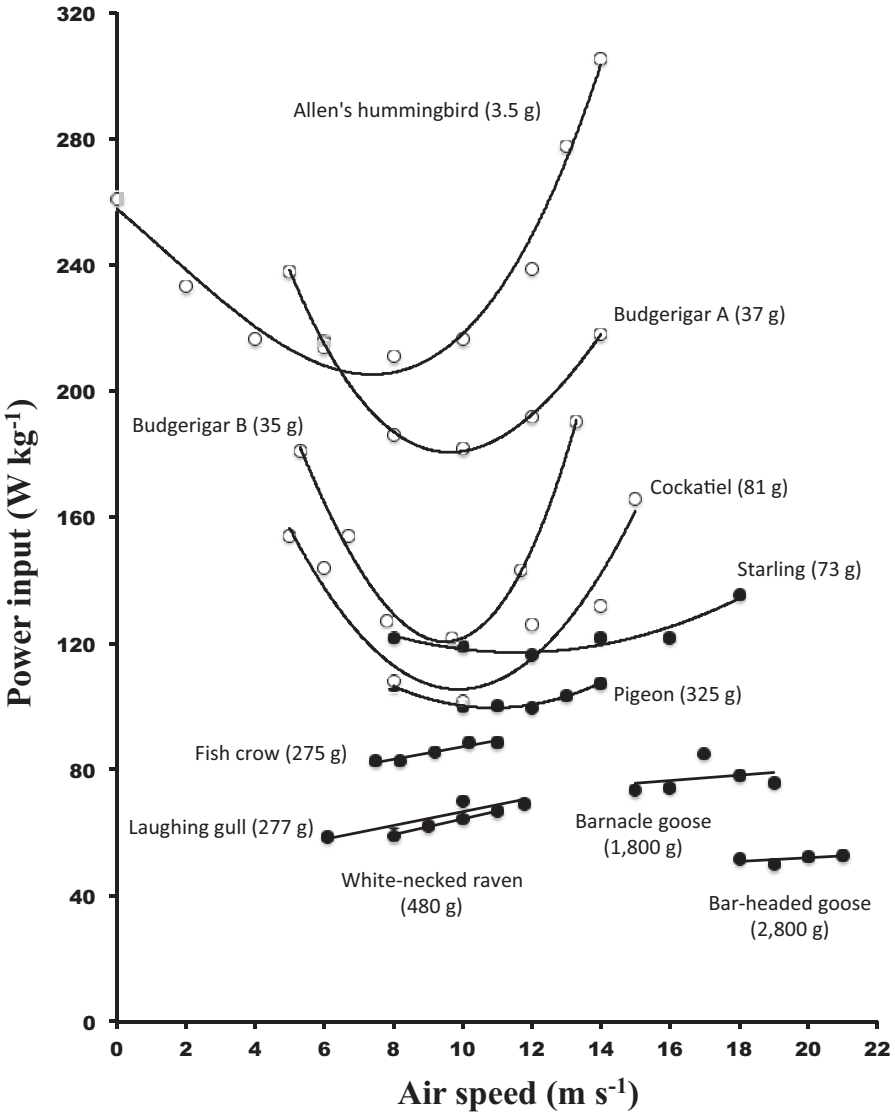

FIGURE 46.12 Power input (W/kg), converted from measurements of rates of oxygen consumption, measured at different air speeds for 10 species of birds during horizontal flapping flight in a wind tunnel. Data taken from: Allen's hummingbird, *Selasphorus sasin* (Clark and Dudley, 2010); cockatiel, *Nymphicus hollandicus*, and budgerigar, *Melopsittacus undulatus* A (Bundle et al., 2007); budgerigar B (Tucker, 1968a,b); European starling, *Sturnus vulgaris* (Ward et al., 2001); pigeon, *Columba livia* (Rothe et al., 1987); fish crow, *Corvus ossifragus* (Berstein et al., 1973); laughing gull, *Leucophaeus atricilla* (Tucker, 1972); white-necked raven, *Corvus albicollis* (Hudson and Bernstein, 1983); barnacle goose, *Branta leucopsis*; and bar-headed goose, *Anser indicus* (Ward et al., 2002).

seven species of birds flying in a wind tunnel (Butler, 1991), recalculated using RMA regression (see above). In addition, using the cardiovascular modeling approach of Bishop and Butler (1995), Butler et al. (1998) estimated the minimum $\dot{V}_{O_2}$ of premigratory barnacle geese (average $M_b = 2.3$ kg) to be around 99 W. The relatively small errors between experimental measurements and these various predictions for flight costs, whether extrapolated toward smaller or larger species using allometric equations, or applying cardiovascular modeling approaches (Bishop and Butler, 1995; Bishop, 1997), suggest that the measurement of *P*i is reasonably reliable across different studies.

46.3.3.3 To flap or not to flap: that is the question

The nature of flapping flight itself, or whether to utilize a specific type of "gait" (flap-glide or flap-bound), or to specialize in soaring and gliding for as long as possible,

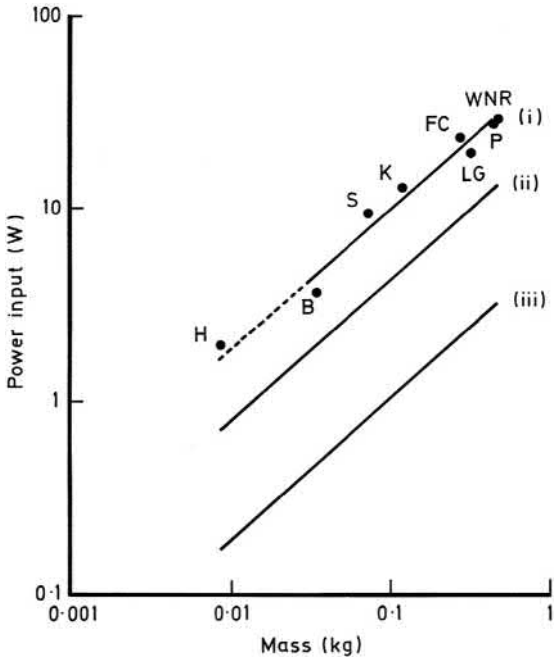

FIGURE 46.13 The relationships between power input (*P*i) and body mass, M_b, using least-squares regression analysis for (i) seven species of birds during forward flapping flight in a wind tunnel; *B*, budgerigar *Melopsittacus undulatus*; *FC*, fish crow *Corvus ossifragus*; *K*, American kestrel *Falco sparverius*; *LG*, laughing gull *Larus atricilla*; *P*, pigeon *Columba livia*; *S*, starling *Sturnus vulgaris*; *WNR*, white-necked raven *Corvus cryptoleucus*. Minimum values of power input (*P*im) were used to construct this curve and $Pim = 50.7M_b0.72$; (ii) small mammals during maximum sustainable exercise where $Pi = 22.6\ M_b0.73$ (data from Pasquis et al., 1970); and (iii) resting nonpasserine birds where $Pi = 5.5\ M_b0.73$ (data from Prinzinger and Hanssler, 1980). *From P. J. Butler and A. J. Woakes, (1985). Also included in (i), the minimum* Pi *of the hummingbird* Colibri coruscans *during forward flapping flight in a wind tunnel (H) From Berger (1985).*

has been covered to various degrees in the previous sections. However, a number of birds, especially seabirds, have a more variable strategy in which they constantly vary the ratio (flapping burst duty cycle) between relatively short periods of flapping and short periods of gliding within a limited period of time (the duty cycle). Of course, an individual bird can also vary the frequency and amount of effort exerted (amplitude) in each flap, in order to modulate the wing kinematics and, thereby, the aerodynamic *P*o.

One of the best examples of the complex temporal variations seen in the flapping patterns of birds, along with the detailed fine tuning of specific wing kinematics, is exhibited during the foraging flights of the Manx Shearwater (*P. puffinus*) in the Irish Sea (Spivey et al., 2014). This species has a characteristic pattern of alterations between time spent flapping and time spent gliding, which is frequently changing within a fairly short period of time (the duty cycle). The duty cycle length typically varied between 0.5 and 6 s (median 2.55 s), with the proportion of time spent actively flapping ranging from 20 to 80% of the time. When experiencing moderately strong cross-winds of greater than 8 m/s (Gibb et al., 2017) that were optimal for slope soaring and wing sailing close to the waves, the Shearwaters tend to increase the length of their duty cycle time while also decreasing the flap ratio down to as low as 7%. Very high flap duty cycles were only seen during ascending flights when birds visited their nesting island, or when they were exposed to strong headwinds. Notably, higher flap duty cycles correlated with decreased duty cycle lengths, but f_w and body amplitude movements were only moderately elevated. Hence, more than a threefold moderation of biomechanical *P*o could be achieved by adjusting the flap duty cycle (Spivey et al., 2014), with only a small potential contribution from changes to flap frequency (between 6 and 6.5 Hz) and wing amplitude (as indicated by DBA varying between 7 and 9 m/s/s) (Figure 46.14A), which are only weakly correlated with each other. This may be a general characteristic of the flight of the larger Procellariiformes (Shearwater and Albatross) species that are optimized for utilizing energy available from their windscape environment. Although Black-browed Albatrosses only flapped for around 4.6% of the time in flight, with a typical f_w of 3.5 Hz, heart rate was linearly correlated with the number of wing flaps per minute during cruising flight (Sakamoto et al., 2013).

Like the Manx Shearwater, the Great Frigatebird also had a very constrained f_w (between 2.2 and 2.8 Hz), when it was not soaring and gliding (Weimerskirch et al., 2016). However, in contrast to the Shearwater, DBA varied over a much larger range (typically between 2 and 8 m/s/s), with no correlation with the flap frequency, indicating that amplitude modulation was the main contributor to biomechanical *P*o when flapping, rather than fine tuning of the flap duty cycle ratio (Figure 46.14B). In further contrast with both of these species is the flight of the bar-headed goose which, like most members of the Anseriformes (swans, geese, and duck), fly with almost continuous flapping behavior in the wild. This species demonstrates a third pattern of wing kinematics (Bishop et al., 2015), as it varies *P*o through a combination of both frequency (3.5−4.5 Hz) and amplitude (DBA varying between 4 and 8 m/s/s) modulation and these two variables are very tightly correlated (Figure 46.14C). As might be expected, heart rate is also highly correlated with both f_w and DBA, thus confirming their regulation of both biomechanical *P*o and metabolic *P*i (Bishop et al., 2015).

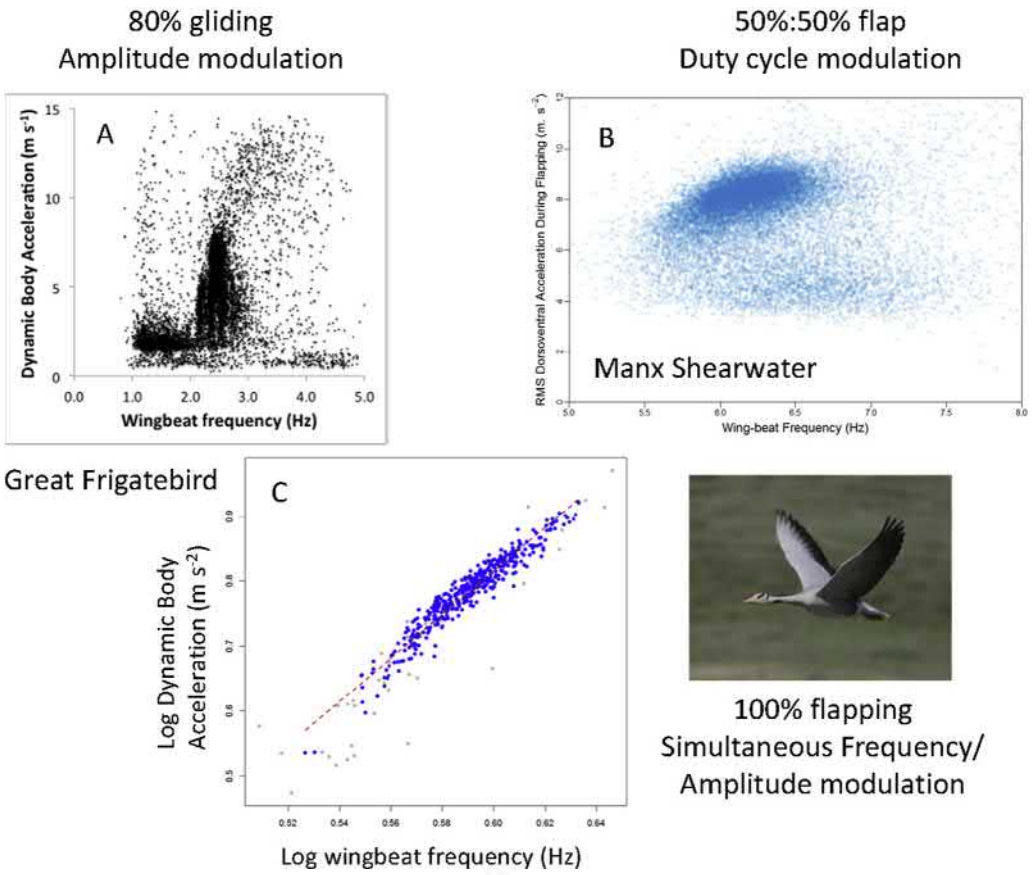

FIGURE 46.14 Wingbeat frequency plotted against Dynamic Body Acceleration for (A) Great Frigatebird, (B) Manx Shearwater, and (C) Bar-headed geese. *Modified from Weimerskirch et al. (2016), Spivey et al. (2014) and Bishop et al. (2015).*

46.3.3.4 Hovering flight and hummingbirds

As discussed above, hovering flight should be relatively costly, at least compared to intermediate air speeds. While this is the case for muscle *P*o, very few species of birds can sustain hovering in still air for long enough so that *P*i can be accurately determined (usually by measuring the rate of oxygen consumption). Only hummingbirds have been studied in which $\dot{V}_{O_2}$ for both hovering and forward flapping flight has been determined for the same bird (Berger, 1985; Clark and Dudley, 2010; Sapir and Dudley, 2012). These studies show that there was a reasonably small, but significant, difference in *P*i between the two forms of flight (Figure 46.12).

The relationship describing the interspecies allometry of hummingbird flight performance, with their unique wing kinematics, has generally been considered to be different from that calculated for all other volant species of bird, with their more conventional flapping motion (Butler, 1991). The DEE of 17 species of hummingbirds was measured with DLW and shown to scale as $\text{DEE} = 115M_b^{0.98}$ ($\text{DEE} = 110M_b^{0.96}$ when accounting for phylogenetic relatedness), while that for all other bird species scaled as $\text{DEE} = 224M_b^{0.68}$ (Shankar et al., 2020). Similarly, for nine species of hummingbirds (Butler, 1991; Wolf and Hainsworth, 1971; Wells, 1993a), hovering $\dot{V}_{O_2} = 449M_b^{0.90}$, $r^2 = 0.94$, and appeared to be similar to the estimates for the minimum oxygen consumption required for the forward flapping flight of hummingbirds, $\dot{V}_{O_2} = 314M_b^{0.90}$ (Bishop and Butler, 1995), but with a smaller intercept. These relationships compare to the scaling for nonhummingbird species during forward flight in a wind tunnel, $\dot{V}_{O_2} = 160M_b^{0.74}$ (Butler, 1991). Interestingly, these two allometric trends for hummingbirds and all other avian species cross over at approximately 15g M_b, which is very close to the size of the largest hummingbird species (*Patagona gigas*). Thus, below this body size, the mass-specific cost of forward flight is estimated to be less for hummingbirds using their unique wing kinematics than for conventional flapping fliers, while above this weight, conventional wing kinematics appear to have the advantage. However, a recent paper by Groom et al. (2018), which also accounts for phylogenetic relatedness, suggests that the energetic scaling relationship during hovering for 25 species of hummingbird is only $\dot{V}_{O_2} = 175M_b^{0.76}$, which is rather similar to forward

flight for birds in general and is difficult to reconcile with the above hypothesis. This study also makes the interesting observation that f_w was the primary scaling variable that was linked to hovering costs ($\dot{V}_{O_2} = c\, f_w^{-1.05}$, $r^2 = 0.76$), with energy cost per wingbeat scaling with M_b as $\dot{V}_{O_2} = c\, M_b^{1.4}$ ($r^2 = 0.94$), while wing loading was not significant (Groom et al., 2018).

The classic work of Chai and Dudley (1995, 1996) showed the remarkable performance of hovering hummingbirds when challenged with hypodense heliox, helium, and normal air atmosphere mixtures. Their results from 1995 show that hummingbirds gradually reduced their hover feeding time from around 25s down to 10s, when air density went from sea level to a simulated height of some 6000 m. Surprisingly, their $\dot{V}_{O_2}$ only appeared to increase between 15 and 36% between the four individual birds (although this was difficult to measure), while wingbeat amplitude increased by 20–24% and f_w by only 4–10%. Under these conditions of a normoxic but hypodense atmosphere, failure to hover was ultimately determined by a biomechanical limitation (although flight times had also significantly reduced) as the wing stroke amplitude approached 180 degrees. The subsequent work, showed that under hypoxic and hypodense conditions, failure could be induced at a higher air density (63% of sea level), with lower stroke amplitude (around 168 degrees), but with oxygen availability at only 12%, indicating insufficient oxygen supply as the cause at an equivalent altitude of around 4500 m or 15,000ft.

46.3.3.5 Scaling of flight muscle efficiency and elastic energy storage

The efficiency with which the flight muscles can produce mechanical power from chemical energy is of great physiological significance as it determines the overall energy required by the animal during exercise. Any excess heat must be lost to the environment in order to prevent hyperthermia. However, in order to estimate efficiency, it is necessary to measure both the *P*i and the *P*o of the flight muscle. As pointed out by Alexander (2005), determination of *P*o generally involves calculations which add a good deal of uncertainty, particularly for flying organisms. Thus, it seems sensible when reporting on the mechanochemical conversion efficiency of flight muscles, to refer to their "apparent" efficiency calculated when specifically combining particular values for aerobic *P*i and *P*o (Bishop, 2005). Pennycuick (1975) recommended that the value of the mechanochemical conversion efficiency of avian flight muscles should be around 0.23 (or 23%) and treated as a constant. This was based on the determination of partial efficiency (i.e., the change in *P*o/change in *P*i) during the flight of budgerigars, laughing gulls, and fish crow (Tucker, 1972; Bernstein et al., 1973), in which partial efficiency ranged from 19 to 30%. However, this runs counter to the more general observation that locomotory muscles for various vertebrate (Alexander, 2005) and invertebrate (Askew et al., 2010) groups exhibit muscle conversion efficiencies that scale positively with M_b and negatively with respect to contraction frequency. Theoretically, it should not be possible for muscle fibers to operate with an overall -efficiency greater than 28% (Rall, 1985) and, in practice, muscle fibers of larger mammals appear to operate with maximal efficiencies of between 20 and 25% (Taylor, 1994).

By using detailed kinematic and morphological analyses, Wells (1993a) calculated an estimate for *P*o (100 W/kg) during normal hovering of the broad-tailed hummingbird (*Selasphorus platycercus*) based on the aerodynamic model of Ellington (1984). $\dot{V}_{O_2}$ was measured as 50 mL/g h, which gave an estimated efficiency of 9–11% (assuming perfect elastic storage of energy). By adding weights to the birds, Wells (1993b) determined that maximum *P*o of the pectoral muscles for this species during hovering was around 117 W/kg and that the efficiency remained approximately 10%. Using the novel and elegant method of flying ruby-throated hummingbirds (*Archilochus colubris*) in an increasing atmosphere of He/O_2, Chai and Dudley (1995) estimated maximum *P*o to be 133 W/kg, with $\dot{V}_{O_2}$ measured as 62 mL/g h, and efficiency of around 10% regardless of the intensity of the flight "effort." The above calculations include an allowance of 10% for the cost of cardiorespiratory function (Tucker, 1973; Pennycuick, 1989), but there is no allowance for BMR. However, taking this into account (Krüger et al., 1982) only increases efficiency by approximately 1% in both studies. They also only studied very small species of hummingbirds with M_b of around 4 g. The recent study by Groom et al. (2018) extended the size range and included 12 species of hummingbird (4 taken from the literature). They calculated a phylogenetically adjusted positive scaling with M_b of Efficiency $= 7.6\% M_b^{0.38}$, with estimates ranging from 10 to 19%, which were inversely related to f_w. It should be noted that if we extrapolate this relationship to that of the largest species of hummingbird at 17.5 g, *P. gigas*, it would have predicted an efficiency of 22.5% at a f_w of 15 Hz, which is similar to that of elite humans cycling (Carlsson et al., 2020) with a cadence of typically around 1.5 Hz. The median mass for all birds is 38.6g (Blackburn and Gaston, 1994) which would predict an efficiency of 30% using this equation, so we would expect that efficiency might scale differently for birds with more conventional wing kinematics.

Biewener et al. (1992) used calibrated strain recordings from the humerus of flying birds to measure the force and estimate the power generated by the pectoralis muscles. Mean *P*o for three starlings (*S. vulgaris*), flying in a wind

tunnel (for unstated duration), was 1.12 W at an estimated speed of 13.7 m/s and M_b 70−73 g. Torre-Bueno and Larochelle (1978) reported mean *P*i to be 8.9 W for three starlings of mean mass 73 g and flying in a wind tunnel for 30 min over a range of speeds from 8 to 18 m/s. Thus, after subtracting BMR (Prinzinger and Hanssler, 1980) and allowing 10% for the cost of cardiorespiratory function, the estimated efficiency of the flight muscles for this species is 15.4%. Ward et al. (2001) estimated that flight muscle efficiency in two starlings flying in a wind tunnel varied between 13 and 23% depending on the bird, the flight speed, and the aerodynamic model used to calculate *P*o. This introduces the hypothesis that efficiency may not be a constant and could vary depending on specific kinematics and *P*o. In a second study using strain gauges (Dial and Biewener, 1993), mean *P*o for four pigeons was 10.5 W/kg, with M_b 301−314 g and flying at approximately 8 m/s along a 47 m long corridor. They used a *P*i value of 106 W/kg (cf. Rothe et al., 1987) to estimate flight muscle efficiency as 11.2%. However, Rothe et al. (1987) estimated that their measurements of *P*i were elevated by between 15 and 30% by the presence of the mask and tubing. If a mean overestimate of 22% is assumed, the actual value of *P*i would be 87 W/kg, which would give an efficiency of 13.8%. If the value of *P*i, after adjustment for the drag on the mask and tube, is taken from Butler et al. (1977) for pigeons of mean mass 442 g and flying at 10 m/s (61 W/kg), a flight muscle efficiency power of 19.9% is obtained. The latter estimate would appear more credible, given the M_b of the pigeons and their relatively lower f_w. Hedh et al. (2020) used PIV to measure *P*o and ^{13}C NaBi to measure *P*i in blackcaps weighing 17−22 g and found an overall efficiency of 21%, which was equivalent to a muscle conversion efficiency of 30% after accounting for BMR and cardiorespiratory costs. We can see that measuring, or estimating, flight muscle efficiency often involves a number of data uncertainties and assumptions.

Bishop (2005) attempted to estimate the maximum $\dot{V}_{O_2}$ and, ultimately, flight efficiency for 15 species of birds studied during migratory climbing flights by Hedenstrom and Alerstam (1992). The estimated *P*i was based on the cardiovascular modeling approach (Bishop and Butler, 1995; Bishop, 1997) and was then compared to the estimated aerodynamic *P*o based on the model of Pennycuick (1989). This analysis suggested that the "apparent" mechanochemical efficiency of the avian flight muscles scaled allometrically with M_b, as $30\%M_b^{0.14}$ (M_b in Kg) (Figure 46.15), or $11.6\%M_b^{0.14}$ (M_b in g). Applied to hummingbirds of 4 and 17.5 g (see above) would give predictions of 13.8 and 17%, respectively. Applied to median mass for all birds of 38.6 g and to 70 g European Starlings yields 19 and 21.7%, respectively. Thus, these various studies support the hypothesis that there is an increase in overall flight efficiency with an increase in M_b and a decrease in f_w or strain rate (cf. Rayner, 1990). A phylogenetically controlled metaanalysis of the metabolic flight costs of both birds and bats (Guigueno et al., 2019) also concluded that overall flight efficiency increased with increasing M_b, but also decreased with flight speed (counter to the conclusions of Ward et al., 2001). However, the details of these relationships are a slightly controversial subject due to the potential errors in measuring and calculating *P*i and *P*o. In particular, the fact that the larger species of birds (e.g., great than approximately 1 kg) appear to have efficiencies of over 30% is a significant issue. Of course, it is possible that the muscle efficiencies of larger species of birds do eventually reach a plateau and this would provide a further limitation to the evolution and

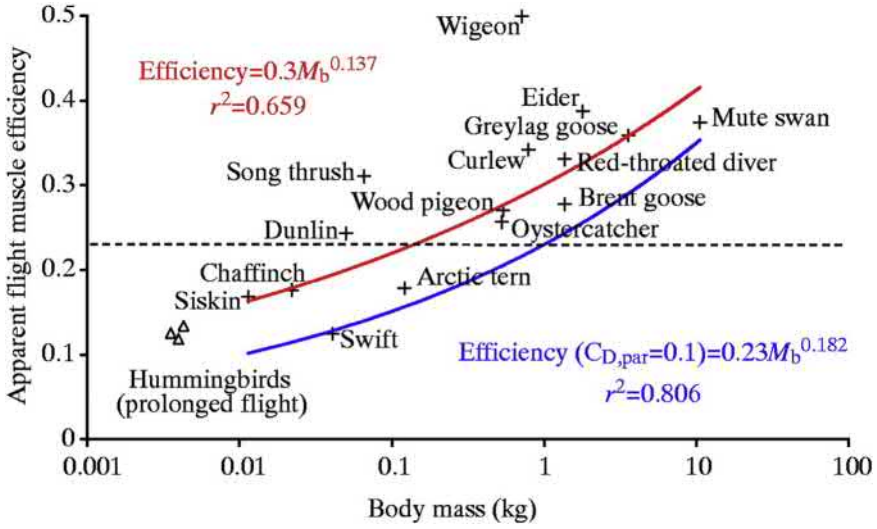

FIGURE 46.15 Estimated "apparent" flight muscle mechanochemical efficiency plotted against body mass (kg) for 15 bird species during migratory climbing flights over Sweden (see Hedenström and Alerstam, 1992). The wigeon, *Anas penelope*, is left out of the analysis as an outlier. The red regression line is based on the estimated sustainable biomechanical power output continuously available, calculated using default values for the parasite body drag coefficient (**C**D,par) ranging from 0.25 to 0.4 (Pennycuick, 1989). The blue regression line is based on a value for CD,par of 0.1. Estimates of efficiency for three species of hummingbirds (**Δ**) are also plotted. *Based on Bishop (2005).*

functional ecology of flapping flight performance. However, the uncertainties in the various calculations of aerodynamic and biomechanical *P*o are likely to be a significant confounding factor.

Typically, aerodynamic models such as those of Pennycuick (1975, 1989) and Rayner (1979) do not include the costs of accelerating and decelerating the wing during each cycle. It is argued that the inertial costs are recovered aerodynamically by assuming that the energy used to accelerate the wing can be recovered by doing either useful aerodynamic work at the end of the wing stroke or by using elastic storage of wing kinetic energy to reaccelerate the wing in the following beat. Additionally, it may be that the inertial costs are relatively small during forward flight at medium to fast speeds. Thus, Wells (1993a), Chai and Dudley (1995), and Groom et al. (2018) tend to favor calculations that hummingbirds are able to store the "inertial energy" and interpret *P*o assuming "perfect elastic storage" following each downward beat. This assumption reduces the value for the calculation of the power required to fly, especially for small species of birds that have high f_w. Bird flight muscles lack any associated specialized elastic components, such as long tendons, so any elastic component is likely to be a property of the cross-bridges and connective tissue of the muscle (Alexander and Bennett-Clark 1977). Dial et al. (1987) measured the electrical activity of the pectoralis muscles of the pigeon during flight and demonstrated that the pectoralis muscles are active before the end of the upstroke of the wings and could act like an elastic spring (Goslow and Dial, 1990).

Van den Berg and Rayner (1995) suggest that it may be necessary to consider the inertial cost. They estimated that the inertial power requirement should scale as approximately 5.8 $M_b^{0.80}$ (allowing for a 25% reduction due to wing flexion on the upstroke). Whatever the merits of each side of the debate, it seems possible that perfect elastic storage may prove to be unrealistic. Thus, any increment of the inertial costs that must be met by the flight muscles will increase the estimate of the "apparent" efficiency of the flight muscles. If "near" zero elastic storage is correct, then the inertial costs would dominate the total cost of hovering flight in hummingbirds (Spedding, 1994).

46.4 The flight muscles of birds

46.4.1 Flight muscle morphology and fiber types

The flight muscles of birds are structurally similar to the striated muscles of other vertebrates and consist of large numbers of long fibers, or cells, aligned essentially in parallel (Figure 46.16A). Each fiber can have a distinct biochemical character. At its simplest, each fiber can be specialized either for aerobic or anaerobic energy consumption, they can vary in diameter and cross-sectional area, and are supplied with various metabolites and oxygen via a network of capillaries (Figure 46.16B). Different species of birds have different amounts of flight muscle with respect to M_b (Hartman, 1961), termed the flight muscle: mass ratio by Marden (1987), and these muscles are composed of four main cell or fiber types (cf. Rosser and George, 1986a), so called slow oxidative fibers (SO, Type I), fast oxidative glycolytic fibers (FOG, Type IIa), fast glycolytic fibers (FG, Type IIb), and fibers which are intermediate (I, Type IIab) in their oxidative ability between the FOG and FG fibers.

Table 46.1 lists the major characteristics of these different fiber types. Essentially, the SO fibers have relatively slow rates of shortening, but are relatively efficient in producing force during isometric contractions, utilize oxidative metabolic pathways in the biosynthesis of energy-rich adenosine triphosphate (ATP), and are resistant to fatigue. FOG fibers are also capable of oxidative metabolism and resistance to fatigue, but can also use carbohydrates as a fuel during anaerobic metabolism, have relatively faster rates of shortening, and are relatively efficient in producing force while shortening in length. FG fibers are susceptible to fatigue and are restricted to anaerobic metabolism of carbohydrates, but produce more power per unit mass of muscle than SO and FOG fibers. One reason for the latter is that they contain a lower volume fraction of mitochondria and associated structures and, therefore, have room for more myofibrillar proteins.

The function of SO fibers is considered primarily to be of advantage in postural muscles (e.g., in the back and neck muscles) and also in the legs during rest, due to their economic production of force during isometric contractions. In birds, SO fibers have only been found in the deep layers of the pectoralis muscles and a few small muscles of the wing (coracobrachialis, triceps, and extensor metacarpi radialis) of a limited number of species (Talesara and Goldspink, 1978). The latter are generally adapted for gliding and soaring modes of flight, that is, species belonging to the avian orders of the Procellariiformes, Pelecaniformes, Ciconiiformes, Accipitriformes, Pelecaniformes, and the Gruiformes (Rosser and George, 1986a; Meyers, 1993; Rosser et al., 1994; Meyers and Mathias, 1997). Thus, Rosser et al. (1994) found that the deep "belly" of the pectoralis muscle of the American White Pelican (*Pelecanus erythrorhynchos*) is composed exclusively of SO fibers. Other authors have also reported SO fibers in the deep layers of the pectoralis muscles of the turkey vulture *Cathartes aura* (Rosser and George, 1986b) and red-tailed hawk *Buteo jamaicensis* (Rosser and George, 1986a) and associated with their soaring behavior. The SO fibers detected in various muscles of the double-crested cormorant, *Phalacrocorax auritus*, were considered to function during their wing-spreading posture frequently

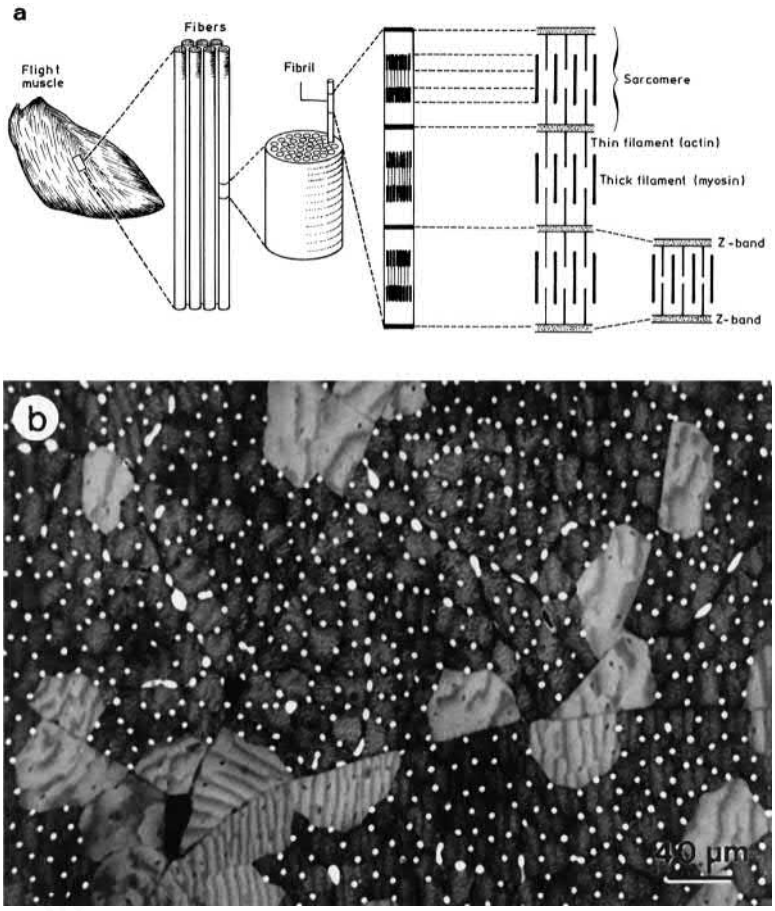

FIGURE 46.16 (A) Schematic illustration of the structure of a bird's pectoral muscle. The whole muscle is composed of many different fibers or cells, each of which consists of many fibrils and each fibril contains many thin actin filaments interspersed between thick myosin filaments. These filaments are organized into sarcomeres, which shorten during contraction as the actin and myosin filaments slide past each other. (B) Light micrograph of a 1 µm thick transverse section of pectoralis muscle of the pigeon *Columba livia*. Fast oxidative glycolytic fibers (dark and small) and fast glycolytic fibers (pale and large) can be clearly identified. Capillaries are empty following vascular perfusion fixation. Bar = 40 µm. *(A) Modified from K. Schmidt–Nielsen (1997). (B) From Mathieu-Costello (1991).*

TABLE 46.1 Simplified characteristics of muscle fiber types.

Property	Slow Oxidative SO (Type I)	Fast Oxidative Glycolytic FOG (Type IIA)	Fast Glycolytic FG (Type IIB)
Speed of contraction	Slow	Medium-fast	Medium-very fast
Aerobic capacity	High	High	Low
Anaerobic capacity	Low	Moderate	High
Capillary supply	Good	Good	Poor
Triglyceride stores	High	Medium-high	Low
Glycogen stores	Medium	Medium-high	Medium-high
Fatigue resistance	High	High	Low
Cross-sectional area	Small	Small-medium	Medium-large

adopted on land following diving (Meyers, 1997). Similar to the White Pelican, the deep layer of the pectoralis in both the Laysan and Black-footed Albatross (*Diomedea immutabilis* and *Diomedea nigripes*, respectively) consisted of 100% SO fibers, with significant contributions also found in the coracobrachialis cranialis and the extensor metacarpi radialis muscles. This fits with the extreme gliding performance of these species and supports the idea of a tendinous mechanism (the shoulder lock) that limits wing elevation above the horizontal and reduces the energetic cost during long foraging journeys (Pennycuick, 1982; Meyers and Stakebake, 2005). However, it is not always the case that

birds that regularly use soaring and gliding modes, as part of their flight performance repertoire, have specialized in SO fibers to this extent. A study of the histochemistry of the California gull (*Larus californicus*) showed that only relatively low percentages of SO fibers were present in their wing muscles and they completely lacked the deep layer to the pectoralis major muscle typically found in gliding specialists (Meyers and Mathias, 1997).

The most abundant type of fiber to be found in the flight muscles of birds capable of prolonged flapping flight is the FOG (George and Berger, 1966; Rosser and George, 1986a). In general, the flight muscles of small birds are entirely composed of FOG fibers, while larger birds have a mixture of different fiber types. However, there is a large degree of interspecies variation. George and Berger (1966) classified the pectoralis muscle of birds into six groups, with each fiber type listed in order of relative numerical abundance: (1) fowl type (FG, I, FOG); (2) duck type (FOG, FG, I); (3) pigeon type (FOG, FG); (4) kite type (mainly I); (5) starling type (FOG, I); and (6) sparrow type (FOG). While most species can be broadly assigned to one of these groups, there are many exceptions. Clearly, each individual species is adapted to cope with its own unique requirements based on its behavioral ecology, its detailed morphology, and the environmental conditions in which it lives.

Even more importantly, the histochemical classification of muscle fiber types can be misleading from a functional perspective. In reality, the fast-twitch fiber types are arbitrary classifications within a continuum of oxidative to glycolytic potentials, which may also be affected by amount of use (or training). In addition, the term "fast" is also slightly arbitrary, as there is likely to be a continuum for the rates at which the flight muscles are optimized to contract, due to the scaling of f_w with M_b (Pennycuick, 1990, 1996). A small hummingbird may beat its wings at up to 50 Hz, while a large swan may only have a wingbeat of around 2.4 Hz. Therefore, there are likely to be many associated differences in the molecular characteristics of the contractile proteins from different species of birds. As a consequence, the FOG fibers of a hummingbird are not biochemically identical to the FOG fibers of a swan. It is probable that, even within the muscle of an individual bird, the FOG fibers of the deep layers may have slightly different characteristics to the FOG fibers from the more peripheral layers. Rosser and George (1986a) suggest that, given sufficient detailed knowledge about the protein isoforms of muscle, it is conceivable that almost all muscle fibers could be described as a unique subtype.

Despite the difficulties outlined above, it is still possible to draw some interesting conclusions about the functioning of avian flight muscles by quantifying their fiber type compositions. The Galliformes, such as the domestic chicken and the ruffed grouse (*Bonasa umbellus*), have a majority of FG fibers in their pectoralis muscles (Rosser and George, 1986a). This is matched by their relatively small M_h and a low capacity to supply the muscles with oxygen (Bishop and Butler, 1995; Bishop, 1997). These birds are restricted to anaerobic flights of short duration. Typically, Galliformes birds live close to the edges of forests, have relatively short wings and relatively large flight muscles, and escape predation by being adapted for rapid take-off followed by short flights into dense vegetation or into the branches of trees. The South American ecological equivalent of the Old World Galliformes, the Tinamous, also has very small hearts and large flight muscles (Hartman, 1961) and lives on the forest floor.

The Galliformes contrast with their closest relatives, the Anseriformes (the ducks, geese, and swans) (Prum et al., 2015). Although of similar body size, the Anseriformes have relatively longer wings and live in open, uncluttered habitats. Their pectoralis muscles contain a higher proportion of FOG fibers interspersed among the FG fibers, and their relative M_h is also much larger (Magnan, 1922; Hartman, 1961). Thus, their wing morphology determines that they are slightly faster (Rayner, 1988; Pennycuick, 1989), and their muscle physiology and cardiovascular adaptations determine that they are able to prolong these flights over relatively long distances.

The aerobic nature of the flight muscles of some relatively large species of birds, such as the bustards and swans, has an important consequence for the interpretation of the size limitations to flight performance in birds. It is necessary to distinguish between "burst" flight performance and "prolonged" or aerobic flight performance (Marden, 1994) and to compare flight muscles which are adapted for similar types of flight. The data of Marden (1987) and Pennycuick et al. (1989) on the maximum lifting ability of flying animals during take-off refer only to "burst" flight performance, and bird species that have predominantly anaerobic FG flight muscle fibers will be at an advantage during take-off compared to species that have predominantly aerobic FOG muscle fibers.

Caldow and Furness (1993) studied the histochemical adaptations of two ecologically similar seabirds, the great skua (*Catharacta skua*) and the herring gull (*L. argentatus*). They found that both species had FOG fibers exclusively in their pectoralis and supracoracoideus flight muscles, but that the mass-specific activity of both the oxidative and glycolytic enzymes (see below) were higher in the muscles of the great skua and concluded that this adaptation enabled the skua (Stercorariidae) to be a more effective aerial kleptoparasite than the herring gull (Laridae). The mass of the pectoralis muscles is relatively small in the herring gull (12% of M_b), but it has a moderately large M_h (0.9% of M_b), which is consistent with the fact that its flight muscles consist entirely of FOG fibers (Bishop and Butler, 1995).

Hummingbirds are considered the most aerobic of all avian species, with 100% FOG in their pectoralis muscles

and the largest hearts of any species (Bishop, 1997; Welch and Altshuler, 2009). Assessments of their "anaerobic" burst flight performance have been assessed during loading-lifting studies during take-off (Chai and Millard, 1997; Altshuler et al., 2010) and shown that even large species can lift extra weight for a few seconds but that they tend to show a negative scaling of maximum muscle-specific *P*o with M_b. However, very brief bursts of power are also required for foraging and evasive maneuvers during flight and, for hummingbirds, it has been shown that the best predictor of the ability to perform complex turns and maneuvers was load-lifting ability and burst muscle capacity (Dakin et al., 2018). The other key variable was the relative surface area of the bird's wing and, therefore, wing loading.

46.4.2 Biochemistry of the flight muscles

As discussed by Marsh (1981), the sustained, long distance flights performed by many migrating birds require two interacting adaptions: the ability to store sufficient fuel reserves for the flight and the ability to maintain supplies of oxygen and fuel to the working tissues. Due to the very high energy density of lipids (39.3 kJ/g), compared to pure carbohydrates (17.6 kJ/g) and proteins (17.8 kJ/g), the energy for migratory flights is predominantly stored as fat in adipocytes. Thus, adaptations for the efficient oxidation of fatty acids and the potential for a high aerobic capacity are some of the most important features of most avian flight muscles. The relatively high mass-specific energy output required from the flight muscles necessitates high capillary and mitochondrial densities and high levels of mass-specific activities for the associated mitochondrial enzymes (Mathieu-Costello et al., 1992).

Hummingbirds are able to sustain the highest mass specific MRs of any vertebrate (Lasiewski, 1963), and Table 46.2 shows data from Suarez et al. (1986) for the maximum activities of various catabolic enzymes in hummingbird flight muscle. The following enzymes are of particular interest: citrate synthase (CS), as an indicator of general aerobic capacity; 3-hydroxyacyl- CoA dehydrogenase (HAD) and carnitine palmitoyl transferase, as indicators of fatty acid utilization; phosphofructokinase, as an indicator of general glycolytic flux; pyruvate kinase (PK), as an indicator of anaerobic glycolysis; and hexokinase (HEX) and glycogen phosphorylase (GPHOS), as indicators of plasma glucose and intracellular glycogen utilization, respectively. As expected, the flight muscles of hummingbirds have some of the highest catabolic enzyme activities ever measured. In particular, mass-specific CS and the HEX activities are even higher (at 448.4 and 18.4 μmol/g min, respectively) in a subsequent study with a modified extraction procedure (Suarez et al., 1990).

Various studies (Suarez et al., 1986, 1990) indicate that while it is possible for hummingbirds to meet almost all their flight requirements by oxidizing lipid fuel, it is also possible for them to meet the requirements of hovering flight utilizing carbohydrate fuels, and they oxidize glucose and fructose equally well (reviewed by Suarez and Welch, 2017). The latter possibility makes sense given that hummingbirds feed mainly on sucrose-rich nectar

TABLE 46.2 Maximum enzyme activities in the flight muscle and heart of the rufous hummingbird *selophorus rufus*[1].

Enzyme	Flight Muscle	n	Heart	n
Glygogen phosphorylase	31.22±2.5	6		
Hexokinase	9.18±0.31	4	10.08±1.9	4
Phosphofructoknase	109.8±13	6	unstable	
Pyruvate kinase	672.4±27	6	507.3±25	6
Lactate dehydrogenase	230.3±23	6	357.3±30	6
Carnitine palmitoyl transferase	4.42±0.46	6	2.83±0.72	4
3-Hydroxyacyl CoA	97.10±13	6	68.51±10	4

(a disaccharide made of glucose and fructose) and so during the day they would have a good supply of pure carbohydrate direct from the environment. Indeed, the majority of floral nectars are dominated by sucrose, with additional amounts of fructose and glucose, to encourage both bird and bat pollinators (Wolff, 2006). However, for long-term storage, carbohydrates are stored as glycogen (a polysaccharide of glucose) which consists of at least 75% water, thus giving it a relatively poor energy density (4.4 kJ/g). It would not be possible, therefore, to store enough carbohydrates to fuel long-distance flight. In fact, it is unlikely that stored carbohydrate could support hovering flight for around 5 min (Suarez et al., 1990). However, in the short term, it is more efficient to oxidize plasma glucose directly to support flight, due to the 16% lower net yield for ATP resulting from the cost of synthesizing fatty acids from glucose for long-term storage. Indeed, this led these authors to suggest that premigratory hummingbirds should behave as "carbohydrate maximizers" by keeping their foraging flights well under 5 min duration. This would provide efficient foraging while allowing excess glucose to be stored as fat. However, while the availability of plasma glucose may not be limiting for hummingbirds, the majority of bird species may place a higher emphasis on carbohydrate "sparing." Bishop et al. (1995) found that HEX activity was relatively low in the pectoralis muscles of adult premigratory barnacle geese, and similar results have been reported for the pigeon and domestic chicken (Crabtree and Newsholme, 1972) and for the migratory semipalmated sandpiper, *Calidris pusilla* (Driedzic et al., 1993).

Many studies have shown that prior to long-distance flights, such as those performed during seasonal migrations, birds increase in M_b primarily due to the laying down of fat stores (Blem, 1976). This is usually correlated with hypertrophy of the pectoralis muscle in order to increase the power available for take-off and forward flapping flight and species-specific changes in catabolic enzyme activities. While Marsh (1981) found no change in the premigratory activity of CS in the pectoralis muscle of the catbird (*Dumetella carolinensis*), he reported a significant increase in the level of HAD (indicating an increase in the potential for fatty acid oxidation). A similar increase in the ability to oxidize fatty acids was found in the semipalmated and western sandpipers, but the level of CS did not change or decrease (Driedzic et al., 1993; Guglielmo et al., 2002). However, some species of small migratory passerine birds do appear to show an increase in the premigratory activity of both CS and HAD (Lundgren and Kiessling, 1985, 1986; McFarlan et al., 2009), while CS activity in the premigratory barnacle goose was around 30% greater than that of postmolting birds approximately 4 weeks earlier in the season (Bishop et al., 1995).

Avian muscle capillarity and diffusion distances have been studied in a variety of different tissues, but no significant allometric trends with respect to different M_b were found for any of the variables measured (Snyder, 1990). However, Snyder (1990) did find a small but significant difference in the capillary to fiber ratio (C/F) between the aerobic fiber types (1.8 caps/fiber) and the glycolytic fibers (1.4 caps/fiber). Capillary density and diffusion distances are primarily determined by the cross-sectional area of the individual fibers, and the author argues that there may be little selective advantage in having a C/F greater than 2.0. Studies on avian pectoralis muscles have generally resulted in similar conclusions. Mathieu-Costello et al. (1992) found that the C/F of the rufous hummingbird (*Selasphorus rufus*) is only 1.55 caps/fiber compared to that of the pigeon, which is 2.0 caps/fiber (Mathieu-Costello, 1991). However, fiber diameter and the cross-sectional area are much smaller in the hummingbirds than in pigeons and, therefore, the capillary density per unit area is much higher in hummingbirds. Mathieu-Costello et al. (1992) consider that one of the most important determinants of the rate of oxygen flux in aerobic fibers is the size of the capillary-to-fiber interface (i.e., the capillary-surface-per-fiber-surface area). However, in order to measure this feature accurately, it is necessary to standardize with respect to both the sarcomere length and the degree of tortuosity of the capillaries.

46.4.3 Neurophysiology and muscle function

Birds are capable of synchronizing the extension of the elbow and wrist joints of the wing during flapping flight, using automated coordinating mechanisms involving skeletal and muscular adaptations (Vazquez, 1994). However, the power and thrust generated during the wingbeat cycle, and the complex kinematics of the wing during the flapping flight of different species, require an active neuromuscular control mechanism and specialized adaptations of the flight muscles.

The detailed movements of the wing during flight actually involve a large number of different muscles (Dial et al., 1991; Dial, 1992a) and their differential (Dial, 1992a; Tobalske and Dial, 1994; Tobalske, 1995; Tobalske et al., 1997) or regional (Boggs and Dial, 1993) activation. For most studies, however, it is sufficient to focus on the functioning of the largest flight muscles, pectoralis and supracoracoideus. Dial (1992b) showed that birds were unable to take-off or perform controlled landings without the use of the muscles of the forearm, but they could sustain level flapping flight following an assisted take-off.

The largest flight muscle, the pectoralis major, can be divided into two anatomical parts (Figure 46.17), the sternobrachialis (SB: which is superficial and lies along the sternum) and the thoracobrachialis (TB: which forms a deep layer lying along the sternum), and these are separated by the membrana intermuscularis (Dial et al., 1987). The

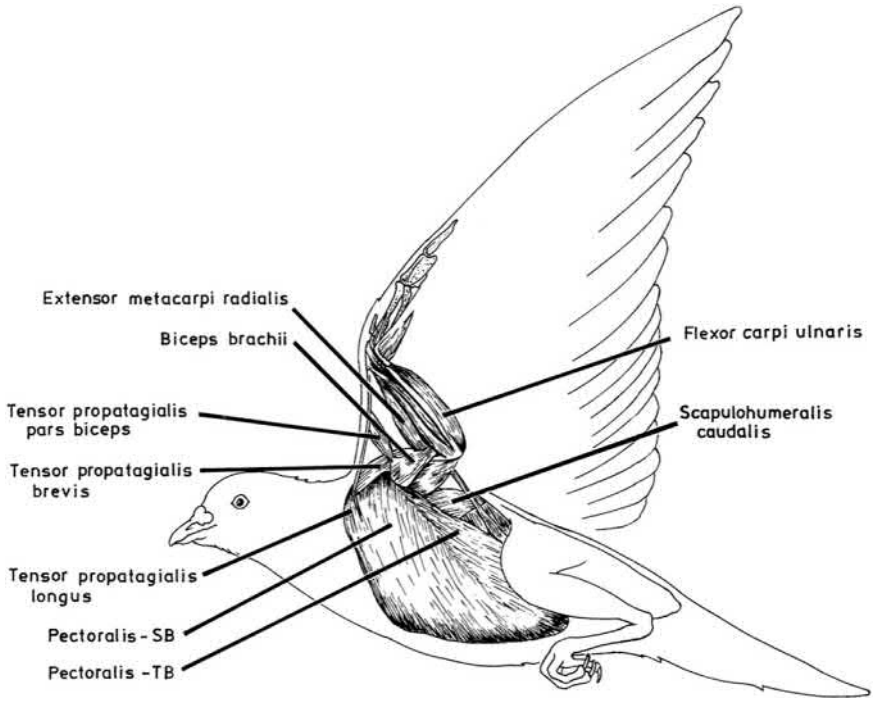

FIGURE 46.17 Illustration of the superficial flight muscles of the wings of a pigeon, *Columba livia*. The supracoracoideus muscles (not shown) are primarily used to power the upstroke and lie directly under the larger pectoralis muscles, which primarily power the downstroke. *Modified from Dial (2003).*

SB is primarily innervated by the rostral nerve branch and the TB by the caudal nerve branch of the brachial ventral cord. In the pigeon, the fibers within the SB and TB have different orientations (Dial et al., 1987), while the SB has a lower percentage of FOG fibers and relatively more FG fibers, and the TB is primarily made up of FOG fibers (Kaplan and Goslow, 1989). Thus, the histochemical analysis and the neuroanatomy support the view that the pectoralis major is made up of at least two functional subunits, each with a potential for independent action on the wing during flight (Dial et al., 1987, 1988; Kaplan and Goslow, 1989; Goslow and Dial, 1990). Dial et al. (1987) showed that both the SB and TB muscles of the pigeon were maximally activated during take-off or during large-amplitude wingbeats. However, during slow flight, the SB was relatively more important and during low-amplitude wingbeats, the activity of the TB could be almost zero. Interestingly, Dial et al. (1987) also indicate that there is a gradual reduction of large-amplitude electromyogram (EMG) spikes during the transition from take-off to level flight and that they reappear during landing. This supports the hypothesis that FG fibers are derecruited during level flight.

Tobalske et al. (1997) studied the neuromuscular control and wing kinematics of the black-billed magpie, both in the wild and while flying in a wind tunnel, and showed that this species has a particularly complex flight style, consisting of alternating high- and low-amplitude wingbeats, and occasional brief glides. This wide study found that the pectoralis consisted of FOG and I fiber types, as in the woodpecker (see below), and that the I fiber types were probably only recruited during the high-amplitude wingbeats. EMG recordings were made from six different wing muscles, and all showed that the relative intensity of the EMG signal exhibited a U-shaped output with respect to flight speed. Minimum intensity was recorded around 4.4 m/s and the highest was recorded during hovering and the top speed of 13.4 m/s. The pectoralis and the biceps brachii muscles showed strong activity during the end of the upstroke and the beginning of the downstroke, while the supracoracoideus, the humerotriceps, the scapulotriceps, and the scapulohumeralis caudalis were important during the end of the downstroke and the beginning of the upstroke.

A more detailed study of the EMG activity of 17 different muscles in the shoulder and forelimb of the pigeon during 5 different modes of flight was conducted by Dial (1992a). He concluded that the temporal pattern of activity did not vary much between different modes of flight, but that the intensity of the EMG signal was very important in determining the role of the different muscles during different modes of flight (Figure 46.18).

Tobalske (1996) studied the muscle composition and wing morphology of six different species of woodpecker, ranging in mass from 27 to 263 g, and related morphology to the scaling of intermittent flight behavior. Intermittent flight consists of regular alternation between periods of flapping and nonflapping. During the nonflapping phases,

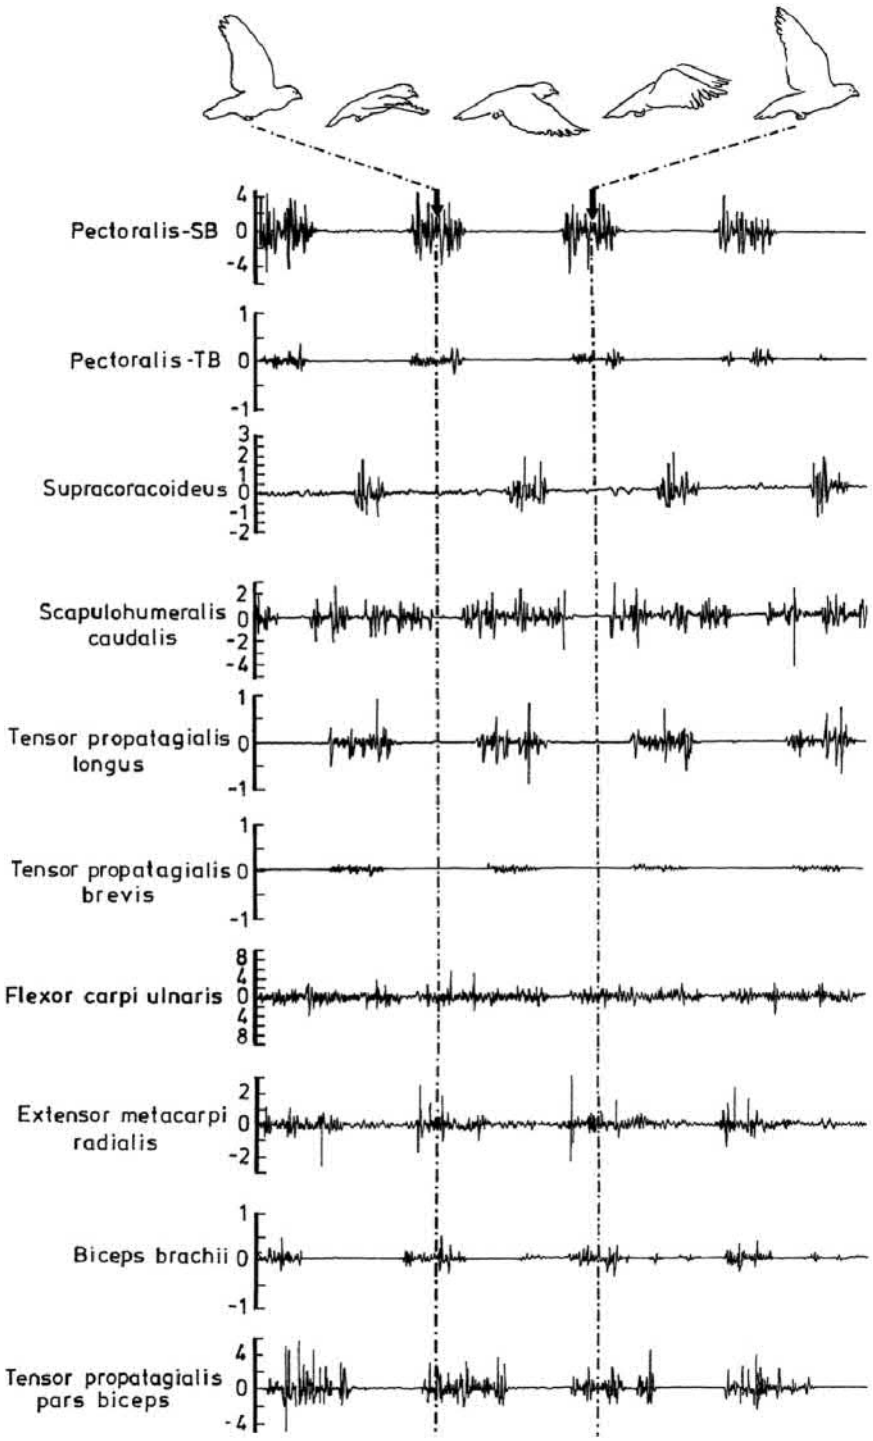

FIGURE 46.18 Electromyogram (EMG) signals recorded during level flapping flight from the various muscles of a pigeon, *Columba livia,* illustrated in Figure 13. EMG activity is presented with reference to the phase of the wingbeat cycle, with each downstroke indicated by the *vertical dashed line*. *Modified from Dial (2003).*

the bird's wings are either held folded at its side (flap-bounding flight) or held fully extended (flap-gliding flight). Biomechanical and physiological analyses suggest that intermittent flight is energetically efficient relative to continuous flapping (Rayner, 1985a), particularly for small species that have high f_w which are relatively "fixed" (Rayner, 1985a). Only FOG and I fiber types were found in these six species of woodpecker, with small species having almost exclusively FOG fibers in their pectoralis muscles, while species >100 g tended to have significant amounts of

I fibers. All six species were capable of exhibiting flap-bounding behavior, although the percentage of time spent flapping increased with increasing M_b. The empirical observations of Tobalske (1996) greatly exceed the theoretical considerations (Rayner, 1985a) that the upper limit for flap-bounding flight should be around 100 g of M_b.

However, the heterogeneous scaling of the fiber type composition of the pectoralis is likely to be one reason why the theoretical figures underestimate bird flight performance (Tobalske, 1996). FG and I fibers have the potential to produce more force per unit area than FOG fibers and, therefore, can produce more power for a given degree of fiber shortening and frequency. Thus, Tobalske (1996) argued that the positive scaling of the percentage and cross-sectional diameter of I fibers in the pectoralis of woodpeckers may be a direct result of the positive scaling of the power required for flight compared to the power available from the flight muscles (cf. Pennycuick, 1989; Marden, 1987; Ellington, 1991). Interestingly, among woodpeckers, the scaling of relative heart muscle mass is negative relative to increasing M_b (Hartman, 1961), which matches the decline in FOG content of the flight muscles. Thus, while large woodpecker species may be able to meet the power required to perform flap-bounding flight, it is likely that they will not be able to prolong these types of flight as easily as the smaller species or, perhaps, that they might utilize a higher fraction of gliding flight.

Lewis' woodpecker (*Melanerpes lewis*) was found to be able to perform both flap-bounding and flap-gliding flight, contrary to theoretical predictions that it should not perform the former (Tobalske, 1996), and this behavior was not well correlated with the morphology of the wing. In addition, Tobalske and Dial (1994) found that the 35-g budgerigar was also capable of performing flap-gliding behavior when flying slowly, but switched to flap-bounding behavior during fast flight, despite the observation that they only have a single fiber type (FOG) in their pectoralis muscles (Rosser and George, 1986a). Thus, the hypothesis that the FOG fibers of small birds should not be used for gliding as it is inefficient appears to be undermined by the budgerigars, with the pectoralis being active during the gliding phases, but inactive during the bound. Tobalske and Dial (1994) predicted that all other species that show intermittent flight should also be facultative flap-gliders and flap-bounders and that the choice of flight mode is simply dependent on flight speed.

46.5 Development of locomotor muscles and preparation for flight

Choi et al. (1993) studied the skeletal muscle growth and development of thermogenesis in European starlings (*S. vulgaris*), the northern bobwhite (*Colinus virginianus*), and Japanese quails (*Coturnix japonica*). The M_b of the altricial starling developed more rapidly than that of the precocial quail species, although the percentage of the M_b that was accounted for by muscle mass was quite similar. The main difference between these groups was in the expression of muscle mass-specific enzyme activities. In particular, the activity of CS did not exceed 50 and 30 μmol/min g in the pectoralis muscles of *Coturnix* and *Colinus* quail, respectively, throughout development. In the starling pectoralis muscle, CS activity increased rapidly, and linearly, during development and reached 142 μmol/min g around fledging at the age of 16 and approximately 230 μmol/min g in adult starlings. In bank swallows (*Riparia riparia*), CS activity increased from around 20 μmol/min g at 2 days of age and reached around 150 μmol/min g after 10 days (Marsh and Wickler, 1982).

A similar study of the barnacle goose found an even more exaggerated developmental pattern (Bishop et al., 1995), with CS expression showing almost no change in activity from hatch (12 μmol/min g) to 5 weeks of age (20 μmol/min g). Subsequently, the activity increased rapidly to 75 μmol/min g at 30 μmol/min g in the pectoralis muscles of *Coturnix* at 7 weeks of age and reached around 100 μmol/min g in the premigratory goslings and adults (see Figure 46.35). The mass-specific activity of four different mitochondrial enzymes showed broadly similar patterns of activity to each other during development (Bishop et al., 1995) and are typified by the results obtained for HAD activity in pectoralis, cardiac, and semimembranosus leg muscle (Figure 46.19A). Throughout most of development, the cardiac muscle had the highest relative capacity for aerobic metabolic flux and fatty acid oxidation. HAD activity in the semimembranosus leg muscle was intermediate in value prior to fledging at 7 weeks (when the birds first begin to fly), but subsequently declined, while CS activity in the pectoralis flight muscle was initially very low, but reached a peak in the premigratory birds (see Figure 46.35). The developmental profiles of various glycolytic enzymes, lactate dehydrogenase (LDH, Figure 46.19B), HEX (Figure 46.19C), and GPHOS (Figure 46.19D), were more tissue specific compared to those of the mitochondrial enzymes. Development of LDH and GPHOS activities in the pectoralis muscle shows a similar exponential increase as that for CS, but values for HEX remain very low at all ages.

Overall, the results suggest that the relative use of circulating plasma glucose by the pectoralis muscle during flight is low, while intramuscular stores of glycogen are of primary importance during short-burst activity and of intermediate importance during longer-term activity and that fatty acid oxidation is the main fuel during long-distance flight (Bishop et al., 1995). In general, moderate activity levels were detected in the semimembranosus muscle for all the enzymes that were measured, suggesting that the leg muscles are capable of utilizing all fuel types in almost equal amounts. However, the cardiac muscle had extremely low levels of GPHOS, indicating that it can only utilize aerobic pathways and that metabolic fuel must be

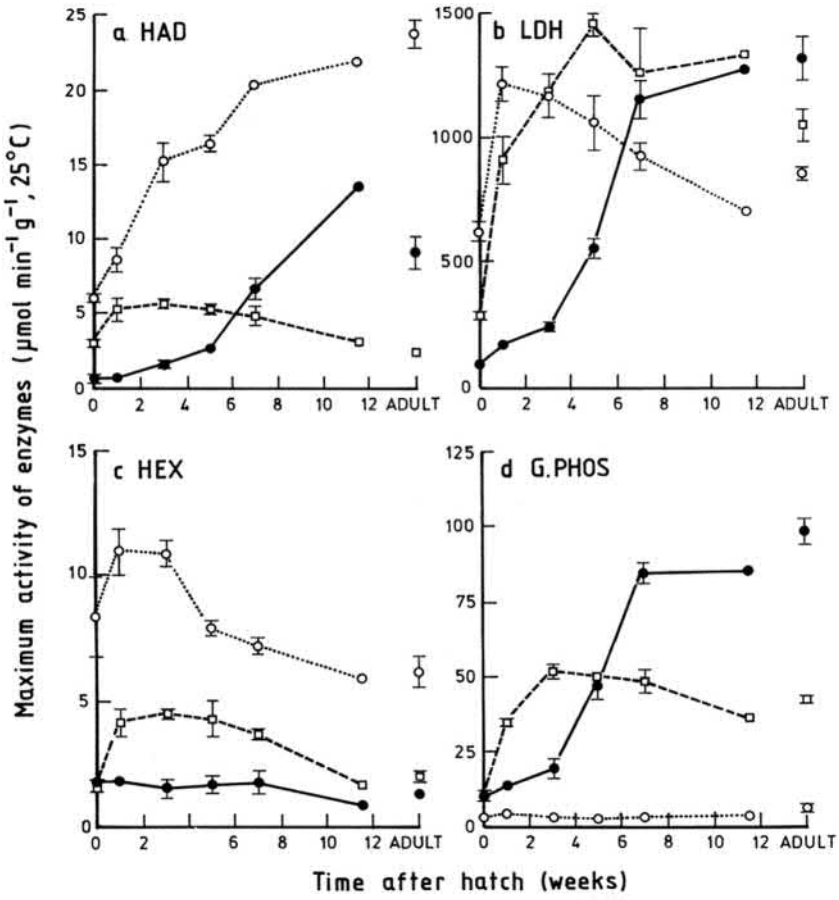

FIGURE 46.19 Mean ± SE of maximum activities of catabolic enzymes (mol/min g wet/wt at 25°C) in pectoral muscle (●——●), heart muscle (○ … ….○) and semimembranosus muscle (□————□) plotted against age of wild barnacle geese, *Branta leucopsis*. (A) 3-hydroxyacyl-CoA dehydrogenase (HAD), (B) lactate dehydrogenase (LDH), (C) hexokinase (HEX), and (D) glycogen phosphorylase (G.PHOS). N = 2−8, except for a single individual at 11.5 weeks of age. Adult geese and 11.5-week-old gosling are premigratory (see text). *Modified from Bishop et al. (1995).*

primarily supplied by blood. LDH values were relatively high in the heart, while PK levels were very low (data not shown), indicating that the heart is capable of oxidizing circulating lactate as a fuel.

The development of the locomotor and cardiac muscles, together with other morphological features, has been studied in a Svalbard population of migratory barnacle geese, from hatch until migration to the wintering grounds in southern Scotland at the age of approximately 12 weeks (Bishop et al., 1996). Up until the age of 7 weeks, the goslings are unable to fly and spend their time walking and foraging. At the age of 5 weeks, the relative mass of the leg muscles is approximately 13% of M_b, while that of the pectoral muscles is only 3.5% of M_b. During the first 5 weeks of their life, there is a strong relationship between mass of the ventricles and mass of the leg muscles. During the following 2 weeks, the flight muscles continue to grow in an exponential manner and by the time the goslings are 7 weeks old, these muscles are an impressive 14% of M_b, whereas the relative mass of the leg muscles has declined to approximately 9% of M_b. From the age of 7 weeks, the mass of the ventricles is proportional to the mass of the pectoral muscles. At 5 weeks of age, ventricular mass is 5.2% of total mass of the leg muscles, and at 7 weeks of age, it is 5.5% of mass of the pectoral muscles. Thus, as might be expected, the output capacity of the heart is closely matched to the oxygen requirements of the dominant set of locomotory muscles.

The challenge for juvenile birds undertaking their first migration may lead to increased mortality compared with mature adults, even in species such as geese and storks where the adults "guide" the youngsters on their journey. Juvenile White Storks (*Ciconia ciconia*) flap their wings 23% more than adults, had higher initial values for DBA, and are estimated to consume 14% more energy during the Autumn migration (Rotics et al., 2016). These flight inefficiencies could be a proximate cause of extra mortality, with juvenile birds that separated from the flock being left behind and with no evidence that they could compensate for the increased cost of transport by increased amounts of resting or refueling. Similarly, failure to maintain body condition can be linked to increased mortality in migrants such as the Red Knot (*Calidris canutus rufa*), in which individuals with lower body condition arrived later to the breeding grounds and appeared to experience decreased breeding success and higher seasonal mortality (Duijins et al., 2017).

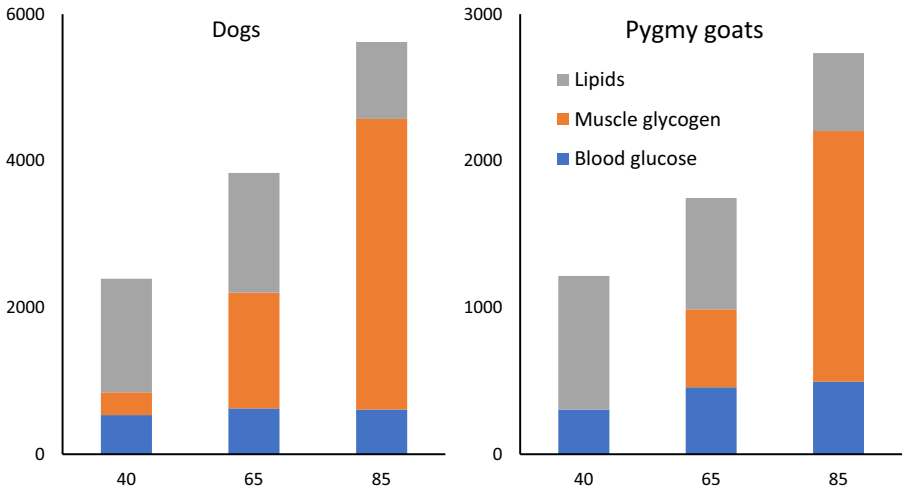

FIGURE 46.20 Substrate oxidation rates at different intensities of exercise in two species of mammals with different aerobic capacities. The large difference in the maximum rates of oxygen consumption of these two species is mainly the result of the larger rate at which glycogen is supplied from stores within the locomotor muscles themselves. *Redrawn from Weber et al. (1996), J. Exp. Biol. 199.*

46.6 Metabolic substrates for endurance flight

The use of fatty acids as the primary fuel during long-distance flights is an important adaptation, as the energy density of fat is much greater than that of other stored fuels. As pointed out earlier, the energy density of dry carbohydrate is 17.6 kJ/g; however, the storage of glycogen in cells involves between 3 and 5 g of water for each gram of glycogen, giving an effective energy density of approximately 4.4 kJ/g compared with that for lipids of 39.3 kJ/g (Schmidt-Nielsen, 1997). Protein may also be used to provide energy, but tissues such as muscle also consist of 70–80% water, so that the energy density of stored protein in vivo is around 5.4 kJ/g. Thus, during a long flight, the majority of energy is provided by fatty acids. However, fatty acid transport in the plasma (from the adipocytes to the working muscles or the liver) may be a rate-limiting step during intense exercise (Newsholme and Leech, 1983; Butler, 1991) as it is insoluble in water and is transported by a carrier protein, albumin. In fact, mammals do not increase the rate of fatty acid metabolism as the intensity of exercise increases. This is achieved predominantly by an increase in carbohydrate metabolism (see Figure 46.20), mainly by the utilization of glycogen stored in the muscles. The rate of fatty acid metabolism may actually decrease with increased intensity of exercise. However, as migrating birds use predominantly fatty acids as their energy source and as their rate of aerobic MR is at least twice that of running mammals of similar size, the rate at which migrating birds need to transport fatty acids may be up to 20 times greater than that of running mammals (Guglielmo, 2010, Figure 46.21).

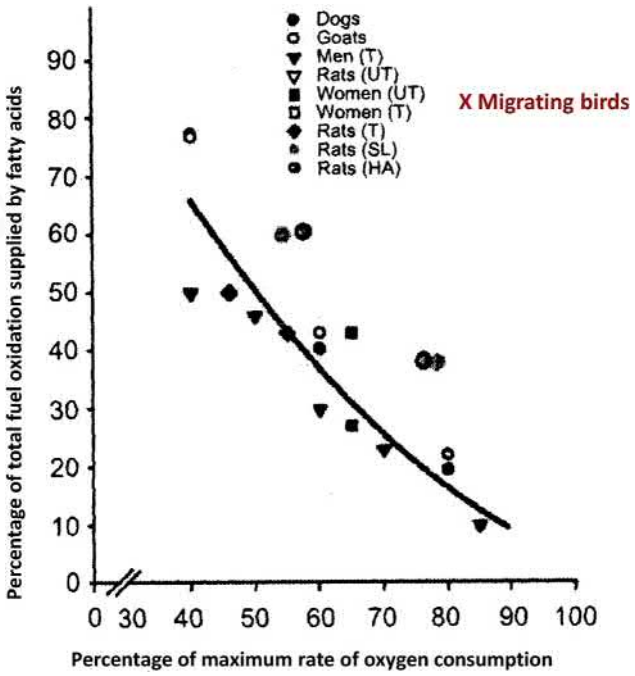

FIGURE 46.21 Percentage supply of fatty acid substrate to the muscles of mammals during increasing exercise intensity. X indicates an estimated value for migrating birds. *From McCLelland (2004).*

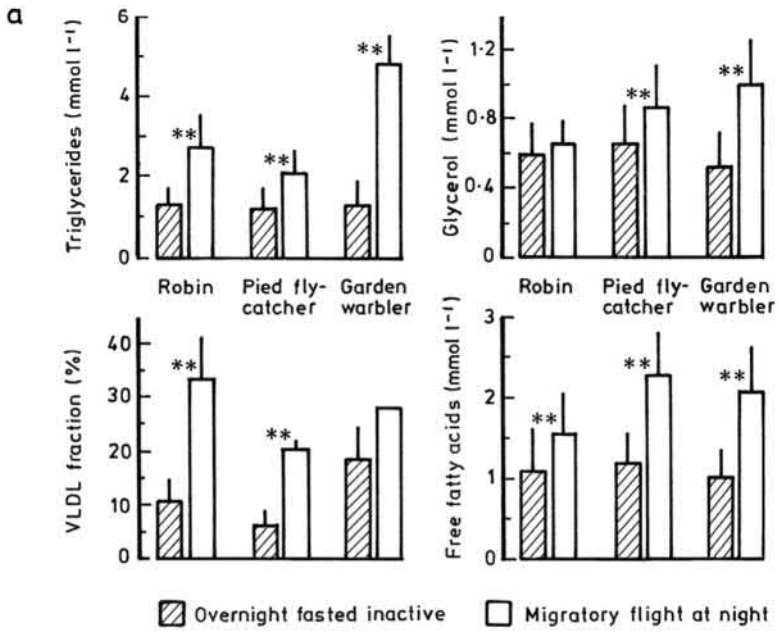
A mechanism has been proposed for how small birds could deliver the high rates of fatty acid required by the flight muscles without increasing the concentration of albumin in the blood. Jenni-Eiermann and Jenni (1992) measured various metabolite concentrations in the plasma of three species of small night-migrating passerines (Figure 46.22A), the robin (*Erithacus rubecula*), garden warbler (*Sylvia borin*), and pied flycatcher (*F. hypoleuca*).



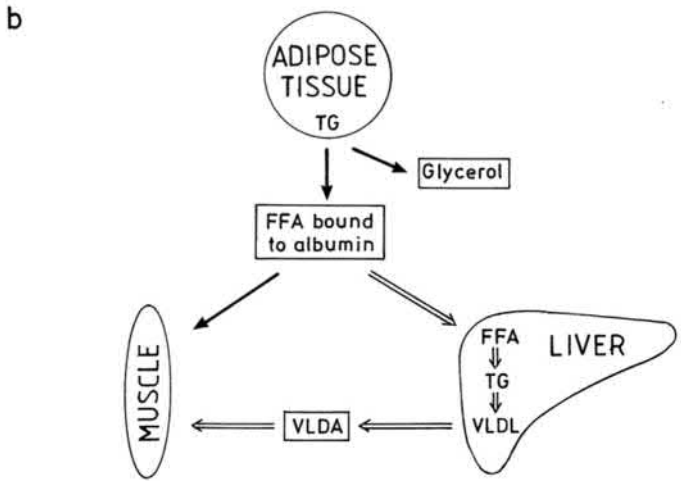


FIGURE 46.22 (A) Means SD of various fat metabolite concentrations and very low-density lipoproteins (VLDL) in the plasma of three species of birds during overnight fasting (crosshatched) or during night time migratory flights (clear). $^{**}P < .01$, Mann–Whitney *U*-test. (B) Diagram illustrating the proposed pathway for fatty acid transport to the flight muscles of small birds. FFA are released from the triglyceride (TG) stores of the adipose tissue and either taken up directly by the muscles or converted to TG by the liver and transported to the muscles as VLDL. The activity of the latter pathway (*double arrows*) is suggested to increase in small birds during flight. *Modified from Jenni-Eiermann and Jenni (1992).*

Their results indicated that during long-distance flights, plasma levels of triglyceride, glycerol, free fatty acids (FFAs), and very low-density lipoproteins (VLDLs) all increased significantly above values at rest.

The rise in triglycerides and VLDL was unexpected, but could provide a mechanism for increasing the FFA supply to the flight muscles. FFA can be reesterified to triglyceride in the liver and subsequently delivered to the blood as VLDL. Thus, the removal of FFA from the blood stream by the liver as well as by the flight muscles will increase the rate at which albumin is able to transport FFA from the adipocytes. Secondly, the VLDL can be hydrolyzed by lipoprotein lipase in the endothelium of the flight muscle capillaries, thus allowing the targeted uptake of the released FFA (Figure 46.22B). Apart from increasing the availability of FFA to the flight muscles, this mechanism has the additional advantage that the overall protein (albumin) concentration of the blood is kept relatively low and prevents unacceptable increase in colloid osmotic pressure. Also, since the proportion of fatty acids in VLDL is 60–70% (compared to only 3% in albumin), there would be a dramatic increase in the rate of fatty acid transport by the circulatory system of these birds. Wind tunnel experiments have failed to replicate the elevated triglycerides observed in field studies, and more investigation of this intriguing mechanism of fatty acid supply is needed (Guglielmo et al., 2017; Guglielmo, 2018).

Transport in the blood is not the only problem; FFAs also have to cross the plasma membrane of the muscle cells, move rapidly through the cytosol, and cross the outer and inner membranes of the mitochondria. Up until the early 1980s, it was thought that the uptake of long chain fatty acids into cells was by passive diffusion. However, evidence now suggests that the bulk of fatty acid transport is mediated by a variety of proteins both in the cell membrane and cytosol of cells. Figure 46.23 shows how the fatty acids are thought to cross the plasma membrane in mammals. Fatty acids cross the plasma membrane by passive diffusion and/or membrane-bound fatty acid binding ($FABP_{pm}$) and fatty acid translocase (FAT or CD36). Once in the cytosol, the fatty acids bind to cytosolic fatty acid binding proteins ($FABP_c$), and are converted to fatty acyl-CoA esters by acyl-CoA synthetase (ACS). They are then bound to acyl-CoA binding protein (ACBP) and translocated to sites of usage within the cell. Alternatively, fatty acid transport protein (FATP), which is also located in the plasma membrane, may transport the fatty acids into the cytosol, but, as FATP is linked to ACS, the fatty acids are immediately converted to fatty acyl-CoA esters and bound to ACBP. Recent evidence suggests that the membrane-bound transport proteins play the major role in fatty acid transport across the plasma membrane (Bonen et al., 2007; Schwenk et al., 2010). $FABP_c$ acts as a "sink" for fatty acids, thereby increasing their solubility in the cytosol, their rate of removal from the inner surface of the plasma membrane, and their rate of intracellular diffusion.

Figure 46.24 shows how the FFAs enter the mitochondria. Firstly, they are converted to their acyl carnitine esters by the enzyme carnitine acyl transferase-1 (CAT 1) which is present on the outer mitochondrial membrane. The acyl carnitine then crosses the inner mitochondrial membrane by the acyl carnitine/carnitine translocase system. Once inside the mitochondria, carnitine acyl transferase-2, which is located on the inner membrane, regenerates acyl-CoA and free carnitine. This transport process could be a major rate-limiting step in the use of fatty acids by active muscles, with either carnitine or CAT 1 being the important factors.

Studies on the flight muscles of birds indicate that they have greater concentrations of these fatty acid transporters than mammalian muscles. For example, the flight muscles of migratory western sandpipers (*Calidris mauri*) have approximately 10 times greater concentrations of $FABP_c$ than a typical mammalian muscle and approximately 14% of total cytosolic protein is $FABP_c$ in sandpipers. This is the highest value reported for any vertebrate skeletal muscle (Guglielmo et al., 1998). Also, the concentration of $FABP_c$ is 70% greater during the migratory period than during winter (Guglielmo et al., 2002). The presence of FAT/CD36 and $FABP_{pm}$ has been demonstrated in the flight muscle of white-throated sparrows (*Zonotrichia albicollis*) and the genes for these are strongly upregulated during the migratory season (McFarlan et al., 2009). These data

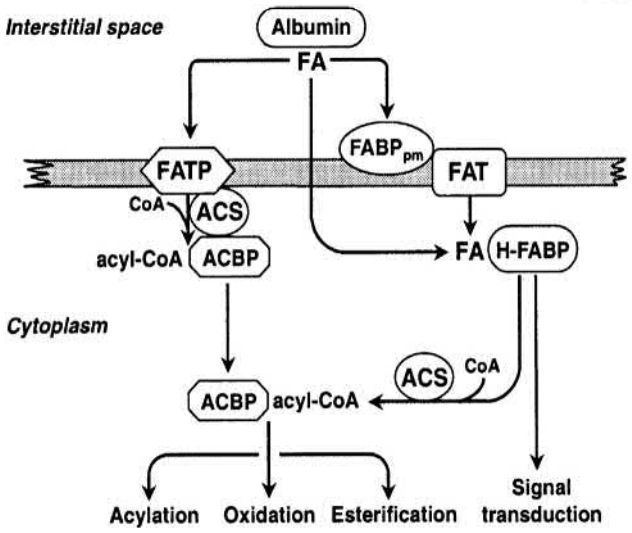

FIGURE 46.23 Long chain fatty acids (FAs) are transported in the plasma of mammals bound to albumin. Following their dissociation from the albumin, their movement across a cell membrane into the cytoplasm is either (i) by passive diffusion, or by membrane-bound fatty acid binding proteins (FABPpm) and fatty acid translocase (FAT/CD36), or by a combination of the two; (ii) by fatty acid transport protein (FATP), which is also located in the plasma membrane. Once inside the cytoplasm, the fatty acids are converted to fatty acyl-CoA esters by acyl-CoA synthetase (ACS), either via binding to a binding protein called heart-type fatty acid binding protein (H-FABP), or directly. Finally, they bind to acyl-CoA binding protein (ACBP). *From Glatz et al. (2003).*

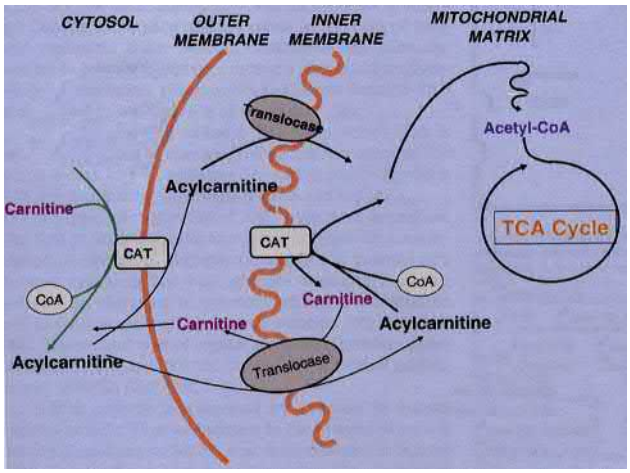

FIGURE 46.24 Transport of long-chain fatty acids (FA) into mitochondria of mammals. Acyl-CoA esters are unable to cross the inner membrane of the mitochondria so they are firstly converted to their acyl-carnitine esters by carnitine acyl transferase-1 (CAT 1) which is present on the outer membrane. Acylcarnitine crosses the inner membrane via the translocase system and, once inside the mitochondrion, acyl-CoA and free carnitine are reformed by CAT 2, which is located on the inner membrane. *From Kiens (2006).*

indicate that at least three of the muscle FATPs are important in the transport of fatty acids during bird migration.

There has been much attention on the possible significance of a number of polyunsaturated fatty acids (PUFAs) in the diet of migratory birds as natural doping agents (Maillet and Weber, 2007; Weber, 2009), although the evidence for PUFAs having an influence on flight performance is somewhat inconclusive (Guglielmo, 2018). Proposed mechanisms for the benefit of PUFAs for flight include the fuel hypothesis, the phospholipid hypothesis, and the signaling hypothesis (Weber, 2009; Price, 2010; Guglielmo, 2018). The fuel hypothesis is based on the fact that for the same carbon chain length unsaturated fatty acids are more soluble, leading them to be preferentially mobilized from adipocytes and used by key muscle enzymes involved in fatty acid oxidation. The phospholipid hypothesis proposes that greater PUFA abundance in membranes of cells and mitochondria enhances their function and increases performance of the whole organism. The signaling hypothesis is based on the fact that PUFAs are ligands for peroxisome proliferator–activated receptors (PPARs) which regulate a variety of lipid metabolism pathways, and thus may improve fatty acid oxidation capacity. European starlings (*Sturnus vulgaris*) expended 11% less energy in 6 hour flights when fed a diet high in 18:2n-6 compared to a diet high in 18:1 monounsaturated fatty acids (McWilliams et al., 2020). Other experimental studies of migratory yellow-rumped warblers (*Setophaga coronata*) found no benefits of high PUFA diets on endurance performance, muscle fatty acid oxidation capacity, or muscle oxidative damage (Dick and Guglielmo, 2019a,b). However, PPARs, fatty acid transporters, and oxidative enzymes of cultured myocytes from a shorebird (sanderling, *Calidris alba*) responded differently to PUFA supplementation than myocytes from yellow-rumped warblers, and PUFAs positively affected mitochondrial metabolism of the sanderling myocytes (Young et al., 2020). It has been hypothesized that marine-associated birds that eat diets high in long-chain PUFAs may rely more on dietary inputs of PUFAs (Guglielmo, 2018). Experimental testing of natural doping on muscle fatty acid oxidation capacity and endurance flight performance in these species would be informative.

Although protein stores are less energy dense than fat stores (see above), it may not be possible entirely to exclude their use during prolonged periods of flight without feeding. The brain and other nervous tissues are extremely dependent on glucose metabolism for the provision of energy (Newsholme and Leech, 1983). As carbohydrate stores are very limited in most animals, during starvation, the major source of glucose is via protein (amino acid) degradation to various metabolic intermediates (called oxoacids), most of which can then enter the gluconeogenesis pathway in the liver. In addition, glycerol that is produced following the hydrolysis of triglycerides can also be converted to glucose. A small number of amino acids (leucine and lysine) are degraded directly to acetyl-CoA and so can contribute to ATP synthesis via the citric acid cycle (CAC) or be converted to fat, as acetyl-CoA cannot enter the gluconeogenesis pathway. Alternatively, excess amino acid production can provide intermediates (e.g., 2-oxaloglutarate, succinyl-CoA, fumarate, and oxaloacetate) for the CAC if these should be in short supply or be converted to pyruvate and then to acetyl-CoA either to contribute to ATP synthesis or to be converted to fat. Certainly, there are a number of studies which show that protein, in the form of muscle and the intestinal tract, is catabolized during long periods of flight (Jehl, 1997) or during "simulated" flights by starvation (Biebach, 1998).

Protein catabolism during migratory flight may not always be for the reasons discussed above. When catabolized, proteins produce more water per unit of energy released (0.155 g H_2O/kJ) than fats (0.029 g H_2O/kJ). Gerson and Guglielmo (2011b) have demonstrated that when flying for durations up to 5 h in conditions of low relative humidity (13%), Swainson's thrushes (*Catharus ustulatus*) have a lean mass (protein) loss of 3.55 ± 0.91 mg/min, whereas when flying in high relative humidity (80%) air, there was no relationship between lean mass loss and flight duration. The greater rate of loss of lean mass when flying in relatively dry conditions led to a $21.7 \pm 4.9\%$ increase in endogenous water production. These data demonstrate that when flying in dry conditions, the rate of water loss induces greater metabolic water production by increasing protein catabolism. However, for those species that do not complete their migration in one nonstop flight, relatively high rates of reductions in flight muscle and the digestive system may result in reduced ability to fly and to process food after arrival at a stopover.

46.7 The cardiovascular system

A major role of the cardiovascular system is to deliver metabolic substrates and oxygen to the tissues undergoing aerobic metabolism and to remove the waste products of that metabolism. Thus, the cardiovascular system in general, and the heart in particular, must be capable of meeting the demands of the flight muscles during sustained, flapping flight. Such aerial ability has only arisen four times during the evolution of multicellular life, including the insects, Pterosaurs, birds, and bats. Dudley (1998) discussed the importance of significant historic variations in the oxygen concentration of the atmosphere of the Earth over the past 600 million years to the evolution of animal flight. During the late Carboniferous and early Permian periods, oxygen levels in the air peaked at 35%, compared to only

20.9% today. As the amount of oxygen is additional to the constant amount of nitrogen, the atmosphere also became denser, thus, making it easier to generate aerodynamic force as well as obtain oxygen for respiration. These two changes clearly stimulated a period of gigantism among flying insects of that time and may have more generally encouraged the evolution of flying invertebrates. While the first feathered dinosaurs did not evolve within a raised oxygen environment compared to the present, the majority of avian dinosaurs and early birds diversified under hyperoxic conditions, while one of the largest birds to ever fly (*Pelagornis sandersi*) with a wingspan of over 6 m (Ksepka, 2014), lived 25 million years ago when oxygen levels were around 25%.

46.7.1 The cardiac muscles

In general, birds have larger hearts and lower resting heart rates than those of mammals of similar M_b (Lasiewski and Calder, 1971; Grubb, 1983). The increased cardiac mass and, therefore, larger V_b in birds is an important factor in attaining a higher maximum $\dot{V}_{O_2}$ ($\dot{V}_{O_2,max}$) during flight than similar-sized mammals do when running. Bats have larger hearts and a higher blood oxygen–carrying capacity than other mammals of similar size (Jurgens et al., 1981), and their $\dot{V}_{O_2}$ during flight is similar to that of birds of similar mass (Butler, 1991). Among birds, those that are not capable of sustained flight, such as Galliformes, tend also to have slightly lower red blood cell concentration or hematocrit (Hct, packed cell volume) and/or hemoglobin concentration ([Hb]) than good fliers (Balasch et al., 1973), and weaker fliers have a slightly lower Hct than stronger fliers (Carpenter, 1975). Studies of exercising animals have indicated that both the locomotor and cardiac musculature, along with associated variables such as Hct, are dynamic structures that can vary in mass seasonally and/or in direct response to demand. When additional energetic "costs" occur seasonally (e.g., due to migratory fattening or the development of secondary sexual characteristics), then the relevant cardiac and locomotor musculature tend also be regulated seasonally (Hickson et al., 1983; Marsh, 1984; Driedzic et al., 1993). For example, Bishop et al. (1996) showed that both cardiac and pectoralis muscles hypertrophy during the premigratory fattening period of the barnacle goose.

Bishop and Butler (1995) suggest that M_h can be used to model the availability of oxygen to the flight muscles of birds. Assuming that the adaptations of the flight muscles are appropriately matched to the cardiovascular system, then the relative M_h of birds of a similar M_b should be a good indicator of the relative aerobic Pi available to the flight muscles. Subsequently, Bishop (1997) calculated that the $\dot{V}_{O_2,max}$ of birds should scale with respect to M_b as 230 $M_b^{0.82}$ (mL/min), while the maximum aerobic power input (aerobic $P_{i,max}$) with respect to M_h should scale as 11 $M_h^{0.88}$ (W). Thus, for studies of the prolonged aerobic flight performance of birds, the estimates of $\dot{V}_{O_2,max}$ or $P_{i,max}$ based on relative M_h should be of more practical value than the use of general scaling equations based on M_b alone.

A detailed phylogenetic analysis of differences in M_h for 915 avian species (Nespolo et al., 2018) showed that relative heart size was consistently associated with four categories of flight capability across the evolutionary spectrum for birds: short or no flight, hovering, flapping flight, gliding, and soaring (Figure 46.25). They argue that their analysis confirms that heart size has a strong constraint on flight capacity and is ultimately the result of evolutionary selection. In particular, they suggest that hovering specialists, such as Trochilidae, exhibit strong selection pressure for large hearts; that the transition of birds from ancestral short flights to prolonged flapping flight positively promoted heart size increases; and that species secondarily evolving as specialist gliders and soaring birds did not necessarily lead to a significant reduction in M_h. The latter, presumably because these species would still have to rely on flapping flight during periods of time when environmental conditions did not promote nonflapping flight modes. The mean values for M_h from selected avian families are plotted in Figure 46.26A (data from Hartman, 1961) and Figure 46.26B (data from Magnan, 1922) and indicate the interfamily adaptive diversity in aerobic capacity. The very small M_h of all three species of the ground

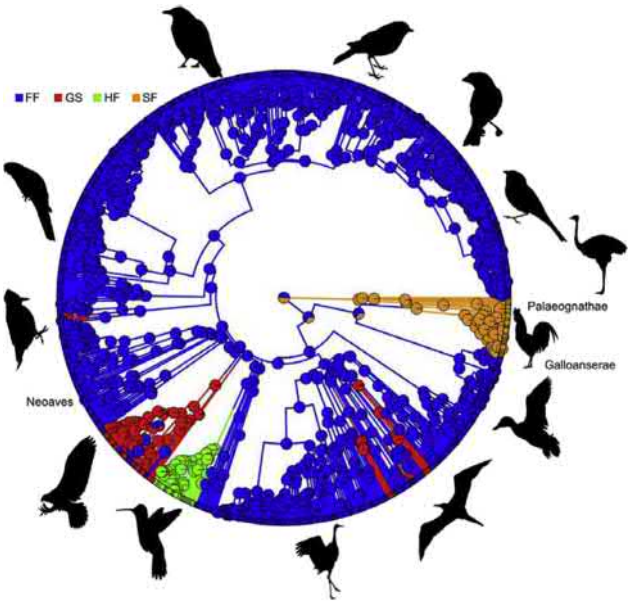

FIGURE 46.25 A summary of the flight mode classification of birds is depicted as a stochastic character map. Each circle at each node represents the most likely flight mode of the common ancestor. They estimate that the common ancestor of all birds had a ¾ probability of having been a short flyer. *FF*, flapping flight; *GS*, gliding and soaring; *HF*, hovering flight; and *SF*, short flight. *From Nespolo et al. (2018).*

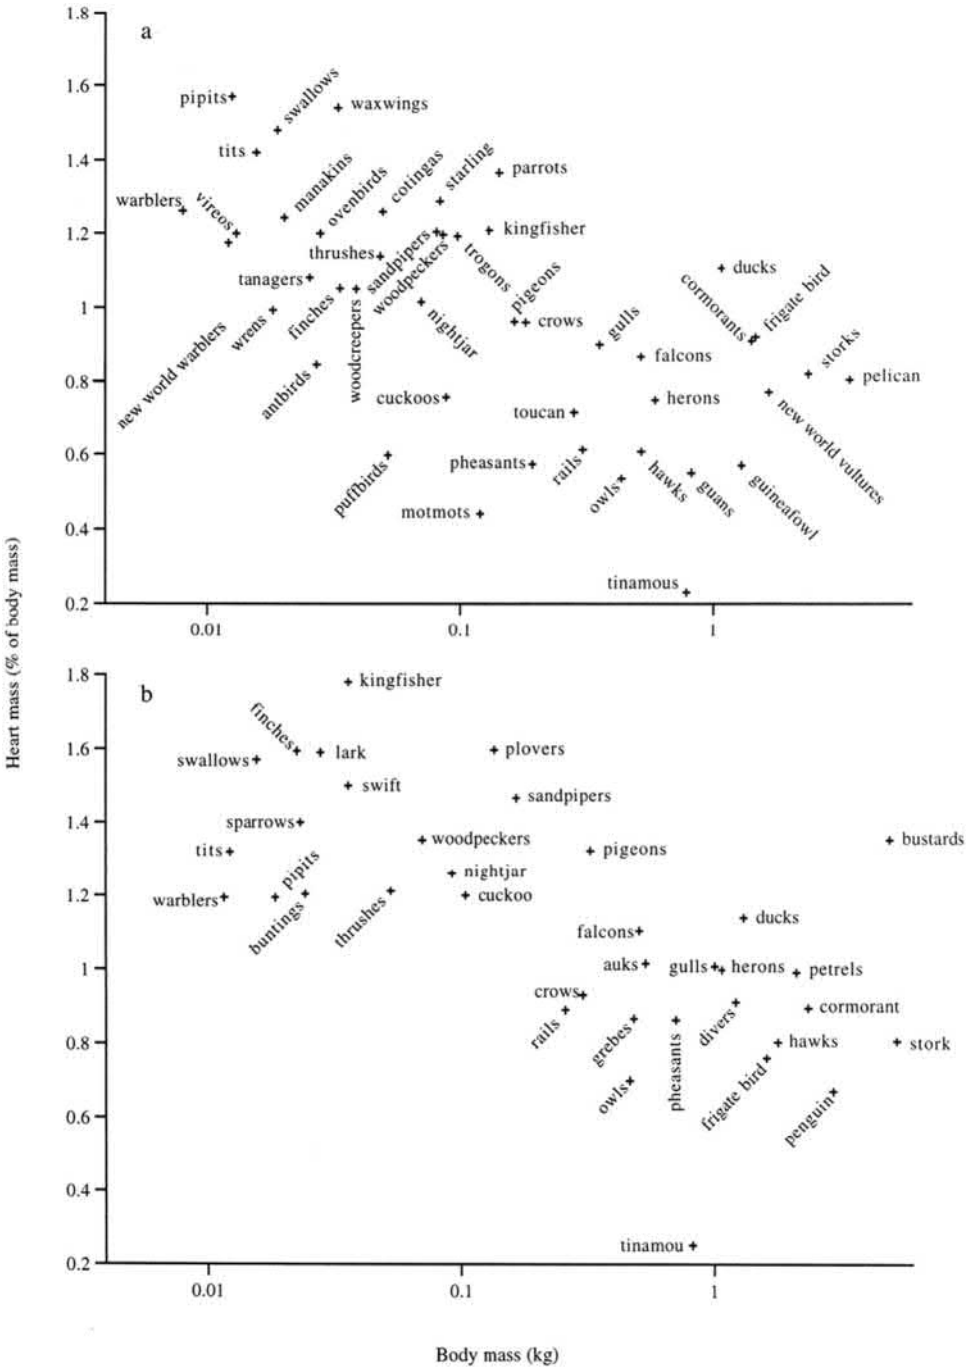

FIGURE 46.26 Mean values for cardiac muscle mass as a percentage of body mass (%), plotted against body mass (kg) for different families of birds. *(A) Data from Hartman (1961) and (B) data from Magnan (1922).*

dwelling South American Tinamidae indicate that the members of this family have the lowest aerobic ability of all bird species. As mentioned above, transitioning from weak to sustained flapping flight would have required the coevolution of a larger M_h, which is discussed by Altimiras et al. (2017) in their study of the aerobic and thermoregulatory performance of two species of Tinamou. Other relatively sedentary forest birds with small M_h include the guans, motmots, puffbirds, and antbirds. This contrasts with the relatively large M_h of other bird families that live predominantly in forest, such as the parrots, trogons, kingfishers, and hummingbirds. Interestingly, Figure 46.26B shows that the M_h values of the bustard family (Otidae), which consists of many partial migrant species (Villers et al., 2010; Kessler et al., 2013), range above the general allometric trend. The relative M_h values

of the 0.83 kg Little Bustard and the 8.95 kg Great Bustard are 1.8 and 1.4%, respectively. These relative M_h values are even larger than those of the mainly migrant species of Anatidae, which typically range from 0.8 to 1.1%. Two other observations appear to substantiate this finding for the Otidae as a group. Crile and Quiring (1940) gave the following values for the relative M_h of the sedentary and mostly terrestrial African Kori bustard: a 5.54 kg female Kori bustard (1.1%) and a 10 kg male Kori bustard (1.0%). In addition, Stickland (1977) shows that while 82% of the area between the pectoralis muscle of the white-bellied bustard is made up of "red" aerobic fibers (i.e., FOG fibers), 100% of the area of the pectoralis muscle of the similarly sized African helmeted guineafowl is made up of "white" anaerobic muscle fibers (i.e., FG fibers).

There are also some other rather interesting intrafamily differences in aerobic capacity indicated in the M_h data of Hartman (1961) and Magnan (1922). The different genera of the Columbidae (pigeons and doves) have relative M_h means ranging from 1.29 to 0.57%, while among the genera of the Falconidae (falcons), these range from 1.14 to 0.6%. In both these families, the genera with the comparatively smaller hearts occur predominantly in tropical forests and are likely to be relatively sedentary. As intrafamily pectoralis muscle mass is fairly constant in these examples, it is reasonable to assume that the relatively sedentary species are more dependent on anaerobic metabolism to support their flight activity, particularly during take-off, and that their flight muscles consist of a relatively greater proportion of FG fiber types. Thus, their flight over short distances is likely to be even more powerful than that for species of Falcons and Pigeons that are specialized for longer distances.

46.7.2 Cardiovascular adjustments during flight

The pigeon (*C. livia*) is the only species in which all but one of the variables of Fick equation (see above) have been determined during flight (Butler et al., 1977; Peters et al., 2005). In the study of Butler et al. (1977), $\dot{V}_{O_2}$ in the pigeons was 10 times the resting value (Table 46.3) when flying in a wind tunnel at 10 m/s. The respiratory system maintained CaO_2 at slightly below the resting value, but $C_{\bar{v}}O_2$ was halved, giving a 1.8-fold increase in $\left(C_aO_2 - C_{\bar{v}}O_2\right)$. There was no significant change in V_S, so the major factor in transporting the extra oxygen to the muscles was the sixfold increase in f_H. Not all of these variables were measured simultaneously on the same birds, which might introduce a small level of uncertainty in the exact relationship between variables. Similarly, measurement of $\left(C_aO_2 - C_{\bar{v}}O_2\right)$ involves cannulation of the blood vessels, which is highly invasive, and could have an effect on cardiovascular responses. Interestingly, as mean arterial blood pressure did not change, total peripheral resistance must have declined by the same proportion as cardiac output (V_b, which is $f_H \times V_S$) increased.

Many more detailed studies on cardiovascular adjustments to exercise have been conducted on mammals than birds. Early research culminated in the hypothesis of symmorphosis, in which it was postulated that all parts of a linked chain of structural variables, should have similar maximum functional capacities (Weibel et al., 1991). In particular, they studied the cardiovascular system, with its role to acquire oxygen from the atmosphere and transport it to the mitochondria of the muscles and nervous tissue. In this regard, it might be expected that the rate of change in oxygen delivery, via the blood to the muscle capillaries,

TABLE 46.3 Mean values of oxygen uptake and cardiovascular variables measured in the pigeon *columba livia* and *emu dromaius novaehollandiae*[1].

	Pigeon	(0.442kg)	Emu	(37.5kg)
	Rest	Flying	Rest	Running
Oxygen uptake (mL/min STPD)[2]	9.0	88.4	156.7	1807
Heart rate (beats/min)	115	670	45.8	180
Cardiac stroke volume (mL)	1.44 (1.14)	1.58	57	102.7
Oxygen content of arterial blood (vol%)	15.1	13.7	15.2	15.2
Oxygen content of mixed venous blood (vol%)	10.5	5.4	9.0	4.6

[1]*Measurements taken at rest and after 6min of steady level flight in a wind tunnel at a speed of 10m/s for the Pigeon and after 20min running on a treadmill at a 6-degree incline and a speed of 1.33m/s for the Emu (from Butler, 1991). Value for cardiac stroke volume in parentheses is recalculated from Butler et al. (1977), as discussed by Bishop and Butler (1995).*
[2]*STPD, Standard temperature and pressure, dry.*

should be matched by the rate of change in oxygen uptake to the cells. Thus, if stroke volume does not change very much between exercise levels, it would be hypothesized that oxygen extraction should match increases in heart rate or cardiac output. Therefore, oxygen consumption should be proportional to f_H^2. While this relationship is generally supported in an interspecies comparison of birds and mammals covering a wide size range (Bishop and Spivey, 2013), results from within-species studies vary considerably and may be subject to a number of experimental influences and confounding variables. Nevertheless, the average exponent for 24 species was close to 2 (Bishop and Spivey, 2013). Maintenance of blood pressure within tight limits between rest and exercise is a general feature seen among vertebrate groups, and supports the hypothesis that there must be a functional link between blood flow delivery, peripheral vasodilation, and an increase in rates of oxygen extraction (Joyce et al., 2019; Wang et al., 2019).

46.8 The respiratory system

The respiratory system is primarily concerned with gas exchange (i.e., the supply of oxygen to and the removal of carbon dioxide from the circulatory system and the metabolizing tissues), but it is also important for the regulation of evaporative water loss and the control of T_b. The issue of T_b regulation, in particular, has received much recent attention in association with the Heat Dissipation Limitation model (reviewed by Speakman and Król, 2010).

46.8.1 Ventilatory adjustments during flight and ventilatory/locomotor coupling

As for the cardiovascular system, there is a variation of Fick's formula for convection that describes the relationship between $\dot{V}_{O_2}$ and the various components of the respiratory system:

$$\dot{V}_{O_2} = f_{resp} \times V_T \times (C_IO_2 - C_EO_2),$$

where f_{resp} is respiratory frequency (breaths/min), V_T is respiratory tidal volume (mL), and ($C_IO_2 - C_EO_2$) is the difference in the oxygen content in the inspired and expired gas (milliliter of O_2 per mL of gas). Data on ventilation are given in Table 46.4 for five species of birds at rest and during forward flapping flight in a wind tunnel. At relatively low ambient temperatures (<23°C), minute ventilation volume $\dot{V}_I$ ($= f_{resp} \times V_T$) increases by a similar proportion as $\dot{V}_{O_2}$ and the proportion of oxygen extracted from the inspired gas ($O_{2,ext}$ effectively equal to $C_IO_2 - C_EO_2/C_IO_2$) during flight is similar to that in resting birds. The relative contributions of f_{resp} and V_T to the increase in V_I during flight vary between species. In White-necked Ravens (*Corvus cryptoleucus*), V_T does not change at all, whereas in the Fish Crow (*Corvus ossifragus*) and black-billed magpies, it doubles, and in starlings there is a fourfold increase. Thus, in the first three species, f_{resp} makes the greater contribution, but in the fourth, volume predominates. Respiratory frequency and V_T in the fish crow (Bernstein, 1976) and f_{resp} in the barnacle goose (Butler and Woakes, 1980) are independent of flight speed. This could mean that, like the starling and the fish crow, $\dot{V}_{O_2}$ of the barnacle goose is also largely independent of flight speed. However, in the budgerigar, both $\dot{V}_{O_2}$ and f_{resp} change with speed in a U-shaped fashion (Tucker, 1968b).

Despite the apparent matching between the increases in V_I and $\dot{V}_{O_2}$ during flight, in the four species listed in Table 46.4, there does appear to be an increase in effective lung ventilation above that required by MR (hyperventilation) during flight in starlings, as indicated by a decrease in the partial pressure of CO_2 (PCO_2, hypocapnia) in the anterior and posterior air sacs (Torre Bueno, 1978a). It can also be seen from Table 46.4 that $O_{2,ext}$ for the hovering hummingbird, *C. coruscans*, is similar to those of the four birds during forward flapping flight, whereas that for *Amazilia fimbriata fluviatilis* it is 50% or less. In mammals, in their investigation of how well the structural design of the respiratory and cardiovascular cascade fitted with the concept of symmorphosis, Weibel et al. (1991) concluded that while most structural variables had similar functional maxima, lung capacity appeared not to be rate limiting within the cascade. This may be similar for birds and, at least during submaximal performance, it may be possible to trade-off small changes in V_T against apposing changes in f_{resp} function. Similarly, we may expect f_H to be able to compensate for changes in cardiac stroke volume to some degree, or f_w to be able to adjust for variation in wing stroke amplitude. Of course, respiratory design and function is not limited solely to the transport of oxygen, but it is important for the removal of carbon dioxide and the rate of transfer of heat and water loss with the atmosphere.

Ever since Marey's (1890) pioneering studies on bird flight, it has been known that f_{resp} may be coordinated with the beating of the wings. Marey himself suggested that the flapping of the wings during flight might have some impact on the air sacs. In crows (*C. brachyrhynchos*) and pigeons, there is a 1:1 correspondence between f_{resp} and the frequency of wingbeating (f_{wb}), whereas ratios as high as 5:1 (f_{wb}:f_{resp}) have been reported for the black duck *Anas rubripes,* quail *C. coturnix,* and ring-necked pheasant *Phasianus colchicus* (Hart and Roy, 1966; Berger et al., 1970). However, the

flights reported by these authors were of only a few seconds duration and it was concluded that coordination was not obligatory. During flights of up to 10-min duration, pigeons in a wind tunnel showed a very close relationship between these two activities. Wingbeats occurred in bursts and, although f_{resp} was often either slower or faster than the f_{wb} between bursts of wingbeating, there was always close coordination between the two when the wings were flapping (Figure 46.27A). Almost immediately upon landing, the pigeons panted at a frequency identical to the mean resonant frequency of the respiratory system (i.e., 10 Hz, Kampe and Crawford, 1973). During flapping flight, however, f_{resp} was slower, at approximately 7 Hz (i.e., the same as f_{wb}).

Studies with decerebrate Canada geese (Funk et al., 1992a,b) indicate that, in the absence of peripheral feedback from the flapping wings, there is predominantly a 1:1 ratio between f_{resp} and f_{wb} and that peripheral feedback is required to create the patterns of coordination seen in free-flying birds. With a 1:1 correspondence, it is possible to imagine how contractions of the flight muscles could assist respiratory air flow, but with higher ratios, this is not always so obvious. Nevertheless, a correspondence of 3:1 has been found in starlings Banzett et al. (1992) and in free-flying barnacle (1.6 kg) and Canada (3.8 kg) geese (Butler and Woakes, 1980; Funk et al., 1993), and it is clear that the wingbeat is tightly locked to fixed phases of the respiratory cycle during flights of relatively long duration (Figure 46.27B). As Tucker (1968b) comments, "It is hard to believe that the contractions of the flight muscles have no influence in ventilation…," more recent studies have attempted to investigate this intriguing possibility.

Jenkins et al. (1988) took high-speed X-ray cine films of starlings flying in a wind tunnel and suggested that the lateral movement of the furcula during the downstroke of the wing and the recoil during the upstroke may facilitate inflation and deflation, respectively, of the clavicular air sac. They also found that the sternum is moved in an expiratory direction during the downstroke and in an inspiratory direction during the upstroke. As the action of the sternum will influence the more posterior air sacs, these authors proposed that the combined action of the movements of the furcula and of the sternum, which are caused by the beating wings, is to produce a secondary respiratory cycling mechanism between the air sacs and the lungs that performs independently of (the slower) inhalation and exhalation.

Boggs et al. (1997a,b) recorded pressures and simultaneous cine radiographic images of the anterior and posterior air sacs, airflow in the trachea, and EMGs of the pectoral muscles in black-billed magpies during short (10–20s) flights in a wind tunnel (Figure 46.28A). Although they found similar patterns of movements of the furcula and sternum in the magpie during flight as Jenkins et al. (1988) described for the starling, they did not find

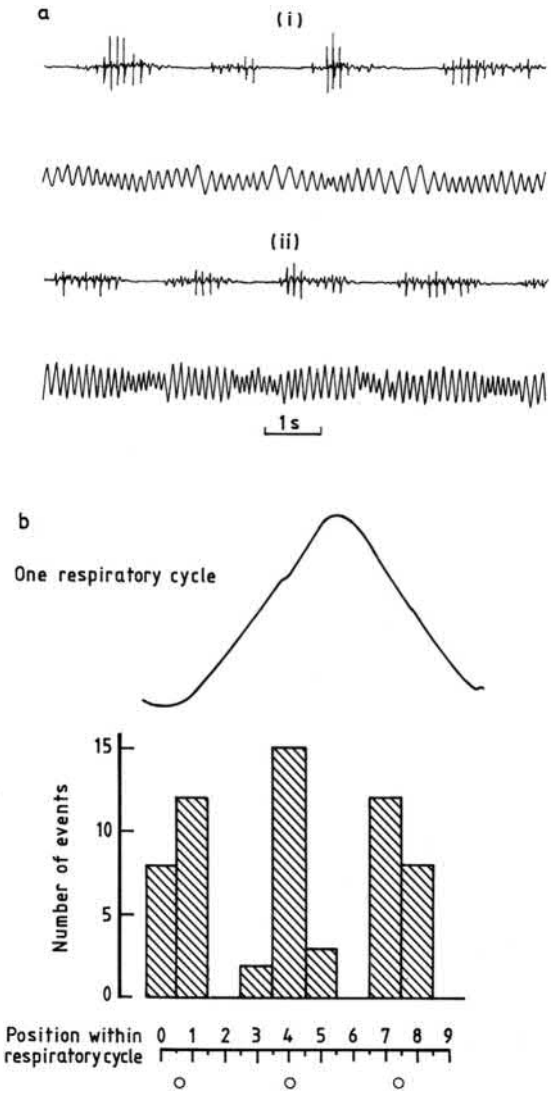

FIGURE 46.27 (A) Traces from a pigeon, *Columba livia* (0.45 kg), flying at a speed of 10 m/s in a wind tunnel, showing changes in respiratory frequency associated with periods of wingbeating and with periods of gliding (i) at the beginning of a flight (1 min after take-off) when respiratory frequency decreased during the gliding period and (ii) later in the flight (6 min after take-off) when respiratory frequency increased during the gliding period. In each series, the traces from top to bottom are electromyogram from the pectoralis muscle and respiratory movements (up to trace, inspiration). (B) Histogram showing the positions during the respiratory cycle at which the wings were fully elevated (called "events") during the flight of a barnacle goose, *Branta leucopsis,* trained to fly behind a truck. Data are from 20 respiratory cycles, which were divided into 10 equal parts. Below the histogram is plotted the mean position of each group of events (○). Above the histogram is a trace of one of *f*resp the respiratory cycles (inspiration, up). *(A) From Butler et al. (1977). (B) From Butler and Woakes (1980).*

that the pressure changes in the anterior and posterior air sacs are consistent with the internal, secondary cycling between the air sacs and the lungs, as postulated by Jenkins et al. (1988). However, the downstrokes and

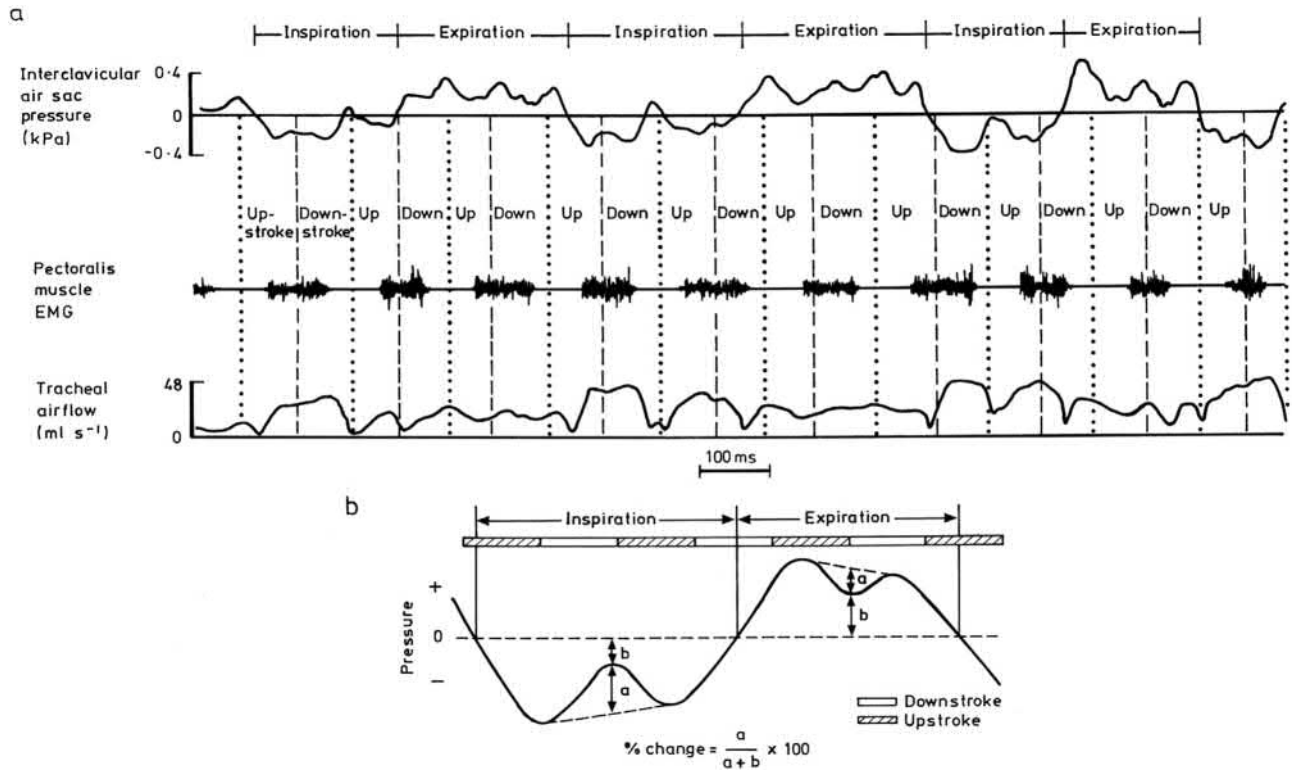

FIGURE 46.28 (A) The relationships between interclavicular air sac pressure, tracheal airflow, and electromyogram (EMG) of a pectoral muscle during flight of a black-billed magpie, *Pica pica,* in a wind tunnel. As the flow signal is not directional, inspiration is taken as that period during which pressure is subatmospheric (below 0) and expiration is that period during which pressure is above atmospheric (above 0). The EMG of the pectoral muscle indicates the upstrokes and downstrokes of the wings. When a downstroke occurs during inspiration, the subatmospheric pressure is driven up toward or above zero and when upstroke occurs during expiration, the supraatmospheric pressure is reduced toward zero. (B) Diagram to indicate how the average changes in air sac pressure shown in (A) were quantified in terms of the percentage change in pressure caused during inspiration or expiration by downstroke or upstroke of the wings, respectively. *(A) from Boggs (1997); with permission. (B) From Boggs et al. (1997a).*

upstrokes of the wings do have compressive and expansive effects, respectively, on the thoracoabdominal cavity, most probably by way of inertial mechanisms. It was only possible to quantify the effect of these influences when the movements of the wings were opposing the action of the respiratory muscles (Figure 46.28B). Thus, the average change in air sac pressure caused when a downstroke occurred during inspiration was 94%, whereas the average change caused by an upstroke occurring during expiration was 41%. The corresponding average changes in flow and volume were 75 and 23% and 35 and 11%, respectively. The conclusion is, therefore, that when the effects of the wings and the respiratory muscles are acting together (i.e., when downstroke occurs during expiration and upstroke during inspiration), ventilation of the lung is substantially enhanced. With the normal 3:1 ratio between f_{wb} and f_{resp}, the pattern of phasic coordination means that there are two upstrokes during inspiration (cf. Figure 46.27B) and two downstrokes during expiration, thus giving a net assistance to inspiration during the former and a net assistance to expiration during the latter. When they spontaneously switch to a 2:1 ratio, they shorten inspiratory time to ensure that upstroke occurs during most of inspiration and that downstroke corresponds with the transition to expiration (Boggs et al., 1997b).

46.8.2 Respiratory water loss

As indicated above, during flight, ventilation rates will naturally increase to meet the demand for additional gas exchange. Water vapor will inevitably be exhaled during respiration, so the higher ventilation rate may increase respiratory water loss. Ambient air temperature, in particular, may increase the risk of hyperthermia, thus further increasing ventilation frequency and rates of respiratory water loss (Carmi et al., 1992; Klaassen et al., 2020). Water may also be lost through excretion, at least during the early phases of flights (Giladi et al., 1997). Nevertheless, Carmi et al. (1993) demonstrated that when at rest or during flight, birds have an ability to maintain plasma volume, despite significant reductions in M_b which are largely the result of water loss. This is of obvious significance during flight, particularly during long-distance migratory flights, when a reduction in plasma volume would result in an increase in

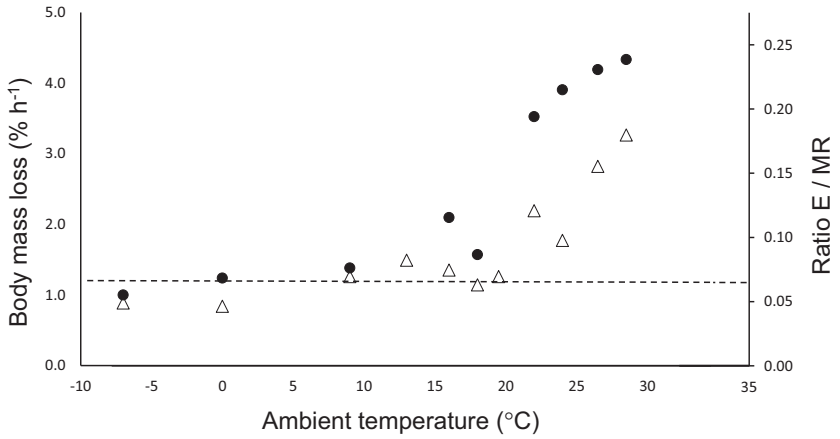

FIGURE 46.29 Data showing the rate of loss of body mass and the ratio of the rate of evaporative cooling to the metabolic rate (E/MR) as a function of ambient temperature in two starlings, *Sturnus vulgaris,* flying in a wind tunnel at between 9 and 14 m/s. *Redrawn from Torre-Bueno (1978b), J. Exp. Biol. 75.*

viscosity of the blood which, in turn, would increase the workload of the heart.

Experiments on birds in captivity and flying in wind tunnels indicate that during flapping flight at T_a above 18°C for the budgerigar and 15°C for the pigeon, water is lost at a greater rate than it is produced metabolically (i.e., the birds are dehydrating; Tucker, 1968b; Giladi and Pinshow, 1999). The starling is in apparent water balance only at T_a below 7°C (Figure 46.29; Torrre-Bueno, 1978b); however, because of the uncertainty regarding the rate of metabolic water production during flight, the author points out that the critical temperature may lie between 0 and 12°C. Only below a T_a of 0°C was the hovering hummingbird *Amazilia fimbriata* apparently in water balance (Berger and Hart, 1972).

Torre-Bueno (1978b) suggested that, during migrations, birds may ascend to altitudes where the air is cool enough to enable a greater proportion of heat to be dissipated by nonevaporative means, thus keeping them in water balance. However, while the air gets cooler with increasing altitude, it also gets less dense and will increase the *P*o required during flapping flight (Pennycuick, 2008; Carmi et al., 1992), thereby limiting the effect of the cooler atmosphere and/or resulting in an increasing ventilation rate. Despite the potential importance of water balance, there are few studies of dehydration in wild migrant birds. Landys et al. (2000) measured the hydration state of Bar-tailed Godwits (*Limosa lapponica*) in "arriving" and "early-refueling" migrants (individuals that had a chance to take a drink) in the Netherlands. The percentage body water (around 58%) was not significantly different between the two groups and suggested they were fully hydrated despite their long flights. Using the model of Klaassen et al. (1999), they determined that they would only be fully hydrated if they had an extremely low body drag coefficient (0.05, see Pennycuick et al., 1996a,b) and did not fly significantly above 3000m (Figure 46.30).

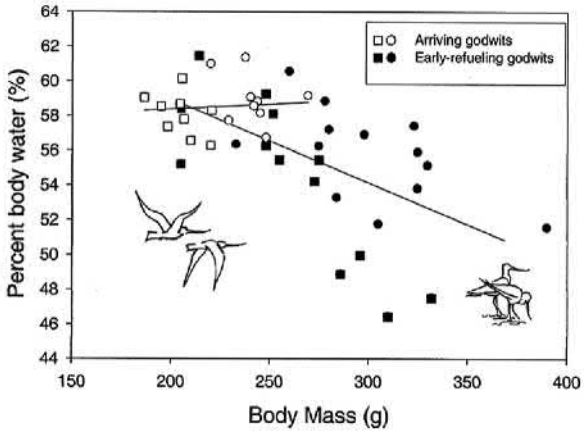

FIGURE 46.30 Percentage of body water plotted against body mass in migratory Bar-tailed Godwits, either on immediate arrival (open symbols) or early after refueling (filled symbols). Squares are males and circles are females. There is no evidence of dehydration for the arriving migrants. *Redrawn from Landys et al. (2000), The Condor 102.*

Many species do occasionally fly at quite high altitudes (Alerstam and Gudmundsson, 1999; Liechti and Schaller, 1999), but it is mostly considered that they do this to take advantage of favorable tailwind conditions. Due to the frictional drag effect of the Earth's surface, wind strength is almost always greater as altitude increases within the Troposphere. Thus, it may be worth climbing higher altitudes during tailwinds, to gain the added advantage of increasing ground speeds and, potentially, a lower overall cost of the journey (Pennycuick, 1978). In a similar study to that of the Bar-tailed Godwit, Senner et al. (2018) studied Black-tailed Godwits (*Limosa limosa*) migrating between the Netherlands and sub-Saharan West Africa. The mean average altitude for 24 migratory flights was 1385 m, with a mean maximum altitude of 3372 m, which is close to the predicted optimal height for maximum range in the Bar-tailed Godwit (Landys et al., 2000). While over 40% of flights recorded altitudes greater than 4000 m, within flight,

patterns were dynamic and the best correlates with a rapid gain in altitude were either high temperatures, or strong tailwinds, or both. Surprisingly, high ground temperature was the strongest predictor of high altitudes, indicating that it was the primary strategic factor. Air temperature at flight altitudes averaged 10.2°C, while average ground temperature was 18.8°C (with maxima above 40°C). Thus, at the highest ground temperatures, the birds may also be trying to avoid excessive T_b, rather than just respiratory water loss (see temperature control 8.3).

Smaller species of birds exhibit higher maximum climb rates while on migration (Hedenström and Alerstam, 1992) and should have a biomechanical and physiological advantage when climbing to higher flight altitudes (Bishop, 2005). However, Carmi et al. (1992) used program 1 from Pennycuick (1989) to calculate *P*i and concluded that smaller species might be better off staying below 1000 m, under low to moderate air temperatures, provided the birds have an effective countercurrent heat exchanger in their respiratory passages (Schmidt-Nielsen et al., 1970). These authors emphasize the importance of efficient $O_{2,ext}$ and the temperature of the exhaled air (T_{exp}) in water conservation during flight. The greater the $O_{2,ext}$, the lower the V_I for a given $\dot{V}_{O_2}$, which favors lower altitudes. The lower the T_{exp}, the less water will be lost in expired air, which favors higher altitudes, if it was not for the added flight costs. However, the best of both worlds might be for migrants to fly at lower altitude at night (when it is cooler) and to rest during the day, especially in warmer climates. Studies of the behavior of primarily nocturnal migrants in the desert areas of Israel indicate that only tailwind speed is closely related to the altitude at which the birds fly (Bruderer and Liechti, 1995), although the majority of flights were below 3500 m (Bruderer et al., 1995). The change to night time flight activity, from normal day time foraging, has been shown to be an abrupt shift on the night of the migration for European Blackbird, *Turdus merula* (Zúñiga et al., 2016).

46.8.3 Temperature control

Birds during flapping flight will produce a lot of heat and coupled with the excellent insulative properties of their feathers; this may make them susceptible to rising T_b during locomotion. If the rate of heat generated exceeds the rate of heat loss for a significant period of time, then T_b will rise and could, in theory, reach critical values under adverse condition. Eider ducks (*Somateria mollissima*) are relatively large seabirds with good insulation and a high cost of flight. Studies show that even during migration they only fly for around 15% of the day (Guillemette et al., 2016) and that they stop regularly during this period. They perform 14 flights per day, with an average duration of only 15.7 min and a rate of T_b increase of 4°C per hour. Higher values of heat storage index (up to 12°C/h) were associated with shorter maximum flight durations, as were higher absolute T_b (overall maximum T_b or 42.6°C). Birds spent 36% of their day cooling down while resting on the water (Guillemette et al., 2017), which is a significant investment of time and was not related to feeding behavior. The authors conclude that hyperthermia in Eiders is the predominant factor determining their short migratory flight durations and their stop-and-go strategy.

The tendency toward hyperthermia will be exacerbated by higher T_a and, as discussion in Section 46.8.2, may stimulate evaporative heat loss via the respiratory system. Thus, the hyperventilation that occurs in starlings during forward flapping flight (Torre Bueno, 1978a) is not simply due to the associated increase in the $\dot{V}_{O_2}$, but could also be the result of the typical small increase in T_b above the resting value that occurs in many birds. However, at relatively low T_a (<23°C), T_b does not tend to change with varying T_a at constant speed in Starlings, White-necked Ravens, and Pigeons flying in a wind tunnel (Torre-Bueno, 1976; Hudson and Bernstein, 1981; Hirth et al., 1987). Above a T_a of 23°C, T_b does increase with increasing T_a in the same three species. In the raven, V_I

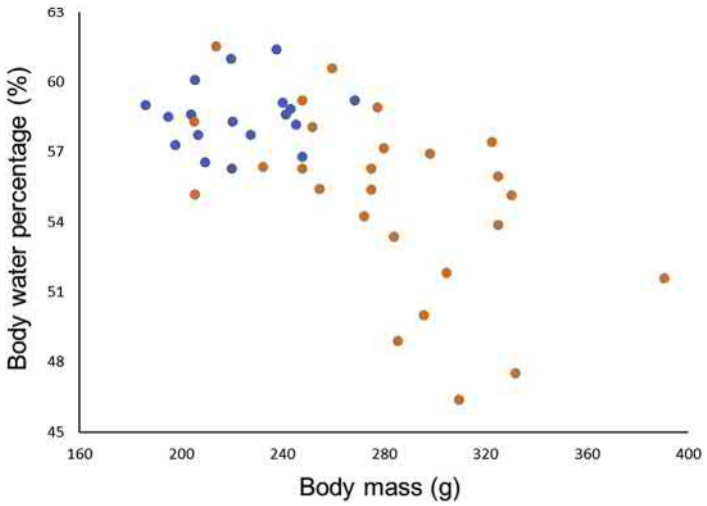

FIGURE 46.31 The relationship between ambient temperature and steady-state oxygen extraction of fish crows, Corvus ossifragus, while at rest and while flying in a wind tunnel. *From Berstein (1976).*

increases with increasing T_b so that, in this species and in the Fish Crow flying at constant speed, V_I progressively rises above that required by the metabolic demands of the bird as T_a increases above about 23°C. Thus, $O_{2,ext}$ falls from a value of 0.19 at a T_a of 20°C to 0.13 at a T_a of 25°C in the flying Fish Crow (Figure 46.31). The increased hyperventilation at higher T_a would tend to cause a lowering of the PCO_2 and induce hypocapnia (see Torre-Bueno, 1978a) and, thus, alkalosis of the blood. It has been demonstrated that the White-necked Raven resorted to so-called compound ventilation when flying at high T_a. A high frequency, shallow ventilatory component is superimposed upon a deeper, lower-frequency component and may serve to reduce hypocapnia during thermal panting (Hudson and Bernstein, 1978).

The physiological significance of the hyperthermia during flapping flight, even at low T_a, is uncertain, although Torre-Bueno (1976) concluded that birds adjust their insulation and rate of heat loss to allow a certain increase in T_b during flight in order to improve muscle efficiency and to increase maximal work output. However, at higher altitudes where oxygen availability may become limiting, increased blood temperature will shift the oxygen saturation curve for Hb to the right and could reduce oxygen uptake at the lungs (Meir and Milsom, 2013). Whatever the significance of the increase in core temperature during flapping flight, brain temperature is maintained at a lower level. In fact, even in birds under resting, thermoneutral conditions, there is approximately a 1°C difference between brain and T_b (Bernstein et al., 1979a). This difference is maintained as kestrels (*Falco sparverius*) become hyperthermic during flapping flight and may even increase (Figure 46.32). The structure that appears to be largely responsible for this phenomenon is the *rete mirabile ophthalmicum* (RMO) (Kilgore et al., 1979; Bernstein et al., 1979a,b), which is closely associated with the circulatory system of the eye. Warm arterial blood from the body is thought to be cooled by the countercurrent exchange with venous blood returning from the relatively cool eye, evaporative surfaces of the upper respiratory tract, and the beak (Midtgård, 1983).

The covering of the bill is highly vascularized and its role in heat exchange and thermoregulation has only recently been appreciated (review Tattersall et al., 2017). The latter authors conclude that the avian bill shows dynamic changes in blood flow and, therefore, rates of heat exchange and that they conform to Allen's rule in which beak size is generally smaller in cooler environments (Symonds and Tattersall, 2010). Bill size may also be correlated with seasonal and local climate conditions. Scott et al. (2008) demonstrated that three species of waterfowl are capable of "dumping" heat using the bill as a thermal window, in a similar fashion to that of their webbed feet. Many tropical species of birds have relatively large bills and Tattersall et al. (2009) showed that the Toco Toucan's (*Ramphastos toco*) massive bill can act as a transient

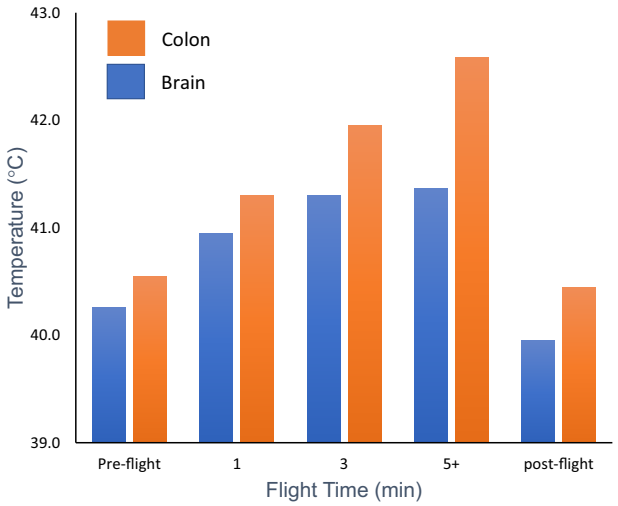

FIGURE 46.32 Mean (± 2 SE) temperatures in the colon and brain of American kestrels, Falco sparverius, before, during and after flying at a speed of 10 m s^{-1} and at an ambient temperature of 23°C. Data at 5+ min were obtained as mean values over the period between 5 min and 15 min after the onset of flight and represent steady-state values. Postflight values are those obtained after reestablishment of steady-state following each flight. *Redrawn from Bernstein et al. (1979a), Am. J. Physiol. 237.*

thermal radiator, accounting for 30–60% of total heat loss while at rest. At an air speed of 6 m/s and T_a or 21°C, maximum heat loss can reach a value of up to 10 W, or 400% of resting heat production, or around 10–20% of estimated flight costs. Similar findings were found for the Yellow-billed Hornbill (*Tockus leucomelas*) of South Africa, which revealed significant heat loss across the bill in T_a between 30 and 40°C (Figure 46.33, van de Ven et al., 2016). Thus, rates of heat exchange from larger billed species are comparable with those via hyperventilation and respiratory losses, at least at low to medium T_a. Even at a T_a of 30°C, respiratory heat loss is only approximately 20% of total heat loss for the budgerigar and fish crow (Tucker, 1968b; Bernstein, 1976) and 30% for the white-necked raven and pigeon (Hudson and Bernstein, 1981; Biesel and Nachtigall, 1987). So, most metabolic heat must be dissipated by means other than active respiratory evaporation. Indeed, herring gulls may lose up to 80% of total heat production through their webbed feet during flight (Baudinette et al., 1976). In the pigeon, the value is probably less, but nonetheless significant, at 50–65% (Martineau and Larochelle, 1988).

In warmer climates, smaller birds should have an advantage with regard to nonrespiratory, or passive heat dissipation (conduction, radiation, and convection), due to their large surface area to volume ratio. However, as T_a approaches T_b, then reliance on respiratory evaporation will increase. In the hummingbird *A. fimbriata,* maximum respiratory heat losses are 40% of the total at a T_a of 35°C (Berger and Hart, 1972). Above this temperature, heat dissipation from the eyes, shoulder, and feet of all but the smaller species of hummingbirds are greatly reduced and behavioral thermoregulation becomes increasingly

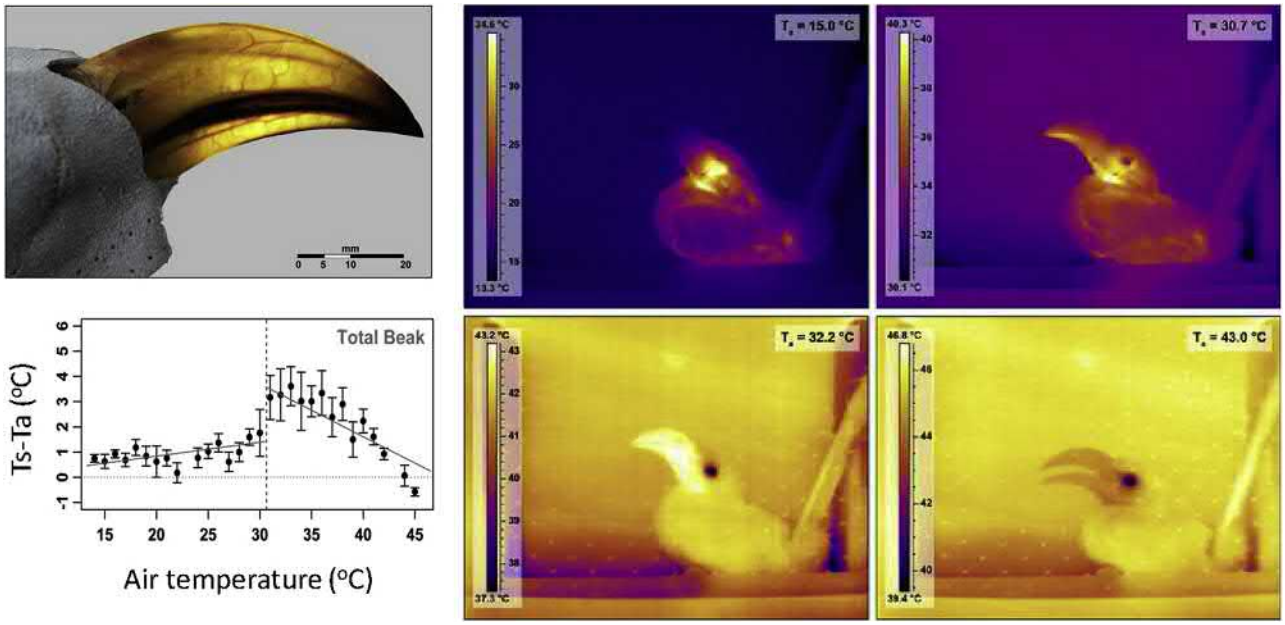

FIGURE 46.33 Regulation of Heat Exchange across the Yellow-billed Hornbill Beak (A) backlit image revealing the vasculature of the beak (B) Difference between the temperature of the air and the beak surface (Ts−Ta) (C) Thermal images of a female hornbill at different temperatures. In particular, at Ta= 32.2°C the bill is much hotter than the rest of the body and is maximizing heat loss, while at Ta = 43°C the bill is relatively cooler and is open to allow for respiratory heat loss. *From van de Ven et al. (2016).*

important via the use of thermal refugia (Powers et al., 2017). Larger species, such as the Blue-throated hummingbird (*Lampornis clemenciae*, 8 g), appeared to have the least tolerance to high T_a and were inactive when they had no capacity for nonrespiratory heat loss. In colder climates, or when flying at higher altitudes with reduced T_a, it might be anticipated that even larger species of birds should have sufficient ability to regulate to an optimal T_b and to maximize flight muscle performance and oxygen delivery. Bar-headed geese (*A. indicus*) exhibit quite stable abdominal T_b (grand flight mean 39.9°C, with minimum 37.3°C to maximum 42.8°C) during their high-altitude autumn migration across the Qinghai−Tibetan Plateau, from the breeding sites in Mongolia to the overwintering sites in India and South eastern Tibet (Parr et al., 2019a,b). In general, T_b did not change in a consistent relationship with absolute altitude, or rate of change in altitude, or heart rate, suggesting that for a substantial part of the migration the birds were able to thermoregulate T_b within a relatively narrow range. The hypothesis that bar-headed geese may strategically regulate at a lower T_b when migrating at higher altitudes, in order to improve lung oxygen uptake due to the thermal sensitivity of their hemoglobin−oxygen binding curve (Meir and Milsom, 2013), was not supported by the findings of Bishop et al. (2015) or Parr et al. (2019a,b).

Nevertheless, there has been much interest in the concept of the heat dissipation limit (HDL) theory (review Speakman and Krol, 2010), in which a limit to the locomotor performance of endotherms is determined by the maximum ability to dissipate heat loads and avoidance of hyperthermia. M_b scaling exponents for the FMRs of birds (0.658) and mammals (0.647) are consistent with the predicted theoretical value of 0.63 (Speakman and Krol, 2010). Experiments on wild birds have used feather clipping to provide a thermal window on the ventral surface of Blue Tits (*Cyanistes caeruleus*; Nord and Nilsson, 2019) and female Tree Swallows (*Tachycineta bicolor*; Tapper et al., 2020). While feeding their chicks, feather-clipped Blue Tits lost less M_b than controls while maintaining a lower T_b and raising larger chicks. Female Tree Swallows were able to feed their chicks at higher rates than controls when conditions were hot. Both these studies and that of the migratory Eider duck (Guillemette et al., 2017) provide experimental support for the HDL theory, at least in a species-specific−dependent context.

46.9 Migration and long-distance flight performance

46.9.1 Preparation for migration

As discussed by Fry and Ferguson-Lees (1972), it is a reasonable expectation that there will be correlated physiological adaptations associated with the extra power required to fly due to the laying down of fat as fuel for long-distance flights. Their work indicated that early in the fattening process of the yellow wagtail (*Motacilla flava*) the flight muscles showed a small hypertrophy. Other studies have also found muscle hypertrophy during fattening for both the pectoralis muscles (Marsh, 1984; Driedzic et al., 1993; Bishop et al., 1996; Jehl, 1997) and the cardiac muscles of birds (Driedzic et al., 1993; Bishop et al., 1996; Jehl, 1997). Thus, as protein as well as lipid is metabolized during long duration flights, it is also replaced during

stopovers, so the increase in M_b before a migration and during stopovers should be described as "fueling" rather than "fattening" (Piersma, 1998).

There has to be a close relationship between the amounts of fuel and flight muscle that are deposited before migration as the greater the fuel load, the greater the mass of flight muscle required to carry that load. A study by Piersma (1998) indicates that the proportions of fat-free tissue and fat that are deposited before long-distance (>1500 km) migration of shore birds vary between similar-sized species depending on the duration and nature of their impending flights. Just before departure, the pectoral muscles and heart tend to hypertrophy, whereas the stomach, intestine, and liver tend to atrophy. Figure 46.34 indicates that the greater fat deposition and atrophy of the visceral organs (such as the liver) are most pronounced in those species that have the longest migrations and

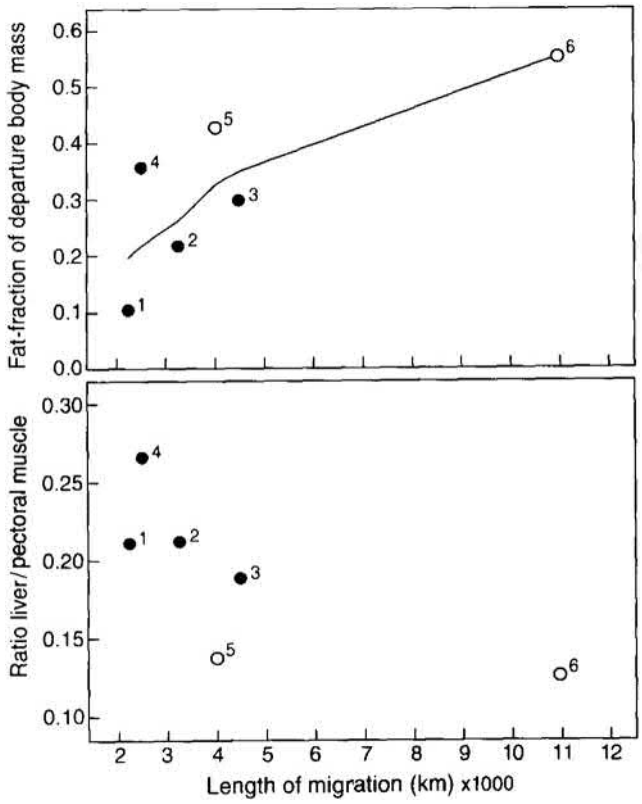

FIGURE 46.34 Fat loads and relative organ sizes before departure of 6 species of long-distance migrants (A) The amount of fat as a fraction of body mass in relation to the distance of the migration to be undertaken (B) The ratio of liver mass to pectoral muscle mass in relation to the distance of migration. Closed circles indicate species that would be able to make stopovers during their migration and open circles indicate subspecies that would not. (1) Golden plover, Pluvialis apricaria (2) Ruff, Philomachus pugnax (3) Bar-tailed godwit, Limosa lapponica lapponica (4) Red knot, Calidris canutus islandica (5) Bristle-thighed curlew, Numenius tahitiensis (6) Bar-tailed godwit, Limosa lapponica baueri. *From Piersma (1998).*

especially in those that have little or no opportunity for an emergency landing (e.g., by flying over an ocean). Of particular interest are the two subspecies of bar-tailed godwit. Although the distances of their migrations are vastly different (4500 km vs. 11,000 km), they both have high fat fractions and low liver to pectoral muscle mass ratios. What they have in common is their inability to make emergency landings during their migrations.

Bishop et al. (1998) compared the development of a captive population of barnacle geese with that of the wild migratory population in order to investigate to what link extent some of the migratory specializations of the cardiac and locomotory muscles might be determined by developmental processes and to what extent they might be modulated by differences in relative levels of activity. Postflight increases in the masses of the pectoralis muscles, of both wild and captive geese, tend to show an appropriate amount of hypertrophy in response to changes in M_b (Figure 46.35A and B). Regression equations were calculated for both the wild adult premigratory geese (pectoralis mass $= 0.5\ M_b^{0.86}$, $r^2 = 0.93$) and captive adult geese (pectoralis mass $= 0.3\ M_b^{0.92}$, $r^2 = 0.90$). The M_b exponents (or slopes) of the two regression equations are not significantly different between the two populations, although the coefficients are slightly smaller in the captive geese. Thus, approximately, 92% of the pectoralis muscle mass of premigratory barnacle geese appears to be almost independent of the experience of flight per se. Indeed, wild adult barnacle geese showed no increase in the amount of time they spent flying before their autumn and spring migrations (Portugal et al., 2012) and Portugal et al. (2009) found that hypertrophy of the pectoralis muscles of captive barnacle geese actually began even before their M_b increased.

Gaunt et al. (1990) studied the flight muscle changes of the eared grebe (*Podiceps nigricollis*) during a staging period at Mono Lake, California, where the food resources were not limiting. Following a postbreeding moult at the lake, the birds become flightless and their flight muscles show a slight atrophy, but due to an abundance of food, the birds put on a large amount of fat and M_b greatly increases. Just prior to departure for the winter grounds, the birds metabolize much of the fat and it is at this time that the flight muscles hypertrophy. In this example, flight muscle atrophy occurs when the birds have plenty of food, while subsequent hypertrophy occurs while the birds are actually reducing in M_b. Marsh and Storer (1981) had originally suggested that the correlation between flight muscle mass and M_b in Cooper's hawk (*Accipiter cooperii*) was a natural analog of "power" training during flight. Subsequent studies have found no obvious mechanistic link between hypertrophy of the flight muscle and M_b, although the authors did associate increased wing flapping with the flight muscle hypertrophy. Dietz et al. (1999) found that two

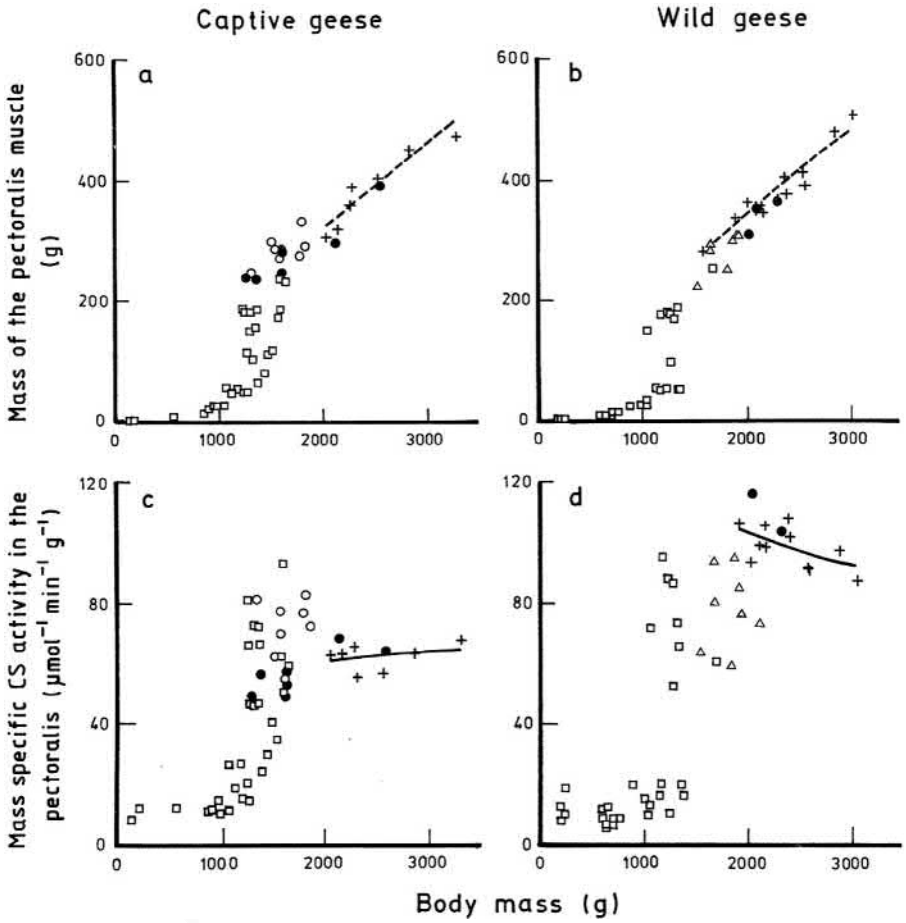

FIGURE 46.35 Scatter diagram of the masses of the pectoral muscles (g) and the mass-specific activity of citrate synthase (CS) in the pectoral muscles (μmol min-1 g wet wt-1) of captive (a and c) and wild (b and d) barnacle geese, Branta leucopsis, plotted against body mass (g). Goslings of 1−7 weeks of age (□), goslings of 12−20 weeks of age (●), adults at 7 weeks after the population hatch date (Δ) and premigratory adults >10 weeks post-hatch (+). *From Bishop et al. (1998).*

subspecies of red knots (*Calidris canutus*), which were kept under a constant photoperiod, showed similar increases in pectoral muscle hypertrophy (44%) during premigratory fattening and that this represented between 29 and 39% of the total mass increase. This suggested that there was no direct photoperiodic control and that the mechanism was likely to be endogenous, possibly with some kind of circannual regulation. It still remains an outside possibility that the relatively infrequent bouts of wing flapping and occasional take-offs exhibited by captive birds might provide a sufficient mechanistic link by which the birds are able to maintain the flight muscle to M_b relationship. However, as mentioned above, Portugal et al. (2012) showed that wild migratory barnacle geese did not show any change in the time spent flying during a 3-week premigratory period, thus, ruling out any overt evidence for flight training prior to the actual migration.

Figure 46.35C and D show the change in maximum mass-specific CS activity in the same barnacle geese (Bishop et al., 1998) for the data on pectoralis muscle mass (Figure 46.35A and B). There is little difference between the two populations up to 7 weeks of age. Specific activities of CS in the pectoralis muscles of the two wild 11.5-week-old juveniles are, at 103 and 116 μmol of substrate/min g, outside the range of that for the 12-week-old captive birds (55−59 μmol of substrate/min g) and the captive adult birds (56−58 μmol of substrate/min g) but similar to the range of wild adult birds (92−106 μmol/min g). The main conclusion from these results is that the captive adults have mass-specific values of activity for CS (mean = 62.1 ± 1.7 μmol/min g) which do not scale with M_b ($CS = 20\ M_b^{0.14}$, $r^2 = 0.11$) and are substantially below those of the wild premigratory birds (mean = 98.6 ± 1.9 μmol/min g, $P < .0001$). Results from captive goslings aged between 12 and 20 weeks also appear to be closely associated with the regression line resulting from the data from captive adult geese.

Peak values for the activity of CS in the pectoralis muscles of wild barnacle geese are found in the premigratory birds, although there is a tendency for the mass-specific activity to decline with increasing M_b ($CS = 862\ M_b^{-0.28}$, $r^2 = 0.33$). Thus, the activity of CS in the pectoralis of adult captive geese, and captive goslings over 11 weeks of age, is only around 60% of that measured in

wild geese. In addition, CS activity in the pectoralis muscles of a group of postmoulting, wild, adult geese was similar to that of long-term captive birds. Thus, it is suggested that the rise in the activity of CS in the premigratory birds may be a reaction to the increase in flight activity per se, while the rise in CS activity during development of the goslings up to fledging could be primarily under endogenous control. In addition, heart ventricular mass is reduced in captive and postmolt wild adults compared to that in wild premigratory birds and is qualitatively similar to the reduction shown in the aerobic capacity of the pectoralis muscle. It is suggested that this reduction in ventricular mass is also likely to be a direct result of the lower activity levels experienced by captive birds (Bishop et al., 1998).

One of the factors which may be important in the development of the aerobic capability of the pectoral muscles of barnacle geese is thyroxine (T_4). Circulating levels of T_4 show a similar developmental profile as mass and mass-specific activity of CS of the pectoral muscles (Bishop, 1997). While artificially accelerating the increase in circulating T_4 did not have a significant effect on either relative mass or on the mass-specific CS activity of these muscles (Deaton et al., 1997), hypothyroidism during development, induced by administration of the drug methimazole, did result in the retardation of their growth, mass-specific CS activity, fractional volume of mitochondria, and capillarity (Deaton et al., 1998). There was no such effect on the mass of the muscles of the leg.

If the mass-specific CS values for the pectoralis muscles of premigratory geese are generalized to the whole muscle, then the largest birds will have the lowest mass-specific aerobic capacity despite requiring the highest relative Po (Pennycuick, 1989). Consequently, during sustained flight, the larger birds may have to fly nearer to their minimum power speeds than smaller geese. This conclusion is also supported by the data on the heart ventricular mass (Bishop et al., 1996), which indicates that there is a tendency for relative M_h to decline slightly with increasing M_b. Thus, given that maximum oxygen consumption is likely to be closely correlated with M_h (Bishop and Butler, 1995; Bishop, 1997, 1999, 2005), it is suggested that during premigratory fattening, Pi available is likely to scale relative to M_b with an exponent value considerably lower than that of the Po exponent theoretically required ($M_b^{1.59}$) for flight performance to be maintained at a similar level according to aerodynamic theory (Rayner, 1990). However, a number of studies have questioned whether the allometric exponent for the scaling of Pi with increasing M_b is similar to that predicted for Po. Tucker (1972) measured the rate of oxygen consumption, from a single gull flying in a wind tunnel at 10.8 m/s, on 13 different occasions and with M_b naturally varying from 0.328 to 0.420 kg. He determined that the cost of carrying the extra M_b was quite small, with an M_b exponent of only $M_b^{0.325}$ but 95% confidence limits of 0.05−0.6. A very similar result was reported by Kvist et al. (2001) using the DLW technique to determine the energy expenditure of red knots flying in a wind tunnel on different days while they naturally put on M_b during the autumn. They calculated an M_b exponent of only $M_b^{0.35}$, with 95% confidence limits of 0.08−0.62. Subsequently, quite low exponents of $M_b^{0.55}$ and $M_b^{0.58}$ were also calculated for flying rose colored starlings, *Sturnus roseus*, and barn swallows, *Hirundo rustica*, respectively, also using DLW (Engel et al., 2006a; Schmidt-Wellenburg et al., 2007). Kvist et al. (2001) suggest that birds may be able to change the mechanochemical conversion efficiency of their flight muscles as they fuel up for the migration. However, it might be expected that birds should maximize muscle efficiency at all times.

46.9.2 Migratory behavior

When migrating, it might be more appropriate for the bird to minimize the time of migration, rather than the energy consumed, particularly if it is important for it to arrive at its destination before most of its competitors (Alerstam and Lindström, 1990). In this case, the optimal flight speed will be greater than U_{mr}. In an analysis of data in the literature for 48 species during migration, Welham (1992) concluded that lighter species do, indeed, fly faster than U_{mr}, but heavier species tend to fly slower. However, in an even more comprehensive study of 138 species (Alerstam et al., 2007), this apparent allometric compression of the expected speed range could be partially explained through the lack of geometric similarity with increases in M_b (e.g., Λ of the wings scales positively). Flight speed was found to be strongly influenced by wing loading and phylogenetic relationships, but some of the variation could not be fully accounted for.

It is now possible to track individual birds of many different species on their migratory flights, some of which cover many thousands of kilometers over land and sea. One of the fastest flights recorded is that of great snipe (*Gallinago media*), despite the fact that it is mostly conducted over land (Klaassen et al., 2011). This species made nonstop flights from Sweden to Central Africa and back again, covering between 4000 and 6800 km at estimated air speeds of 16−26 m/s. Bar-tailed godwit (*L. lapponica*) makes an even longer nonstop flight, largely over the Central Pacific Ocean, while traveling between Alaska to New Zealand (Gill et al., 2009). They averaged 10,153 km in 7.8 days, equivalent to an air speed of around 15 m/s. Other species of wading birds have also been shown to make impressive and rapid migratory flights (Minton et al., 2011; Niles et al., 2012; Johnson et al., 2012) in which they have to greatly increase their M_b greatly before departure (Gudmundsson et al., 1991). More specialized pelagic species of seabird, such as those within the orders

Procellariiformes and Charadriiformes, regularly make quite long foraging trips during the breeding season. In the winter months, they frequently disperse around the oceans of the world on massive migrations, such as that of sooty shearwater, *Puffinus griseus* (Figure 46.36; Shaffer et al., 2006) and Arctic tern, *Sterna paradisaea* (Egevang et al., 2010).

It has been suggested that some species of birds, such as geese, may be able to reduce induced drag by flying in V-formation (Lissaman and Scholenberger, 1970; Hummel, 1995). This would entail their maintaining positions so that the tips of the wings on the inside of the V are close to the centers of the trailing vortices from the wings on the outside of the bird ahead (Hainsworth, 1987). Assuming a fixed wing at maximum span, Hainsworth (1987) found considerable variability in wing tip spacing (WTS) of between −128 and 289 cm, both between and within formations of Canada geese (*B. canadensis*), but found that the median WTS for 55 geese (−19.8 cm) was close to the theoretical optimum (−16 cm) and corresponded to an estimated saving in induced power of 36%. Even so, in order to achieve such savings with beating wings, there would have to be a high degree of synchrony in wingbeat frequencies, as there is little variation in depth (the distance between adjacent birds' body centers, parallel to the flight path) between individuals (Hainsworth, 1988). This author found close synchrony (a difference of <0.1 beat/s) to be present in 48% of the birds he studied and, because of the calm conditions at the time, concluded that this probably represents an upper limit. Indeed, even when not taking wingbeat frequency into account, Cutts and Speakman (1994) calculated mean saving in induced power for 54 skeins of pink-footed geese (*Anser brachyrhynchus*) to be only 14% and concluded that the relationship between depth and WTS supported the communication hypothesis (Gould and Heppner, 1974). This contends that the birds position themselves so as to avoid collisions and to maintain flock unity. Although, not on migration, Weimerskirch et al. (2001) studied the flight performance and heart rate of great white pelicans (*Pelecanus onocrotalus*) while they were flying alone and when they were flying in V-formation. Mean wingbeat frequency was reduced by up to 50% for pelicans flying behind the first two birds in formation, as a result of an increase in the time spent gliding. Heat rate was reduced by 14% for pelicans in formation compared to birds flying alone. If we apply the allometric trend that $\dot{V}_{O_2}$ is proportional to f_h^2 (Bishop and Spivey, 2013), then this would suggest that the mean energetic saving for flying in V-formation was around 27% relative to unaccompanied flight (which is close to the theoretical predictions of Hainsworth, 1987).

46.10 Flight at high altitude

The majority of avian migratory flights occur below 1 km above the ground (Bruderer et al., 2018; Liechti and Schaller, 1999; Berthold, 1993) and reduce in frequency of occurrence with increasing altitudes above this. Thus, migrations where birds climb to higher altitudes to avoid high ground temperatures (Senner et al., 2018), or to select for favorable wind directions (Bruderer and Liechti, 1995), or where traditional flyways route birds over large mountain

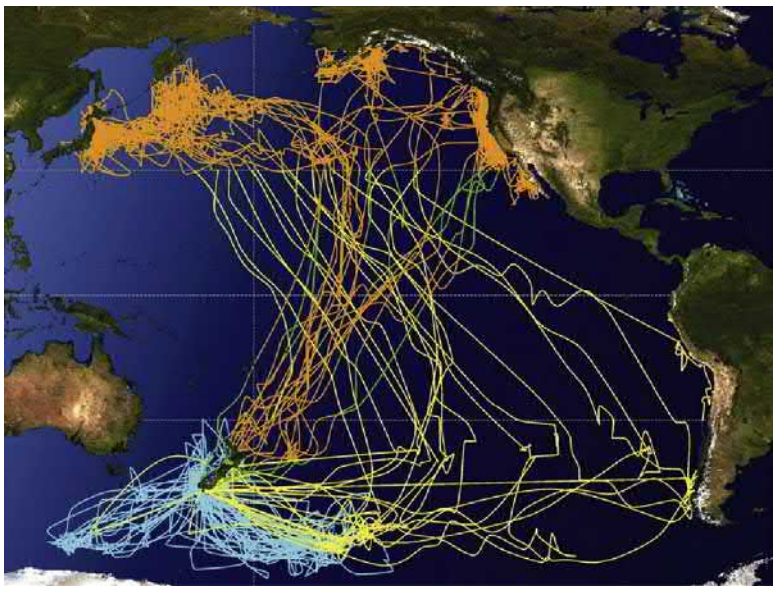

FIGURE 46.36 Geolocation tracks of sooty shearwater, Puffinus griseus, migrations originating from breeding colonies in New Zealand. Interpolated geolocation tracks of 19 sooty shearwaters during breeding (light blue) and subsequent migration pathways (yellow, start of migration and northward transit; orange, wintering grounds and southward transit). *From Shaffer et al. (2006).*

barriers (Hawkes et al., 2011), are of particular interest. Early studies indicated that most small passerines migrating at night fly below 2 km above sea level (Lack, 1960; Nisbet, 1963), although it was demonstrated by Bruderer and Liechti (1995) that wind direction may cause the majority of birds crossing the Negev desert in the south of Israel to fly above 1.8 km in spring, but with 90% below 3.5 km. Occasionally, when a low-level jet offered tailwinds that were particularly strong, birds flying over Israel reached heights between 5 and 9 km (Liechti and Schaller, 1999), and with ground speeds >25 m/s and up to 50 m/s. Even more rarely, some opportunistic observations of various species of birds have been reported at similarly extreme high altitudes (>6km). A flock of 30 swans (probably whooper, *Cygnus cygnus*) was located by radar off the west coast of Scotland at an altitude of 8−8.5 km, where the temperature was −48°C (Stewart, 1978; Elkins, 1979), but it is unclear how these birds managed to reach such high altitudes (Pennycuick et al., 1996a). Bar-headed geese, *A. indicus*, were reported as flying at altitudes of over 8 km (where partial pressure of oxygen (PO_2) is, around 6.7 kPa, approximately one-third of the sea-level value) during their migration across the Himalayas (Swan, 1961). However, these anecdotal observations of larger species performing flapping flight at extreme altitudes are very rare and have almost no environmental context (Bishop et al., 2015). The highest altitudes for flapping flight recorded directly by animal borne devices are for bar-headed goose at 7290 m (Hawkes et al., 2013) and Ruddy Shelduck at 6800 m (Parr et al., 2017). There are also a number of montane bird species that are resident at very high altitudes, such as the Red-billed Chough (*Pyrrhocorax pyrrhocorax*) and Yellow-billed Chough (*Pyrrhocorax graculus*), the latter of which has been recorded nesting at 6500 m (Rahn and Ar, 1974). Thus, birds can certainly fly at altitudes at which nonacclimatized mammals find walking difficult (Tucker, 1968a; review Parr et al., 2019a,b).

46.10.1 Physiology and adaptation

There have been relatively few physiological studies on birds flying at such high altitudes, either real or simulated. Tucker (1968a) trained a budgerigar wearing a $\dot{V}_{O_2}$ mask to fly in a hypobaric wind tunnel for 30s at the equivalent of 6100 m. Two particular aspects of flying at high altitude (low air temperature and evaporative water loss) have already been mentioned. Other aspects are the effect of the decrease in the air density and in PO_2 with increasing altitude, which will have both physiological and biomechanical influences on flight performance. Thus, for small European passerine migrants, air speed increases by 1 m/s/km for flap-gliding species and 1.4 m/s/km for flap-bounding species, while f_w increased by 0.4 and 1.1 Hz/km, respectively (Schmaljohann and Liechti, 2009). Pennycuick (1975) argues that, as birds fly higher, they must fly faster in order to obtain sufficient lift from the wings. However, as air speed increases with height, so does the power required to maintain it. At the same time, the capacity for gas exchange will decrease as the value for PO_2 declines and the blood hemoglobin begins to desaturate. Thus, there must be a particular altitude at which the bird can only just obtain O_2 at a rate sufficient to maintain even its minimum power speed, at which point it will not be able to climb any higher under its own power.

Gudmundsson et al. (1995) studied the migration of brent geese (*Branta bernicla*) from Iceland to Greenland and tracked them by satellite as they flew up and across the Greenland ice cap. These authors concluded that the brent geese (fitted with 60 g satellite transmitters) were not able to fly continuously over the Greenland ice cap (mean height of 2135 m) and had to make frequent and long rests during the climb. Gudmundsson et al. (1995) suggested that this evidence supported the biomechanical predictions of Pennycuick (1989) that these relatively large birds were up against the limit of the biomechanical power available from the flight muscles due to negative scaling of wingbeat frequency with respect to M_b. Certainly, smaller species of birds are able to sustain higher rates of climb and to carry larger relative fat loads for fueling migratory flights (Hedenstrom and Alerstam, 1992), so it is within the larger species where we may expect to see this limitation most easily. However, the analyses of Bishop and Butler (1995) and Bishop (1997, 2005) suggest that the limit to the sustained climbing performance of birds, such as shown by the brent geese, is also likely to be related to the mass-specific biomechanical performance of the cardiac muscle and its negative scaling with body size. As geese have both FG and FOG fiber types in their flight muscles (Rosser and George, 1986a), the net effect is that during "prolonged" flight activity the mass of the pectoralis muscle is effectively reduced to that of the "aerobic" FOG fibers. Thus, the maximum sustained power output (P_{ms}) available becomes proportional to the ability of the cardiovascular and respiratory system to supply the working (aerobic) muscle tissue. With an additional contribution from the FG fibers, the brent geese would have the potential to perform short flights up the steeper slopes using anaerobic power, but the birds would require regular stops (as was observed).

Due to its iconic migration over the Himalayan mountains and across the Tibetan−Qinghai plateau (Figure 46.37), the bar-headed goose has been the subject

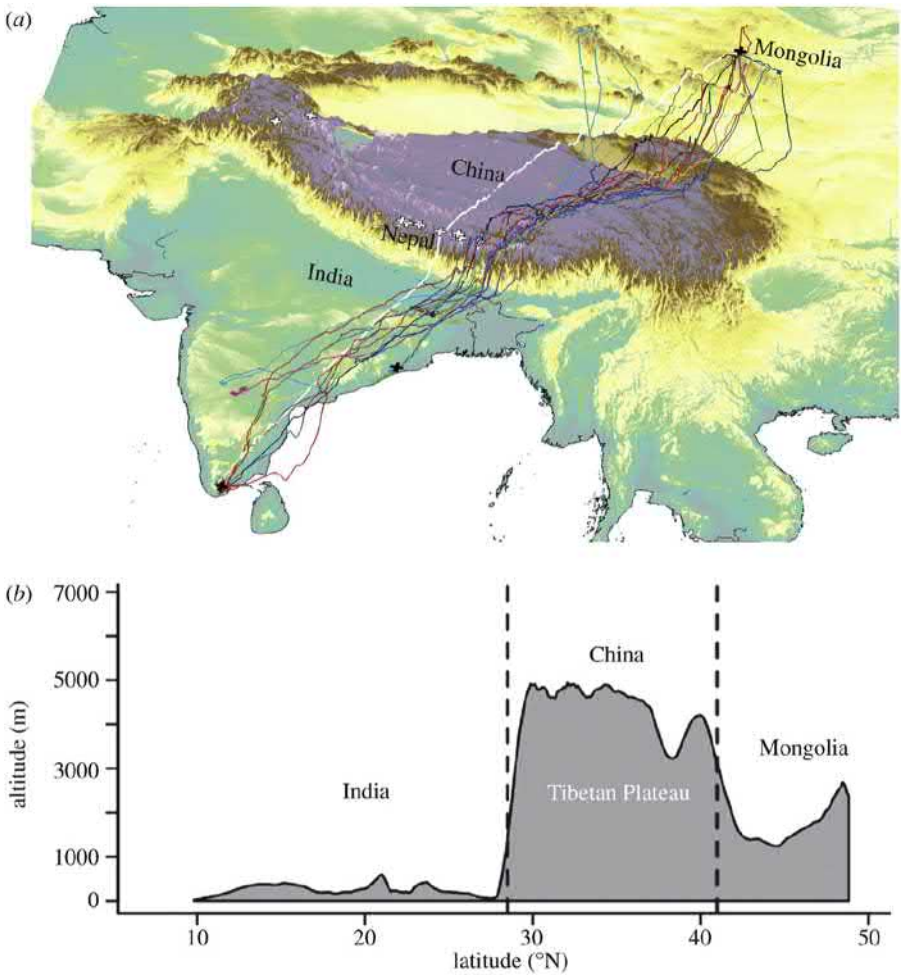

FIGURE 46.37 Satellite tracks of migrating bar-headed geese, Anser indicus: (A) three-dimensional map showing release locations (black crosses) of bar-headed geese in India (n = 2 sites) and Mongolia (n = 1 site). Coloured lines represent 16 individual geese, and coloured background shading indicates elevation. Solid thick white line shows the great circle route. White crosses show locations of the mountains peaks over 8000 m in elevation. (B) Cross-section of land elevation underlying the route of the northwards migration, based on the arithmetic mean of all flights. *From Hawkes et al. (2013).*

of a number of studies concerned with the physiological adaptations for flying at high altitude (reviewed in Butler, 2010; Scott, 2011; Scott et al., 2015; Butler, 2016; Lague, 2017; Parr et al., 2019a,b). Unlike Pekin ducks, bar-headed geese do not significantly increase their Hct and [Hb] when exposed to simulated high altitude (Black and Tenney, 1980). This means that there is no increase in the viscosity of the blood, thus preventing a possible reduction in its circulation. This is more than counterbalanced by the higher affinity for oxygen (low P_{50}) of the Hb of the goose (P_{50} for blood of the bar-headed goose at pH 7.5 is approximately 5kPa compared with 7.5 kPa for the duck), which allows the maintenance of a higher CaO_2 (and hence $(C_aO_2 - C_{\bar{v}}O_2)$) at high altitudes than in the duck (see also Meir and Milsom, 2013).

A comparison between the bar-headed goose and the plain-dwelling greylag goose, *Anser anser*, indicates that their Hb differs by only four amino acid substitutions, one of which (α^{119} Pro→Ala) may, by altering the contact between the α1 and β1 chains, confer a small increase in the O_2 affinity of the Hb from the bar-headed goose (Perutz, 1983), and this is then amplified by the interaction with inositol pentaphosphate (Rollema and Bauer, 1979). The complementary substitution (β55- Leu→Ser) at the same position may have a similar effect on the P_{50} of the Hb of the Andean goose *Cloephaga melanoptera* (Weber et al., 1993). A comparative analysis of eight species of high and low altitude Andean waterfowl species investigated the potential convergence in the functional binding properties of their Hbs (Natarajan et al., 2015). Their results showed that multiple mutations and historical paths can lead to similar functional changes. A similar comparative analysis of Andean waterfowl studying their pectoralis muscle enzyme biochemistry (Dawson et al., 2020) indicated that most species had decreased glycolytic capacity (e.g., LDH and PK) and increased myoglobin concentration and lipid

β-oxidation capacity (e.g., HAD activity); however, some metabolic changes required longer evolutionary time to emerge than others. HEX activity only increased in newly established high-altitude taxa, while only the longest established species exhibited an increase in ATP synthase activity (Figure 46.38). Acute or temporary movements to high altitude in typically lowland-living species may have different acclimation effects to those of long-term evolutionary adaptions.

It is clear from the data of Black and Tenney (1980) that the respiratory system of bar-headed geese is able to maintain a very small difference between the PO_2 of inspired air (P_IO_2) and that in the arterial blood (PaO_2), when at simulated high altitudes. For example, when at sea level, $P_IO_2 - PaO_2$ in bar-headed geese is approximately 7 kPa, whereas at a simulated altitude of 10.67 km, it is only 0.5 kPa. The associated stimulation of hyperventilation results in a large increase in respiratory minute volume ($\dot{V}_I$) that helps to maintain such a small difference between P_IO_2 and PaO_2. However, it also causes a decline in $PaCO_2$ and, therefore, an increase in arterial pH and the bird becomes hypocapnic and alkalotic. Scott and Milsom (2007) showed that the increase in $\dot{V}_I$ in bar-headed geese was the result of a larger increase in tidal volume and a correspondingly lower increase in respiratory frequency than that of the low-land living greylag goose (*A. anser*) or Pekin duck.

In a number of mammals (dog, monkey, rat, and human) the hypocapnia induced by hyperventilation causes a reduction in cerebral blood flow. This is not the case in ducks and bar-headed geese (Grubb et al., 1977; Faraci and Fedde, 1986). Also, hypoxia causes a greater increase in cerebral blood flow in ducks than it does in dogs, rats, and human (Grubb et al., 1978). At high altitude, of course, both of these factors occur together (hypocapnic hypoxia), and under these conditions, hypocapnia appears to attenuate the increase in cerebral blood flow caused by hypoxia (Grubb et al., 1979). However, these authors found that

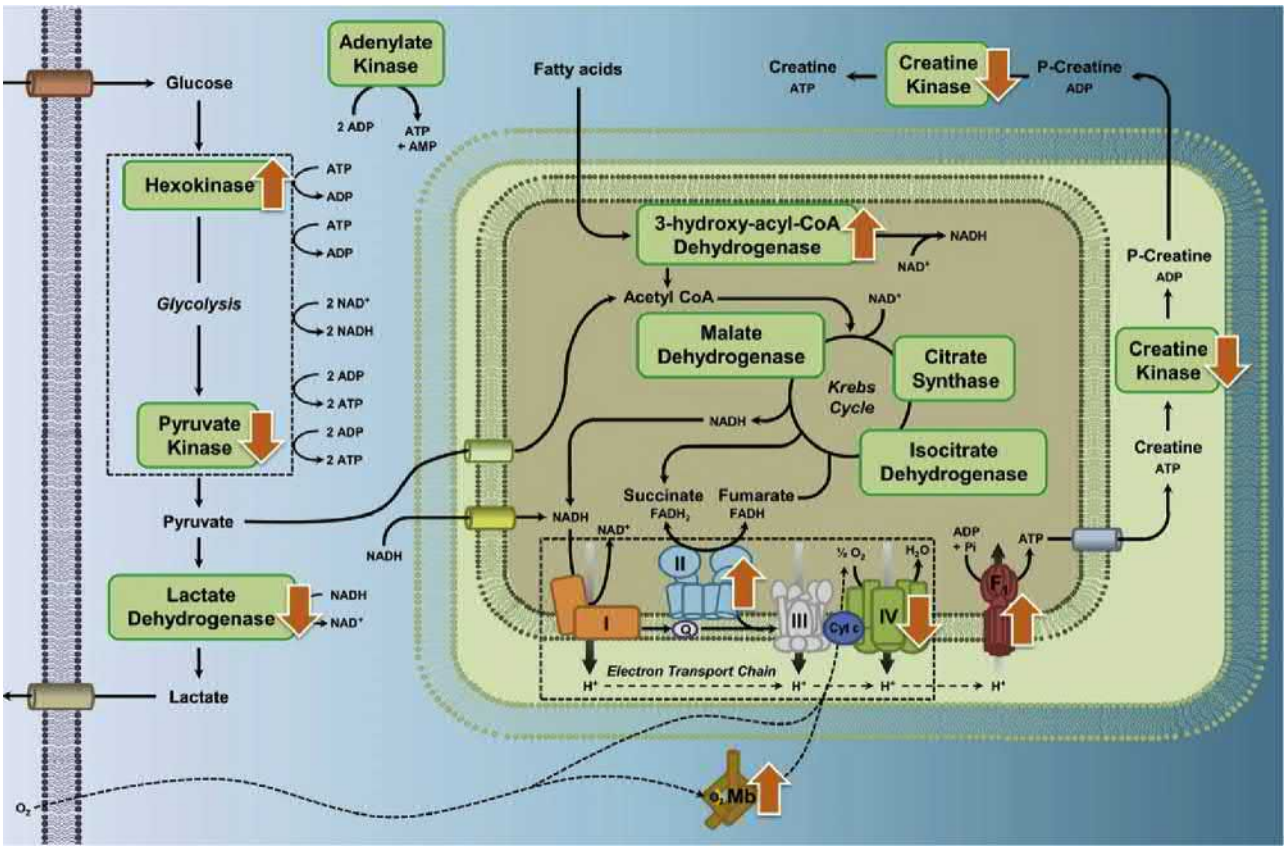

FIGURE 46.38 Enzyme pathway diagram illustrating highlighting differences in metabolic enzyme activity and myoglobin content in high-altitude waterfowl compared to their close low-altitude relatives. There were increases in the activities of hexokinase, ATP synthase, HOAD, and mitochondrial complex II (succinate dehydrogenase). There were decreases in activities of pyruvate kinase, lactate dehydrogenase, creatine kinase and complex IV (cytochrome c oxidase). There were no changes in activity for the enzymes citrate synthase, isocitrate dehydrogenase, malate dehydrogenase, complex I (NADH-ubiquinone oxidoreductase), and adenylate kinase. *From Dawson et al. (2020).*

blood oxygen flow is similar at a given O_2 content in both normocapnic and hypocapnic ducks. This is because during hypocapnia and alkalosis, there is a leftward shift of the O_2 equilibrium curve, as a result of the Bohr effect, so that a given O_2 content is achieved at a lower PO_2. In fact, in bar-headed geese, the alkalosis during severe hypoxia is greater than that in Pekin ducks which, together with the higher affinity of their Hb for O_2, means that at a given (low) PaO_2, CaO_2 is much (at least two times) greater in the geese (Faraci et al., 1984a). In addition, the pulmonary vasoconstrictor response to hypoxia is smaller in the bar-headed goose than in other birds and mammals (Faraci et al., 1984b). Thus, similar (or even greater) O_2 deliveries to the brain and heart can be achieved in hypoxic bar-headed geese at lower cerebral and coronary blood flows than in hypoxic ducks. Indeed, this species of goose is able to maintain, or even to increase, its perfusion of all tissues during severe hypocapnic hypoxia (Faraci et al., 1985).

Delivery of O_2 to the locomotory muscles is also influenced by the architecture of the capillaries. Capillary density and capillary:fiber ratio are greater in the skeletal muscle (gastrocnemius) of bar-headed geese than in that of Canada geese (Snyder et al., 1984), and this is a genetic adaptation that is not dependent on exposure to low atmospheric oxygen during development. Perhaps surprisingly, there was only a 24% increase in the capillary:fiber ration of the bar-headed goose flight muscle compared with that of the barnacle goose and no significant difference in capillary density (Scott et al., 2009). All of these factors are, no doubt, very important features when the bar-headed geese need to fly at higher altitudes. Scott and Milsom (2006) suggested that adaptations to decrease the value for hemoglobin P_{50} and to increase tissue diffusion capacity might be the most beneficial for high flying birds.

It has been suggested that the more effective lungs of birds, compared with those of mammals, may contribute significantly to the ability of birds better to tolerate high altitude (Scheid, 1985). However, Shams and Scheid (1989) concluded that, although the parabronchial lung of birds does confer an advantage at a PO_2 equivalent to that at the top of Mount Everest, the major difference between birds and mammals is the ability of the former to tolerate lower $PaCO_2$, thus enabling the respiratory system to maintain PaO_2 at as high a level as possible. In a subsequent paper, the same authors (Shams and Scheid, 1993) reported that when hypoxia is accompanied by the appropriate hypobaria (reduced atmospheric pressure), V_I and PaO_2 are slightly, but significantly, greater. Although the authors have no explanation for these differences, they would allow a bird at the elevation of Mount Everest to gain another 700 m in height before the "increase" in PaO_2 was eliminated. Gas exchange across the RMO is thought to enhance the supply of oxygen to the brain (Bernstein et al., 1984), and improvement in gas transport as a result of acclimatization to high altitude (Weinstein et al., 1985) may be other ways in which birds are adapted for survival and activity at high altitudes.

Despite all of these apparent adaptations to life at high altitude, there is very little accurate information with regard to the heights that bar-headed geese typically fly at during their migrations. Hawkes et al. (2011) tracked bar-headed geese flying north out of India and climbing up and through the Himalayan mountains, on their way to breed in China and Mongolia (Figure 46.39). The birds typically climbed between 4 and 6 km in 7−8 h in a single day, with regular sustained climb rates of between 0.2 and 0.6 m/s. Over the whole migratory period, the data suggested that bar-headed geese normally minimize flight altitude by traveling through the mountain valleys and only flying as high as the terrain dictates (Hawkes et al., 2013). Maximum altitudes reached were 7290 and 6540 m, for southbound and northbound geese, respectively, but with 95% of locations recorded <5489 m. Arlene Blum (1980) reports seeing bar-headed geese flying over the summit ridge of Annapurna I at >7622 m and took photos of them. Clearly, it is possible that occasional rare flights to very high altitudes could occur, but it is likely that these flights are only possible if assisted by favorable wind conditions in the mountains, or whether they are sustained entirely by the various physiological adaptations for flight at high altitude.

Experiments on bar-headed geese running on a treadmill under hypoxic conditions, similar to those at the top of Mount Everest, indicated possible severe limitations to oxygen uptake (Fedde et al., 1989). Under normoxic conditions, running at 0.6 m/s and at a two-degree incline caused a doubling of $\dot{V}_{O_2}$ and of cardiac output. Under the severe hypoxic conditions of only 7% atmospheric O_2, there was a decline in resting $\dot{V}_{O_2}$ and, surprisingly, $\dot{V}_{O_2}$ did not increase significantly during the subsequent 6 min of exercise. Cardiac output also apparently remained unchanged during exercise, although there was a significant reduction in V_S. The authors suggest that there may be a hypoxic depression of cardiac contractility, but clearly this cannot occur when the birds are flying at high altitude. It may be that the birds used in this study were stressed by the surgical techniques associated with the cannulations and so on (cf. Woakes and Butler, 1986). Certainly, their resting heart rate was almost 3x higher than that of resting barnacle geese (Butler and Woakes, 1980; Ward et al., 2002). In a similar study of bar-headed geese (Hawkes et al., 2014), they obtained similar blood gas and metabolite values to those of Fedde et al. (1989) but significantly

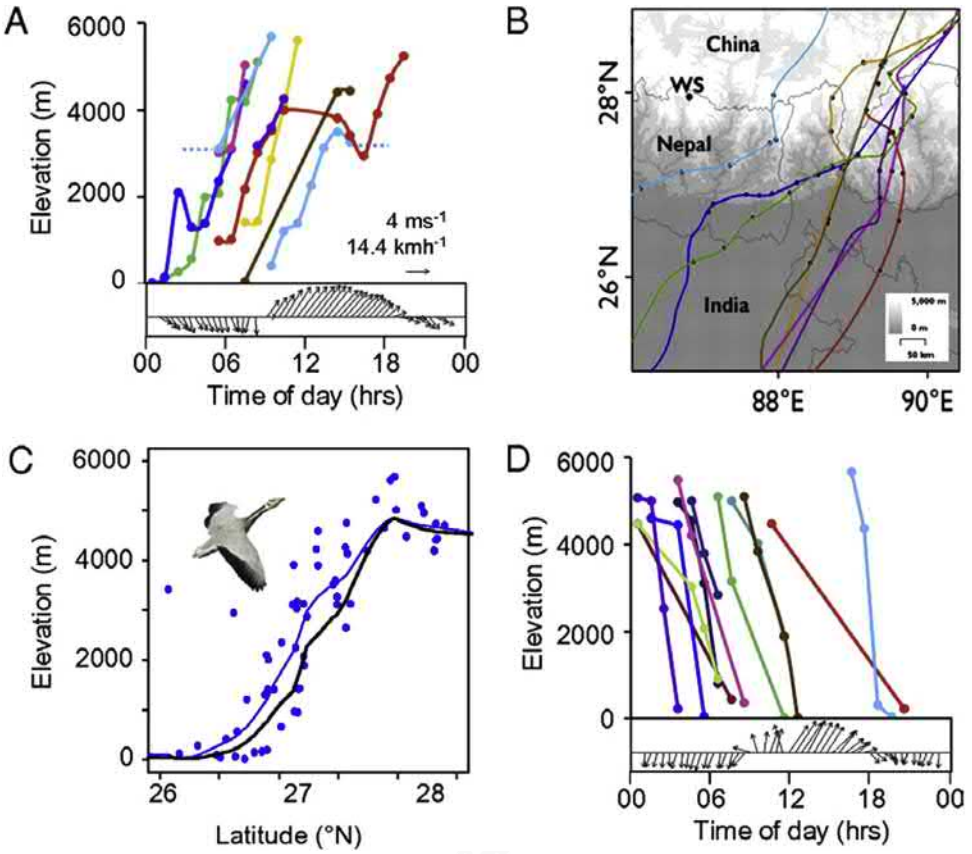

FIGURE 46.39 Timing of migrations with 30-min average wind speed and direction from the Nepal Climate Observatory at Pyramid station for bar-headed geese, Anser indicus, migrating (A) northward (n = 8) and (D) southward (n = 12) over the Himalaya. Arrows show cardinal direction (north pointing up to 0°) in which the wind was blowing and arrow length (indicated in A) is proportional to wind speed in A and D. (B) Map showing the northward migration routes; weather station (WS) location is indicated. (C) Elevation of the mean northward track across the Himalaya (for all crossing locations from all eight geese), blue circles show individual data points and blue line shows Lowess smoother for mean ground elevation under the track (black line). *From Hawkes et al. (2011).*

lower resting heart rates during normoxia and hypoxia. They also used accelerometry to assess the biomechanical cost of locomotion and found that the requirement for oxygen was not different between running in hypoxia and in normoxia. Finally, it was noted that, while lactate levels had risen significantly in the geese running in hypoxia (Hawkes et al., 2014), it could only account for a maximum of 10% of the locomotory costs after 6 min of running, which was not compatible with the 50% reduction in $\dot{V}_{O_2}$ measured in the severely hypoxic geese (Fedde et al., 1989). Put together, these results suggest that there was a problem with the experimental determination of $\dot{V}_{O_2}$ by Fedde et al. (1989) under hypoxic conditions during running, and that the maximum running speeds of bar-headed geese are not significantly affected by severe hypoxia (Hawkes et al., 2014).

These recent studies of bar-headed geese in the wild (Takekawa et al., 2009; Hawkes et al., 2011, 2013) are beginning to reveal the true nature of their migration across the Himalayan Mountains and Tibetan–Qinghai plateau. Technological approaches are allowing the simultaneous recording of altitude, heart rate, and accelerometry during their migratory flights (Figure 46.40; Bishop et al., 2015). These data indicate that even a comparatively gentle climb rate of around 0.1 m/s, between an altitude of 3600 to 4000 m, required a heart rate of well over 400 beats/min, compared to a maximum heart rate of around 500 beats/min (Ward et al., 2002). However, overall the mean heart rates are remarkably low and indicate that there is still much to discover with regard to the maximum flight performance of these high-flying birds.

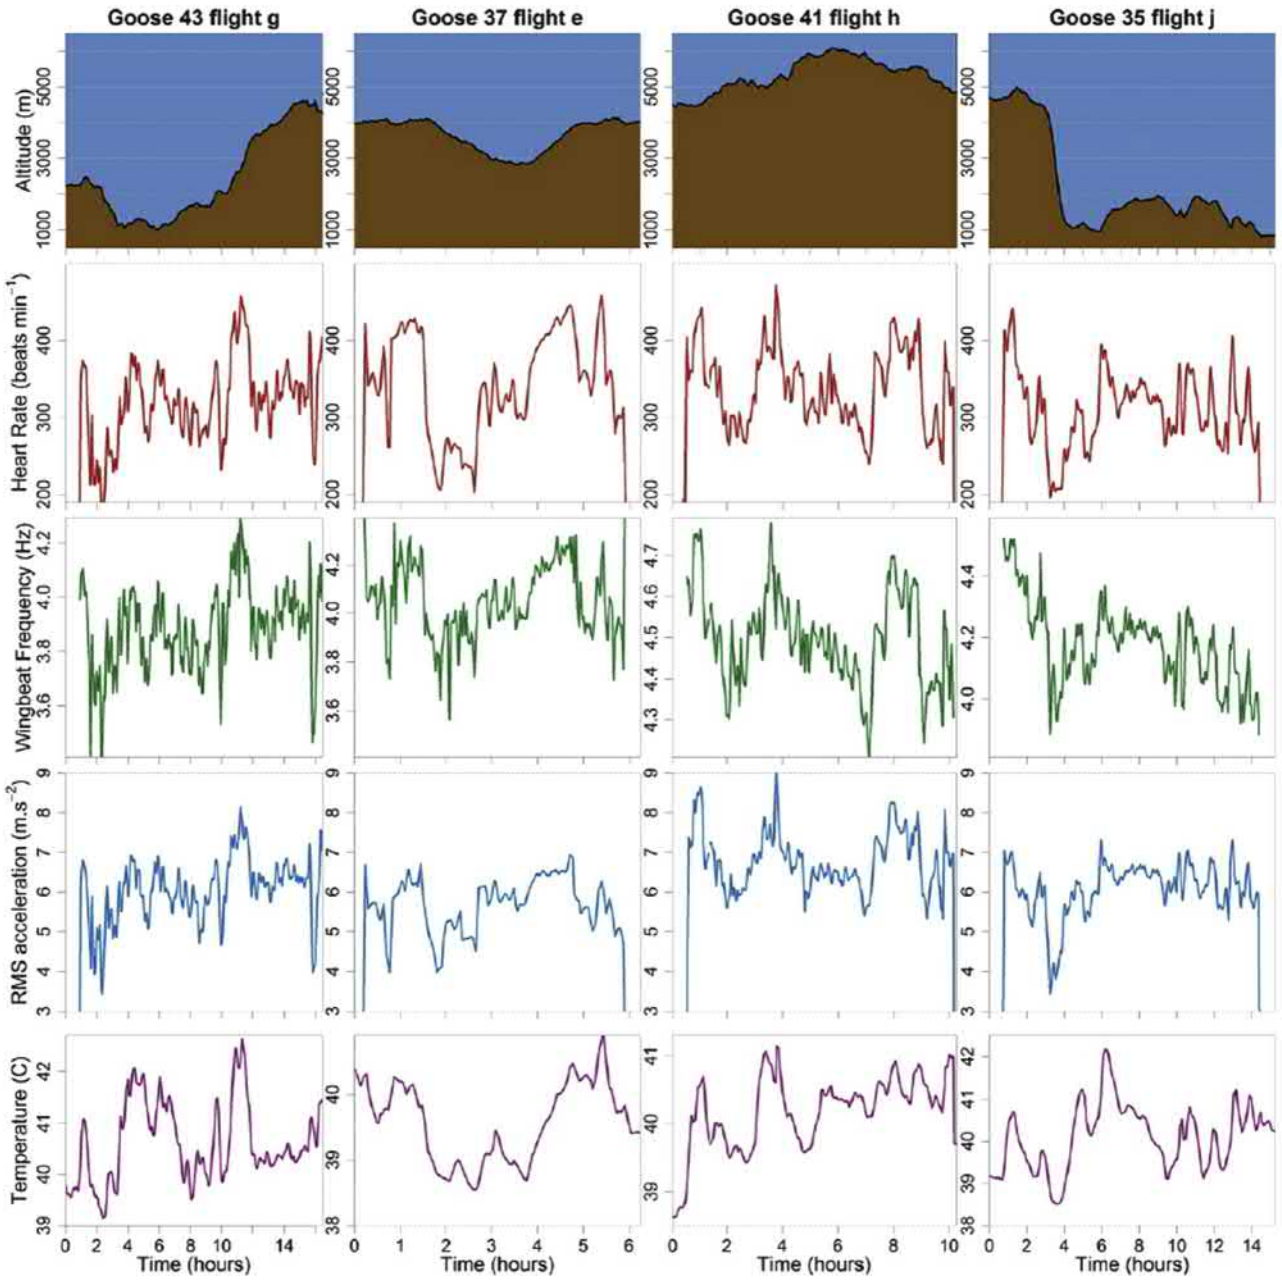

FIGURE 46.40 Examples of simultaneous recordings of altitude (row 1), heart rate (row 2), wingbeat frequency (row 3), root mean squared vertical body acceleration (row 4) and abdominal body acceleration (row 5) from wild bar-headed geese on their autumnal migration. P43 travelled South from Mongolia and ascended onto the Tibetan Plateau (column 1); goose P37 (column 2) and goose P41 (column 3) were traversing the Tibetan Plateau; goose P35 (column 4) crossed the Himalayas and descended into India. *From Bishop et al. (2015).*

T Testosterone
T3 Triiodothyronine
T4 Thyroxine
TSH Thyroid-stimulating hormone
VA opsin Vertebrate ancient opsin photopigment

47.1 Introduction

Approximately 19% of the ~10,000 species of birds in the world migrate on a regular basis (Kirby et al., 2008), and this is closer to 50% of species if only birds that breed at latitudes above 35° north and south are considered (Newton and Dale, 1996a, 1996b). The physiological feat of migration has been equated to such athletic feats in mammals as running 130 consecutive marathons (semipalmated sandpiper, *Calidris pusilla,* migrates ~ 5000−7500 km nonstop; Anderson et al., 2019) or completing three trips to the moon and back in a lifetime (arctic tern, *Sterna paradisaea,* migrates ~80,000 km a year over a 30 year lifespan; Egevang et al., 2010). The strategies migratory birds use to complete these annual peregrinations vary among bird species with some birds completing their long-distance migration in one, nonstop flight while most fly intermittently, taking advantage of stopover sites along their routes to rest and refuel. Regardless of strategy, all avian migrants face the same physiological challenges while aloft, albeit to different extents, including: (1) burn fat at a very high rate while fasting and combatting the negative effects of lipid peroxidation, (2) maintain adequate hydration while not drinking and losing water due to elevated breathing rates, (3) obtain adequate oxygen while oxidizing fat for fuel, and especially when flying at high altitudes with low-oxygen content, (4) avoid becoming too hot (heat gained from metabolism and the environment) or too cold (heat loss to the environment), and (5) meeting these challenges under a seasonal time constraint. Additionally, birds that stop to rest

Sturkie's Avian Physiology. https://doi.org/10.1016/B978-0-12-819770-7.00017-7

and refuel at stopover sites have the added physiological challenge of rapidly regaining energy stores with initially reduced gut size and function. Clearly, the physiological challenges associated with long-distance flight are significant and require specialized morphological and physiological adaptations and acclimatizations.

The energy costs of bird flight are substantial and have been the focus of ornithological research since the 1960's when Greenewalt (1960) recorded hummingbirds flying in front of a fan and examined changes in flight speed with changes in fan speeds. The ability of researchers to fly birds in a controlled environment led to significant breakthroughs not only in the field of aerodynamics but in the understanding of the physiology of flight as well. For example, classic studies of birds flying in wind-tunnels have shown that forward flapping flight is energetically more costly than running or swimming per gram body mass (Butler, 1991; Bishop and Butler, 2015). Importantly, the advantage of flying on migration, instead of running and swimming, is revealed when travel distance is considered. Specifically, energy required per gram body mass to travel a given distance (i.e., the cost of transport) is considerably less for a flying migrant compared to a running or swimming migrant (Tucker, 1970; Schmidt-Nielsen, 1972; Bishop and Butler, 2015). With an increase in technology and the ability to track migrating birds throughout the globe, we now know the physiology of migratory flights of free-living birds to be a highly complex, synergistic process between an organism and its ever-changing environment.

In this chapter, we will review, within the context of the migration life history of birds, the neuroendocrine and physiological adaptations that allow birds to meet the challenges of long-duration flights, the preparations they implement to begin their journeys, and the in-flight adjustments they make in order to successfully complete their journeys. We will conclude with a discussion about the flexible phenotypes of birds in relation to how they physiologically respond to the challenges of migratory flight in a dynamic seasonal environment, and some of the important mysteries that remain in terms of the physiology of birds during migration.

47.2 Adaptations of birds for long-duration migratory flights

Flapping flight requires both lift to stay aloft and thrust to move forward through the air (Tobalske, 2016). Birds have evolved feathers and wings that enable them to fly because their collective shape produces lift as air flows over and around them. Combine feathers and wings with a skeletal system that is both strong yet light (hollow bones), and a muscular system that provides the power and endurance, and you have the anatomical skeletal-muscular foundation for the evolution of long-distance migration of birds. Bishop and Butler (2015) provide a thorough description of the biomechanics of bird flight, and how the muscles of birds produce the power required for flight, in general, and the long-duration flapping flight used by birds in migration, in particular. Most pertinent to our review of the physiology of long-distance migration in birds is that (a) self-powered flight is the most demanding form of locomotion in terms of its energy cost per unit time—thus, fuel storage and use is critical; (b) on the other hand, flight is much more efficient than running or swimming. In short, the cost of transport for a flyer (in units of energy required for a bird of a given mass to travel a given distance) is appreciably less than that of a runner or a swimmer—thus, overcoming the fuel storage and use challenges of long-duration flapping flight allows migratory birds to travel far for their size.

47.2.1 Cardiovascular and respiratory general adaptations

The energetic costs of flapping flight have driven adaptive responses in the cardiovascular and respiratory systems of birds. In general, birds have larger hearts, lower resting heart rates, higher exercising heart rates, and higher $\dot{V}O_2$ max than nonflying mammals of similar size (Bishop and Butler, 2015). Adaptations in the vascular system of birds such as increased number of capillaries in each muscle fiber along with mitochondria that are in closer proximity to capillaries allows for efficient exchange of respiratory gasses (Powell, 2015). In addition, the structure of the avian respiratory system contributes to a bird's ability to efficiently exchange large volumes of gas as is needed during flight. Taken together the design of air sacs increases ventilation, the increased surface area in the lungs, unidirectional flow across the respiratory surface, and increased cross-current gas exchange with the blood all contribute to a bird's ability to obtain oxygen, supply oxygen to active tissue, and remove carbon dioxide from the blood at a greater rate than mammals of similar size (Dzialowski and Crossley, 2015; Scott et al., 2015). In general, birds are also more tolerant of hypoxia than mammals at least in part because of differences in their sensitivity to hypocapnia (low-partial pressure of arterial blood carbon dioxide (Scott et al., 2015)). Hypocapnia sensitivity of cerebral blood vessels is one of the main mechanisms in which mammals limit hyperventilation, thereby decreasing oxygen delivery to the brain, and likely limiting overall energetic output (Ogoh and Ainslie, 2009; Ainslie and Ogoh, 2010). Migratory bird insensitivity to hypocapnia especially in cerebral blood vessels allows for extreme hyperventilatory rates without blood flow interference to the brain (Faraci, 1991). In turn, this hyperventilation allows for decreased arteriole partial pressure of carbon dioxide subsequently increasing arteriole partial pressure of oxygen due to the Bohr effect (Powell, 2015). Thus, birds are able to maintain

high-oxygen delivery to tissues even in low-oxygen environments such as those at high altitudes. Additional vascular adaptations that enable birds to meet the high-oxygen demands of long-duration flight while retaining essential blood solute concentrations include an overall higher hematocrit level and greater hemoglobin concentrations (Minias et al., 2013; Bishop and Butler, 2015) compared to nonmigratory birds or mammals and the maintenance of plasma levels throughout a long flight regardless of body mass changes (Carmi et al., 1993). Monthly comparison of hematocrit of White-crowned sparrows (*Zonotrichia leucophrys gambelli*) revealed that migrant subspecies were consistently greater than residents, a difference that increased 10−15% further during both seasonal stages of migration (Krause et al., 2016). Interestingly, recent experiments that directly manipulated hematocrit in short-distance migratory Yellow-rumped warblers (*Setophaga coronata*) found that birds with elevated hematocrit performed better at simulated high altitudes (in a wind tunnel) but not at lower altitudes (Yap et al., 2018); many more such manipulative experiments are needed to better understand how variation in hematocrit affects migratory flight performance.

47.2.2 Metabolism and damage control

Mitochondria generate the cellular energy required by birds (and all animals) to fuel their basal metabolism as well as that required for all activity including flapping flight (Bottje, 2015). Associated with this role as powerhouse of the cell, mitochondria are also the major site for generation of reactive species (RS)—thus an effective antioxidant protection system has evolved to reduce or avoid the negative physiological effects of RS production, the components of which are shared by all eukaryotes (Bottje, 2015; Cooper-Mullin and McWilliams, 2016; Skrip and McWilliams, 2016). Most pertinent to our review of the physiology of long-distance migration in birds is that (a) increased metabolism, like that required for long-duration flapping flight, is associated with increased RS production which may overwhelm the antioxidant system and cause oxidative imbalance or "stress" and thus damage to, for example, lipids, proteins, and DNA in cells; (b) repair of damaged structures is energetically expensive—thus, understanding how the antioxidant system of migrating birds contends with RS production is as important as understanding how the power for long-duration flight is generated.

How birds overcome the potential constraints of redox imbalance (so-called "oxidative stress") associated with their relatively high baseline and active metabolic rates has been the subject of much conjecture (Buttemer et al., 2010; Munshi-South and Wilkinson, 2010; Jimenez et al., 2019), although recently a key adaptation of the master antioxidant response of birds has been revealed (Castiglione et al., 2020). The transcription factor NF-E2-related factor 2 (NRF2) is the major cellular pathway for regulating the antioxidant response of metazoans against oxidative imbalance within cells. Under steady-state conditions, KEAP1 binds NRF2 and keeps it at low levels in the cell. Under conditions of increased metabolic rate and thus RS production, KEAP1 repression is relaxed allowing NRF2 to accumulate, bind to an antioxidant response element, and activate expression of a host of antioxidant target genes. Castiglione et al. (2020) demonstrate that a mutation in the KEAP1 coding sequence, likely caused by intrachromosomal rearrangement, in the Neoaves ancestor has led to constitutive activation of the NRF2 master antioxidant response in living birds, and this enhanced response lowers the risk of macromolecular oxidative damage and thus a decrease in oxidative stress.

47.2.3 Immunity

The avian immune system is broadly similar between mammals and birds although most of what we know about "birds" is based on studies of domesticated chickens (reviewed in Schat et al., 2014; Kaiser and Balic, 2015). Birds and mammals have both an innate and adaptive immune response and the latter includes both cell-mediated (T-cell dependent, developed in the thymus) and humoral (B-cell dependent, developed in the Bursa of Fabricius) immune responses—note that in mammals, the B-cells are derived from bone marrow. Given the high costs of maintaining the immune system (Klasing, 2004; Hasselquest and Nilsson, 2012), birds during migration may reduce immune function to spare these costs (Hasselquest, 2007; Buehler and Piersma, 2008) or since they may encounter more pathogens they may instead upregulate immune function (Møller and Erritzøe, 1998; Buehler et al., 2010) or they could reallocate resources and so maintain immune function (Lee, 2006). The balance of evidence to date at least in terms of innate immune function suggests that it may be compromised during migration in birds (Owen and Moore, 2006; Hegemann et al., 2012; Nebel et al., 2012; Eikenaar and Hegemann, 2016) although many more such studies are needed.

47.2.4 Sensory systems and navigation

Migratory birds must be able to orient and navigate during migration, and birds have evolved several key sensory mechanisms that enable successful navigation (for example, see Mouritsen, 2015). However, this topic is beyond the scope of this chapter. Several recent reviews provide excellent entry into this realm of bird migration physiology (Berthold et al., 2003; Wiltschko and Wiltschko, 2009; Mouritsen, 2018; Muheim et al., 2018).

47.2.5 Endocrine system and the environment

Migration represents the morphological, behavioral, and physiological adaptations to seasonal environments—locations with transient resources sufficient to support breeding at one time of the year and another at a distance for survival, thus creating seasonal movements in spring and autumn. To take advantage of seasonal productivity in support of breeding and rearing young (Baker, 1938; Perrins, 1970), migratory species must maintain synchrony with the environment by relying on environmental cues in conjunction with endogenous rhythms to coordinate patterns of movement and stasis.

The endocrine system is the crucial link integrating the environmental cues with behavioral and physiological cycles that contribute to seasonal migrations. Whereas, the endocrine regulation of reproduction of Aves has been thoroughly studied, less focus and progress has been made on migration. To understand why, it is valuable to consider what migration is. It is a complicated biological process with a variety of forms extending from obligate migration that occurs on a strict time table relying on seasonally reliable resources necessary for breeding and survival to facultative forms, i.e., nomadic and irruptive movements of species that respond reactively to resources that vary unpredictably (Watts et al., 2018). Furthermore, migrations occur over multiple seasons and generations incorporating great distances, various environments, habitats, and climate. Together such variables make for a difficult system to study in its entirety. One approach that has contributed to understanding the relationship of the environment and endocrine systems is Finite State Machine Theory (Jacobs and Wingfield, 2000; Ramenofsky and Wingfield, 2007) by focusing on the unique conditions of each life history stage. For example, the life history of a calendar migrant includes two migration stages—vernal and autumnal—that occur at separate times of the year under differing environmental conditions and regulated by unique neuroendocrine mechanisms. Each stage is composed of three sequential phases—(1) development, the initiation of molecular, biochemical, and genetic processes; (2) mature capability, where all morphological, physiological, and behavioral traits are expressed and actual migration begins; and (3) termination, the disorganization of the migratory traits and beginning of the next life history stage (Figure 47.1). Each phase is regulated by the environmental-endocrine nexus that affects its timing and progression. Current knowledge of the mechanisms regulating the two stages are not thoroughly defined but presenting migration in this format provides an integrated focus for future studies.

47.3 Endocrinology of migration

47.3.1 Vernal stage

47.3.1.1 Synchronization with the environment: initial predictive cue

Though not thoroughly known for all migratory species, a general consensus from many is the cue response to the vernal increase in daylength or photostimulation (Rani and Kumar, 2014; Hahn et al., 2015). The mechanism involves coincidence of the light phase of the photoperiod occurring during the peak of the circadian rhythm of photosensitivity that takes place for most species between 12 and 15 h after dawn. The reaction resides in the extraretinal photoreceptors of the basal hypothalamus in association with the putative photopigments VA opsin and Rod opsin which are

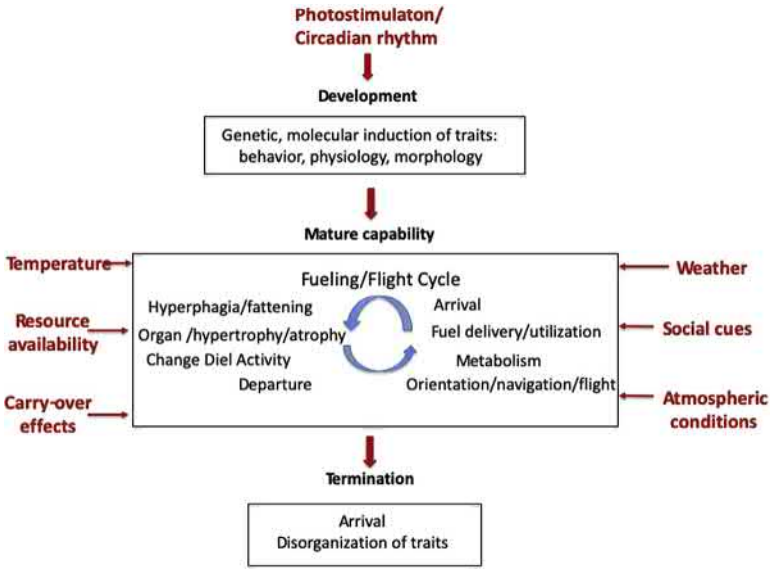

FIGURE 47.1 Three phases of the migration life history stage. Initial predictive cue of photostimulation induces the development phase and continues its effect throughout the entire stage. Local environmental and conditional cues (*red font*) affect the rate of progression through the substages of mature expression and termination.

co-expressed in the gonadotropin-releasing hormone (GnRH) and arginine vasotocin neurons (Follett et al., 1974, 1998; Meddle et al., 1997; Rastogi et al., 2013). Evidence of photostimulation was demonstrated in the First-day Release Model in which activation of the early immediate gene (*c-fos*) was detected 18 h after dawn of the first long day indicating cellular activity in the basal tuberal hypothalamus of Japanese quail (*Coturnix c. Japonica*) (Meddle et al., 1997). As a result, plasma levels of luteinizing hormone from the anterior pituitary could be detected at 22 h after dawn that in turn induced synthesis and secretion of testosterone from the gonads affecting both migration and breeding life history stages. Given that one cue, photostimulation, initiates both migration and breeding life history stages, the question becomes how are they separated to occur sequentially? Photostimulating white-crowned sparrows with low-penetration green light Wang et al. (2013) was able to separate photoperiodic responses of the migration and breeding stages. Birds developed migratory traits of mass increase, fattening, and nocturnal migratory restlessness but without gonadal recrudescence. Separation of the neuroendocrine control over initiation of migration and breeding have further support from the electrolytic lesion studies in the distinct locations of the hypothalamus in both White-throated, *Zonotrichia albicollis*, and white-crowned sparrows that demonstrated separate pathways for migratory fattening and restlessness versus gonadal development (Kuenzel and Helms, 1967; Stetson and Erickson, 1972; Yokoyama, 1976). Taken together these results suggest separate locations for photoreception and transduction for the two stages: one regulating the migratory life history and the other a more attenuated response of gonadal development and eventual breeding.

47.3.1.2 Developmental phase: hyperphagia and fattening

The initial response to photostimulation is increased food intake—hyperphagia—that leads to elevated body mass and fat stores providing fuel, lipid, and protein to support migratory flight (Ramenofsky, 1990; Lindström and Piersma, 1993). Unlike other homeostatic processes, the alterations of body mass during migration is regarded as rheostasis where the *set point* of body mass is defended but fluctuates throughout the fueling flight cycles of the stage (Mrosovsky, 1990; Jenni et al., 2000; Cornelius et al., 2013; Boswell and Dunn, 2015). The hormone action of these processes is not thoroughly understood for most migratory species but the basic principles are drawn from migratory European quail (*Coturnix coturnix*) and domesticated fowl that focus on the gene expression of opposing sets of neurons of the central melanocortin system in the arcuate nucleus of the mediobasal hypothalamus and considered the control center for body weight (Boswell, 2005; Boswell and Dunn, 2015) (Figure 47.2). Two neuropeptides synthesized in the arcuate nucleus—neuropeptide Y (NPY) and agouti-relate protein (AGRP)—act to promote feeding and mass gain. Opposing these actions are the interconnected neurons that express pro-opiomelanocortin (POMC) and cocaine-and amphetamine-regulated transcript (CART) genes. Given its basal position in the hypothalamus, the arcuate nucleus sits adjacent to the third ventricle and median eminence where the neurons are exposed to circulating levels of proteins, metabolites, and hormones that provide peripheral information. The arcuate nucleus expresses receptors for such metabolic compounds as cholecystokinin (CCK), ghrelin, corticosterone, insulin, and leptin and may serve as interpreters of metabolic state with regulatory capacity to promote or inhibit food intake via the NPY, AGRP or POMC, and CART pathways. Empirical studies using intracerebroventricular (ICV) injections into White-crowned sparrows report that while NPY stimulated food intake, the octapeptide CCK inhibited offering further support for the diverse pathways of control for feeding in a migratory bird (Richardson et al., 1992, 1993).

47.3.1.3 Thyroid hormones

Thyroid hormones play broad regulatory roles in avian physiology including metabolism, thermoregulation, breeding, molt, and migration (Groscolas and Leloup, 1986; Jenni-Eiermann et al., 2002; Zeng et al., 2013). In older literature, migratory fattening and restlessness were associated with elevated activity of the thyroid gland (Wingfield et al., 1990). Additionally, measurements of

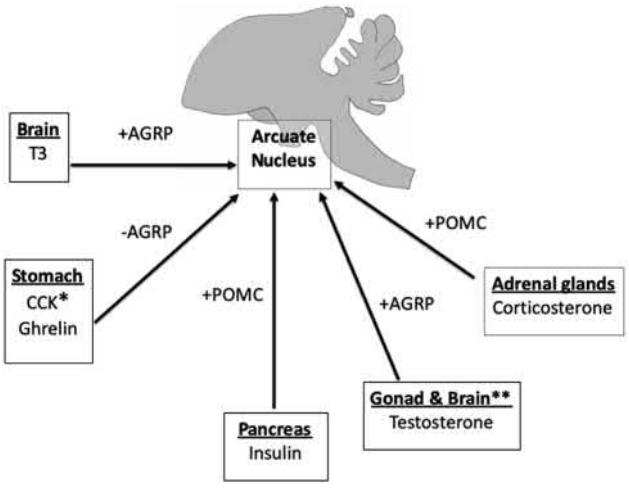

FIGURE 47.2 Suggested model for the endocrine influences on food intake via neuropeptides in the arcuate nucleus of the avian hypothalamus, * Synthesized both in gut and brain, ** possible pathway. *Adapted from Boswell and Dunn (2015).*

plasma levels of thyroxine (T4) and triiodothyronine (T3) were increased during the early stages of vernal migration (Chandola and Pathak, 1980; Smith, 1982; Pant and Chandola-Saklani, 1993). More recently, chemical inhibition of thyroid hormone disrupted prenuptial molt, fattening, mass gain, flight muscle hypertrophy, expression of migratory restlessness, and gonadal recrudescence while administration of T4 reversed these effects (Pérez et al., 2016, 2018). These results indicate a major role for thyroid hormones across the vernal stage.

Regarding photostimulation, thyroid hormones are considered central to molecular mechanisms regulating breeding (Rani and Kumar, 2014, Boswell and Dunn, 2017; Pérez et al., 2018). For a number of seasonally breeding birds, photoperiod is linked to release of thyroid-stimulating hormone (TSH) from the pars tuberalis of the pituitary gland. TSH stimulates expression of the biosynthetic enzyme Type II iodothyronine deiodinase to direct conversion of T4 to the biologically active T3 in the mediobasal hypothalamus that, in turn, stimulates release of GnRH from the median eminence to initiate breeding (Hahn et al., 2015; Nishiwaki-Ohkawa and Yoshimura, 2016). Evidence is accruing in Siberian hamsters and domestic chicks that the hypothalamic T3 may also exert effects on food intake and fattening through the AGRP neurons of the arcuate nucleus (Boswell and Dunn, 2017) (Figure 47.2). Whether these effects take place with photostimulation during migration are unknown but currently under investigation in a First-day Release Model with acute photostimulation of short-day white-crowned sparrows that will test directly whether long-day exposure induces expression of AGRP and increases food intake in the vernal stage.

47.3.1.4 Testosterone

Additionally, testosterone is implicated in regulating spring fattening. In a number of species, low levels of testosterone circulating during the winter stage are necessary for expression of hyperphagia and fattening in both sexes in the vernal but not the autumnal stages (Schwabl and Farner, 1989; Wingfield et al., 1990; Deviche, 1995; Ramenofsky and Nemeth, 2014), a condition challenged by others (Weise, 1967; Boswell et al., 1993). The mechanism by which testosterone could influence migratory fattening is through the androgen receptor (AR) on the arcuate nucleus stimulating the AGRP/NPY/feeding center pathways, as documented in mammals (Diano et al., 1997) (Figure 47.2). The timing of this effect is not known but could vary across migratory species.

47.3.1.5 Insulin and glucagon

The pancreas is the source of 3 proteins, insulin, glucagon, and pancreatic polypeptide; the former two are considered major regulators of food intake in birds acting directly and/or through their effects on carbohydrate and lipid metabolism (Hazelwood, 2000). Only a few studies have investigated these in migrating birds (Goodridge, 1964; Totzke et al., 1997; Cornelius et al., 2013). What is known is that insulin and glucagon have opposite effects on plasma glucose that in turn may influence food intake. Surprisingly, intramuscular injections of either glucagon or insulin decreased feeding in captive white-crowned sparrows (Boswell et al., 1995). Plasma glucose is exceedingly high in birds even though plasma insulin falls within the normal range suggesting peripheral insensitivity to insulin (Sweazea et al., 2006). ICV administration of insulin increased feeding indicating a marked diversion from mammals and suggesting central control of food intake by insulin (Boswell et al., 1995). Besides its effect on carbohydrate metabolism, glucagon has a biphasic effect on lipid production. At elevated levels, glucagon promotes lipolysis enhancing release of free fatty acids (FFAs), a source of energy, into the circulation. At lower range, this is reversed with increased lipogenesis and fat storage (Goodridge, 1964). Testing the effects of metabolites on feeding reported a predominant sensitivity to lipid as opposed to carbohydrate, a reasonable conclusion given the major role that lipid plays during migration (Boswell et al., 1995). Taken together, it is suggestive that glucagon levels cycle throughout migration with lowest levels occurring during the migratory fattening to support lipogenesis countered by elevated levels during flight promoting lipolysis making fatty acids available for oxidation (Goodridge, 1964). More comprehensive studies on the pancreatic peptides are needed.

47.3.1.6 Glucocorticoids (Box 47.1)

Corticosterone in birds has long been associated with hyperphagia, fattening, and stress physiology in migrants, but results across numerous studies and species have not revealed consistent patterns (Landys et al., 2006; Ramenofsky, 2011; Wagner et al., 2014; Eikenaar, 2017). One of two views contributing to these divisions is the Migration Modulation Hypothesis (Holberton et al., 1996) that addresses stress physiology with the hypothesis that neotropical migrants would not show the expected stress response to capture and handling with two predictions: (1). baseline levels of corticosterone remain elevated during migration to promote hyperphagia and lipogenesis, (2). suppression of the stress response to avoid the deleterious effects of catabolism on flight muscle (Long and Holberton, 2004). The alternative view is that most migrants display a robust stress response throughout migration with plasma levels varying seasonally across the stages and in healthy birds within physiological range (Level B (Box 47.1)). Corticosterone concentration is

BOX 47.1 Aligning corticosterone, physiological state, and allostasis.

Corticosterone, the predominant adrenal steroid of birds, is associated with many aspects of the migration life history stage including behavior, metabolism, and allostasis—measure of energy requirements over time (Blas, 2015; Ramenofsky, 2011; Landys-Ciannelli et al., 2002; Romero et al., 1997). Corticosterone acts in concert with other metabolic hormones such as CCK and insulin by regulating availability of energy in the forms of circulating FFAs and glucose to maintain homeostasis (Eikenaar, 2017). To fully appreciate the multiple functions and levels of control of corticosterone, we refer to the hypothalamus-pituitary-adrenal (HPA) axis by considering its actions at three physiological states and hormone levels. Level A is considered the basic homeostasis that maintains life (Romero et al., 2009). Level B involves the activation of the HPA for fluctuations in response to predictable, daily or seasonal demands for energy, allostatic load, across the annual life history stages. Level C, further activation of the HPA that tend to be transitory as the individual reacts to an acute and unpredictable event or stressor. The induced behavioral response is to move away or adopt an emergency life history stage (ELHS) to alleviate effects of the stress (Romero and Wingfield, 2016). To assess function of the HPA axis, two measurements of circulating corticosterone are collected: the first is the baseline measure collected within the first 3 min of capture and reflecting the current and unprovoked energetic state of the organism. The second sample is the acute or Level C collected at the peak of the response to capture and handling indicating the maximal response of the corticosterone synthesis and secretion (Figure 47.3).

regulated by the enzyme 11β-hydroxy steroid dehydrogenase, and it acts through two cellular receptors, the high-affinity mineralocorticoid receptor (MR) and low-affinity glucocorticoid receptor (GR). Considering these multiple levels of control, corticosterone is regarded as a pleiotropic hormone with multiple effects acting in permissive roles with critical metabolic compounds that affect energy balance and allostasis including: insulin, insulin-like growth factor-1, adipose tissue lipoprotein lipase, low-density lipoprotein, FFA, NPY action (Savard et al., 1991; Remage-Healey and Romero, 2001; Landys et al., 2004a, 2006; Blas, 2015; Mishra et al., 2017), and growth hormone (GH) (Tsipoura et al., 1999). All of which contribute to the complexity and often confusion over corticosterone's action. Taking a more comprehensive view of the interactions of hormones and metabolic compounds in terms of allostasis and stress at each substage may provide a more complete assessment of the role of this steroid in migration.

47.3.1.7 Leptin

The protein hormone leptin is known as a strong regulator of energy balance in mammals synthesized almost exclusively in the adipose tissue and signaling presence or deposition of fat—positive energy balance (Zhang et al., 1997). Thus it is considered a hormone with autocrine, paracrine, and endocrine functions promoting homeostasis of energy stores and has been coined an *adipostat* in mammals regulating food intake according to energy balance—fat content (Friedman-Einat et al., 2014; Friedman-Einat and Seroussi, 2019). Recent identification in birds of a leptin ortholog and characterization of leptin activity has questioned whether it functions either as a hormone or an *adipostat*. The leptin ortholog shows no expression in adipose tissue but is found in brain, adrenal gland, and gonad. So far, the avian leptin receptor LEPR is expressed only in the pituitary. Given these diversions from mammals, it is unlikely that avian leptin is acting as an homeostatic adipostat and offers preliminary support for the Rheostasis Model during migration that would allow for greater range of body mass and fat stores (Cornelius et al., 2013; Friedman-Einat et al., 2014; Watts et al., 2018).

47.3.1.8 Ghrelin

Acting in opposition to leptin, this 28-amino-acid peptide is secreted from the stomach and other digestive organs of birds when body condition is low. Ghrelin is reported to be a GH-releasing factor in chickens and mammals that relays information to the arcuate nucleus of nutritional state. In rats, both intraperitoneal (IP) and ICV injections of ghrelin increased food intake. This effect is most apparent during fasting with ghrelin acting on the NPY/agouti-related peptide (AGRP) neurons in the arcuate nucleus (Nakazato et al., 2001). In quail, plasma ghrelin was elevated in fasted

birds but dropped once feeding commenced. The results obtained with injections were less clear; at low concentrations, IP injections enhanced feeding but at greater dosages both IP and ICV injections decreased feeding suggesting a biphasic effect. Other studies in which ghrelin was administered reported that food intake in neonatal chicks was inhibited (Kaiya et al., 2009). Although presently controversial in domestic fowl, these results suggest that ghrelin could regulate feeding during migration, particularly when birds are lean, as they would be following flight. In a recent study, lean Garden warblers, *Silvia borin* captured in the morning upon arrival at a stopover site on the Mediterranean Island of Ponza measured elevated plasma levels of the acylated ghrelin (Goymann et al., 2017). After refueling throughout the day in captivity, injections of the unacylated form of ghrelin decreased food intake and increased migratory restlessness at night pointing to either a biphasic effect on behavior of hormone concentration or different responses to the chemical forms of the hormone. By contrast, plasma ghrelin was not associated with nocturnal departure in fully fattened European blackbirds (*Turdus merula*) at an autumn stopover (Eikenaar et al., 2018b). These outcomes may represent species or seasonal differences calling for a more complete understanding of ghrelin's role during migration.

47.3.1.9 Prolactin

Understanding prolactin's role in migratory feeding and fattening has been problematic. Administration of this pituitary protein increases fattening in a number of migratory species (Meier and Farner, 1964; Yokoyama, 1976). Also, central effects of prolactin have been identified in specific sites of the hypothalamus of migratory and nonmigratory birds (Yokoyama, 1976; Buntin et al., 1993). Prolactin levels, like other pituitary hormones, vary seasonally as photostimulation induces secretion of vasoactive intestinal peptide, the stimulatory hypothalamic neuropeptide that induces production and secretion of prolactin from the pituitary (Figure 47.4). This information led to the hypothesis that prolactin could be acting in conjunction with gonadal steroids and corticosterone that were also elevated with photostimulation to induce migratory fattening and restlessness. However, questions have been raised in a number of migrants as the photoinduced peak of prolactin corresponds only weakly with onset of feeding, fattening, and migratory restlessness (Hall and Gwinner, 1987; Schwabl et al., 1988; Holberton and Dufty, 2005). Timing of peak prolactin levels appears to align its function with the autumnal stages of refractoriness and postnuptial molt (Dawson et al., 2001). So, even though prolactin injections increase fattening in birds, prolactin function in relation to migratory fattening is far from resolved.

47.3.1.10 Hormones of flight muscle hypertrophy

In addition to fueling, the pectoralis flight muscles undergo hypertrophy in numerous migratory species (Fry et al., 1972; Driedzic et al., 1993; Jehl, 1997; Bauchinger et al., 2005; Banerjee and Chaturvedi, 2016) during migration that entails increased size of the muscle fibers serving to enhance contractile force and flight performance (Marsh, 1984; Gaunt et al., 1990; Evans et al., 1992; Vezina et al., 2021) (Ramenofsky et al., in prep). Though not well

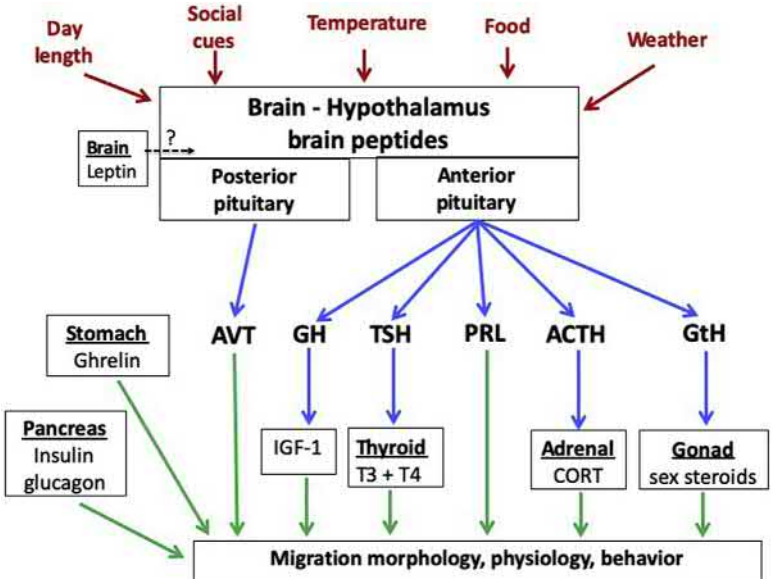

FIGURE 47.4 Flow chart of the environmental cues on the neuroendocrine—endocrine system influencing migratory morphology, physiology and behavior. *Red arrows*—environmental cues influence the activity of hypothalamic brain peptides, *Blue arrows*—pituitary hormones regulated by the brain peptides affect peripheral endocrine glands. *Green arrows*—hormones of the endocrine glands regulate migratory functions. Role of leptin at present is uncertain (Friedman-Einat and Seroussi, 2019).

understood in migratory birds, anabolic steroids—testosterone and 5α-dihydrotestosterone (DHT)—are likely candidates for regulating phenotypic changes given reports of AR gene increasing expression in flight muscles of Golden-collared manakin (*Manacus vitellinus*) during sexual displays (Fuxjager et al., 2012). Furthermore, elevations of androgen signaling via DHT, AR mRNA and the androgen dependent gene, insulin-like growth factor 1, showed increased levels of expression in White-crowned sparrows at spring departure when flight muscles were enlarging (Pradhan et al., 2018). Regulation of muscle hypertrophy could be a function of vernal photostimulation that activates androgen secretion and gonadal recrudescence (Blanchard and Erickson, 1949; Wingfield et al., 1990; Bauchinger et al., 2007). Or it is possible that testosterone secreted during the winter stage has an early priming effect on muscle as it does on fattening (Wingfield et al., 1990), something that is unknown at present. Nevertheless, the circulating levels of androgen are low as birds prepare for vernal departure suggesting intramuscular cell signaling pathways may direct muscle remodeling and thus avoiding the systemic and behavioral effects if levels of androgen were elevated at this substage (Bauchinger et al., 2007; Pradhan et al., 2018). In addition to androgen, corticosterone is implicated in flight muscle hypertrophy at vernal departure. Elevation of baseline corticosterone was associated with increased expression of the high-affinity MRs expression in White-crowned sparrows (Pradhan et al., 2019). This relationship is thought to promote the anabolic stimulation of the muscle fibers, contributing to hypertrophy. Such effects are not known for the autumnal stage.

In addition to the phenotypic changes orchestrated by the endocrine system, integral components of the muscle fibers alter during this vernal substage. Myosin heavy chain (MyHC) expression is associated with the muscle's mechanical capabilities (Reiser et al., 1996). Changes in the expression of the MyHC isoform during the development phase may represent an adaptation for upgrading the muscle mechanics for impending long-distance flight (Velten et al., 2016). Again, hormonal mechanisms regulating these molecular processes are not known but deserve further study during the autumnal stage.

47.3.1.11 Mature expression—hormones of the fueling and flight cycle

Stopover in both the vernal and autumnal stages provides the clearest example of the fueling and flight cycle as flight temporarily ceases upon arrival for rest, fueling, and then departure (Delingat et al., 2006, 2009) offering an excellent opportunity for tracking metabolic hormones. During the 4500 km journey from Africa to a stopover site along the northern Dutch coast in spring, Bar-tail godwits (*Limosa lapponica*) cease travel for approximately one month to rest, continue prenuptial molt and refuel before continuing northward to the breeding grounds. One indication that baseline corticosterone levels align with allostatic load was noted initially by Landys-Ciannelli et al. (2002). Birds arrived in lean condition having lost on average 55.3% from their African departure body mass with elevated baseline levels of corticosterone suggesting a heightened allostatic load resulting from the "wear and tear" of a long continuous flight. Similarly, elevated baseline levels are reported in recently arrived Semipalmated sandpipers at a vernal stopover in Delaware Bay (Tsipoura et al., 1999), Gray Catbirds (*Dumetella carolinensis*) along the Gulf Coast of the United States (DeSimone et al., 2020), and Garden warblers on the Mediterranean Island of Ponza (J. Wingfield and M. Ramenofsky, in preparation). Measurements of body mass of the sandpipers throughout the period of arrival varied over a range of 10 g indicating the different stages of recovery of birds across the flock. Over this period plasma GH was negatively correlated with mass. Given the lipolytic functions of GH, the data suggest hormone action would supply fatty acids to meet the energetic demands of flight and arrival until sufficient refueling achieved positive energy balance observed in the heavier birds of the flock (Tsipoura et al., 1999). During the refueling phase of the godwits, the baseline corticosterone declined 55% from arrival. The corticosterone response levels of both the refueling and arriving birds were similar, however the peak for the arriving birds reached their maxima more rapidly suggesting a heightened sensitivity of negative feedback possibly related to allostasis and/or CNS functions required for flight (Landys-Ciannelli et al., 2002; Eikenaar et al., 2013; Romero and Wingfield, 2016). Once refueling achieved positive energy balance, godwits became aphagic while digestive organs atrophy to conserve body mass and metabolic costs for the ensuing flight (Piersma, 1998; McWilliams and Karasov, 2001). Baseline corticosterone increased around the time of departure and has been associated with the upregulation of HPA for regulating metabolic and behavioral functions for impending flight and organ remodeling (Reneerkens et al., 2002b; Eikenaar et al., 2013, 2018a; Pradhan et al., 2019). However, such upregulation was not identified in the short-hop migrant, Gray catbird (DeSimone et al., 2020) suggesting a divergence in preparation for flight depending upon species and migratory strategy. Nonetheless, studies of both captive and free-living migrants offer further support for the association of corticosterone with expression of migratory flight in the vernal and autumnal stages (Schwabl et al., 1991; Ramenofsky et al., 1999; Landys et al., 2004b; Falsone et al., 2009; Eikenaar et al., 2014; Ramenofsky and Wingfield, 2017). Taken together the results from these studies offer insight into the effects

of corticosterone and GH, providing endocrine support for the behavioral and metabolic processes during flight, at arrival, and preparation for departure during stopover.

47.3.1.12 Termination: arrival biology

Reaching the breeding grounds heralds the termination phase that includes the substage of arrival biology (Wingfield et al., 2004). This substage requires flexibility and coordination of morphology, behavior, and physiology given the quixotic environmental conditions birds may face in early spring. Observational studies note that migratory behavior changes as birds approach breeding areas and begin to search widely for optimal habitats (Hahn et al., 1995). Studies of captive birds, report changes in intensity of migratory restlessness and orientation near the conclusion of the migratory period, suggesting transition to more wandering and searching behaviors expressed even in captivity (Helms, 1963; Wiltschko et al., 1980; Ramenofsky et al., 2003). Elevated corticosterone during arrival has been proposed to support these behaviors (Ramenofsky, 2011, 2012; Romero and Wingfield, 2016) providing examples of the pleiotropic effects of corticosterone influenced by its multiple sites of control at the enzymatic, receptor, and state levels.

Field studies document that winter conditions may prevail at high altitudes and latitudes after birds arrive with storms likely forcing delay of the onset of breeding (Morton, 2002). In these cases, migrants retain elevated levels of corticosterone that promote escape to refuges until conditions on the breeding grounds improve (Reneerkens et al., 2002a; Hahn et al., 2004; Ramenofsky and Wingfield, 2007; Cornelius et al., 2013; Ramenofsky and Wingfield, 2017).

Throughout the vernal stage, hypothalamic-pituitary-gonad (HPG) axis function progresses with increasing levels of gonadotrophin (GtH), testosterone, and DHT, so males are ready to breed once females arrive and environmental conditions allow (Wingfield and Farner, 1978a; O'Reilly and Wingfield, 1995; Ramenofsky and Wingfield, 2006; Covino et al., 2015, 2017; Lymburnera et al., 2016). For females, the story differs as the final stages of oogenesis, yolk deposition, egg laying, and behaviors regulated by estrogen and progesterone are held in check under the regulation of the hypothalamic peptide gonadotropin-inhibiting hormone (GnIH) (Tsutsui et al., 2000; Bentley et al., 2009). This peptide is thought to act as a "brake" on reproduction by its central effects on sexual behavior and hypophysiotropic control of steroidogenesis and ovulation (Wingfield et al., 2016). Under extreme conditions, interactions of elevated corticosterone and GnIH may serve to extend the more mobile or nomadic phase of arrival biology until conditions improve sufficiently for GnIH levels to decline and activation of the breeding stage to proceed. Regulation of GnIH function is not well understood, but environmental conditions appear to play a major role guiding synchronization of egg laying with the potential peak of food abundance (Perrins, 1970; Ramenofsky and Wingfield, 2017). Onset of breeding marks the termination of the vernal migratory stage.

47.3.2 Autumnal stage

47.3.2.1 Development phase

In many ways, autumnal migration appears similar to that of the vernal stage, as it can be divided into the same three phases. The traits are similar that include hyperphagia, fattening, organ remodeling, fueling flight cycles, etc. But major differences exist that provide important clues to the endocrine regulation and biological significance of each stage. For example, the recognized mechanisms that regulate activation of the vernal stage are not operating in the autumnal stage. Daylength is decreasing rather than increasing and many migrants are known to be photorefractory with a loss of responsiveness of reproductive development to long photoperiods (Dawson et al., 2001). The HPG regresses with circulating levels of GtHs and gonadal hormones decline to basal precluding further breeding attempts late in the season. For most species, both baseline and response levels of corticosterone have dropped from elevated breeding titers.

47.3.2.2 Thyroid hormones

A number of seminal studies of captive birds have identified that the rate of increase of vernal photoperiods during photostimulation exert latent effects on the timing of photorefractoriness followed by the autumnal events of postnuptial molt and migration (Farner and Follett, 1966; Gavrilov and Dolnik, 1974; Dolnik, 1980; Moore et al., 1982, 1983). Thyroid hormones are considered central by playing organizational roles for both vernal and autumnal stages during photostimulation (Dawson et al., 2001; Pérez et al., 2016, 2018). Timing of the thyroid organizational effects is considered the basis for the separate pathways of control for the two stages (Wilson and Reinert, 1996, 1999). A further understanding is now needed for the hormonal and genomic mechanisms underlying the potential roles for thyroid hormones during autumnal migration.

47.3.2.3 Androgen

Unlike in spring, plasma levels of androgen in the autumn are basal and probably not capable of activating feeding centers in the hypothalamus. Furthermore castration during the previous winter months had no effect on autumnal fattening in white-crowned sparrows (Wingfield et al., 1990). However, both androgen and estrogen are

synthesized locally in the brain and affect autumnal behavior (Soma et al., 2002; Pradhan et al., 2010). So, it is possible that neurosteroids (steroid synthesized in the brain) could influence the arcuate nucleus via AGRP as in spring (Boswell and Dunn, 2015) to affect autumnal hyperphagia and fattening. Whether the molecular pathways associated with vernal flight muscle hypertrophy operate during the autumnal stage are unknown at present but represent intriguing possibilities.

47.3.2.4 Glucagon

One of a very few studies investigating glucagon in migratory birds during the autumnal stage in comparison with winter identified a decrease in plasma levels of glucagon and FFA in captive Red-winged blackbirds (*Agelaius phoeniceus*) while fattening for autumnal migration (Hintz, 2000). Although a surprising result, Goodridge (1964) suggested previously that seasonal patterns of circulating levels of glucagon could contribute to fluctuations in adiposity with elevated levels promoting lipolysis to mobilize energy to fuel such activities as thermogenesis during winter months and lower titers to enhance fat storage for migration. Further studies are needed to more clearly define the roles of glucagon during the autumn stage.

47.3.2.5 Mature expression—hormones of the fueling and flight cycle

Field studies focusing on the transition from breeding to autumnal departure identified that birds express individual schedules that vary according to investment and timing of breeding, molt, social interactions, age, body condition as well as local weather and wind direction (Runfeldt and Wingfield, 1985; Morton and Pereyra, 1994; Bonier et al., 2007; Sjoberg et al., 2015; Chmura et al., 2020). This asynchrony across individuals deviates markedly from the highly synchronous schedules birds express in spring driven by the initial predictive cues and strong selective pressure for birds to arrive on the breeding grounds as early as feasibly possible for reproductive advantage (Smith and Moore, 2005). Investigating the differences may help to further identify the regulatory distinctions of the two stages but very few studies have focused on seasonal comparisons at time of departure (Wingfield and Farner, 1978a).

Among the overland migrant populations of White-crowned Sparrow, body mass and fat scores reached their annual peak just prior to departure, a time when plasma levels of baseline and response corticosterone are comparable with the vernal and autumnal values but at significantly lower levels than the annual peaks reached upon arrival on the breeding grounds and during early stages of breeding (Wingfield and Farner, 1978a; 1978b; O'Reilly and Wingfield, 1995; Krause et al., 2021). By contrast, in trans-hemispheric migrant Barn swallow (*Hirundo rustica*), the baseline levels of corticosteron prior to spring departure exceeded the values in autumn, while the response levels of autumn rose above vernal values (Raja-Aho et al., 2013). Body condition of spring birds was poor compared to autumn leading to question the role of corticosterone at the time of departure. Given the disparate results across the two species it is clear that additional studies of the physiological condition and endocrine state of birds at departure in the vernal and autumnal stages require further investigations.

47.3.2.6 Stopover: arrival

As in spring, the autumnal stopover substage provides advantageous views of the behavioral, physiological, and endocrinological states upon arrival and at departure. A pattern of elevated baseline and response corticosterone levels has been recorded in some but not all migratory species with greater titers measured in vernal than in autumnal stages (O'Reilly and Wingfield, 2003; Romero et al., 1997; Loshchagina et al., 2018; Bauer et al., 2019). When seasonal differences are detected it is suggested that allostatic load of vernal migration for these species exceeds that of autumn. Impending breeding, unpredictable and unfavorable climatic conditions and less reliable sources of food are some of the issues migrants face at higher altitudes and latitudes in spring. In species that cross extreme barriers (oceans and deserts) with routes that are comparable in both seasons, the baseline levels corticosterone may not vary to any great extent. However another mechanism for differential regulation of corticosterone is presented in Dark-eyed junco sampled during spring and autumn stopovers (Bauer et al., 2019). Neither baseline nor response corticosterone varied seasonally but negative feedback was weaker in spring than autumn suggesting a greater response to environmental purturbations. Surprisingly, these findings diverge from the increased sensitivity to capture in the spring arriving Bar-tailed godwits in comparison with refueling birds and possibly suggests a species or migratory strategy difference.

Thus, a more consistent theme arising from a variety of species captured during autumnal migration indicate only moderate elevations of baseline corticosterone, suggesting an allostatic load that falls substantially below stress-induced values Level C (Schwabl et al., 1991; Gwinner et al., 1992; Falsone et al., 2009). At such titers, corticosterone may serve to support metabolic processes supplying energy required for endurance flight in terms of protein-mediated transport of fatty acids into flight muscle and high-oxidative capacity (Lundgren and Kiessling, 1985; McFarlan et al., 2009; Price et al., 2010). Yet, a few extreme cases are reported of birds captured in flight in nearly starved condition with depleted stores of fat, atrophied flight muscle, and baseline corticosterone titers that

reach well into the realm of the acute response to stress Level C (Box 47.1). Fat stores are considered key regulators of systemic protein catabolism that can affect allostatic load, plasma corticosterone, and potentially survival (Schwabl et al., 1991; Jenni and Jenni-Eiermann, 1992; Schwilch et al., 2002; Falsone et al., 2009). Such elevated baseline levels indicate that an individual has entered the ELHS in which corticosterone metabolically promotes protein catabolism and directs a change in behavior from landing to foraging enabling recovery as long as sufficient resources can be accessed (Romero and Wingfield, 2016).

47.3.2.7 Stopover: departure

At departure from stopover sites, birds are metabolically ready for flight with elevated body mass, fat deposits, circulating triglyceride levels, and hypertrophied flight muscle (Sandberg et al., 2002; Fusani et al., 2009; Goymann et al., 2010; Covino and Holberton, 2011). Additionally, baseline levels of corticosterone correspond with orientation at take off and environmental cues conducive for flight namely favorable winds (Lohmus et al., 2003; Eikenaar and Schmaljohann, 2015; Eikenaar et al., 2017b, 2018a). In captive migrants, expression of nocturnal migratory restlessness coincides with increased baseline corticosterone (Ramenofsky and Wingfield, 2017). Taken together, departure involves the interactions of the environment, endocrine system, physiological state, and motivation to fly. The causal relationship of these variables remains to be elucidated fully.

47.3.2.8 Termination—arrival

Generally, arrival at the overwintering sites marks the end of autumnal migration with the loss of such traits as hyperphagia, fattening, flight muscle hypertrophy, and nocturnal restlessness (Romero et al., 1997; Ramenofsky, 2011). For the most part overwintering sites provide sufficient resources for survival but competition for access to roosts sites, quality food, and protection from predators can be intense given presence of resident birds as well as potential influx of breeding birds from the opposite hemisphere (Newton, 2008). Unlike the vernal stage, autumnal arrival is less synchronized, more facultative, and birds may not settle for weeks (Watts et al., 2018). To avoid competition, some cohorts arrive early or continue movement to locate in areas where food is more abundant and environmental conditions less harsh, as noted in the differential migration patterns (Ketterson and Nolan, 1976; Terrill, 1990; Newton, 2008). Given the degree of competition for resources at this stage, it is surprising that levels of androgen and corticosterone levels are basal (Wingfield and Farner, 1978a, b; Romero et al., 1997; Krause et al., 2021). However, the prospects that neurosteroids may be influencing behavior is a possibility but unknown to date. Also, involvement of the metabolic hormones is unclear emphasizing the need for more research during the autumnal stage.

47.3.3 Conclusions to endocrine system

Comparing vernal and autumnal life history stages of migration offers insight into the adaptations of each providing a fuller appreciation of the migratory processes as a whole. In general, there are common traits that support movement in either season that include an engine (muscle) for power, fuel supplies, oriented movement, and a clock (Piersma et al., 2005; Ramenofsky and Wingfield, 2007; Dingle, 2014). Specifically, the two stages and their substages diverge in terms of the environmental conditions encountered, types of available resources, reproductive states, endocrine status, age groups participating, and in many cases the migratory routes. These differences are the most revealing as they convey individual and/or population responses to the selective pressures of the environment, season, fitness, and survival supporting the premise that the two migratory stages are distinct adaptations. But before any conclusions can be fully drawn, more thorough coverage of the endocrinology of the autumnal stage is needed in addition to the studies that track plasma levels of hormones over the course of each stage. Together these points emphasize more work is needed that focuses on the molecular and genomic aspects of the endocrine system, receptor expression, and the metabolic enzymes all playing key roles in determining hormone action during both the vernal and autumnal stages as reported by (Sharma et al., 2018). Such integrative studies will provide a more complete understanding of how the environment influences migration and how individuals will cope with the challenges of climate change.

47.4 Physiological aspects of migratory preparation and long-duration flight: fueling/flight cycle

47.4.1 Introduction

Given that the vernal and autumnal migration stages occur at separate times of the year under differing environmental conditions and evidence to date suggests that the two stages are regulated by unique neuroendocrine mechanisms, we would expect some important differences in the physiology of birds during the two migration stages. In general, physiological ecologists who study migration in birds pay attention to the season in which birds are studied, but few studies have focused on how the physiology of migratory birds differs between vernal and autumnal migration. This paucity of information about the mechanistic underpinnings of physiology during the two migration stages has led us to

organize the following section around several themes (feeding and diet selection, fuel storage and fat quality, fuel use and oxidative balance) that we assume to be relatively common to both migration stages, but that may be produced by different gene-to-physiology-to-behavior mechanisms.

47.4.2 Feeding

47.4.2.1 Hyperphagia

During spring and fall migration, migratory birds increase their daily food intake (e.g., hyperphagia) in an effort to increase energy stores (fattening) to fuel their migratory flights (Odum, 1960; King and Farner, 1965). These periods of intensive feeding and fattening can last a few days to several weeks (Schaub and Jenni, 2001; Chernetsov and Mukhin, 2006; O'Neal et al., 2018), and the duration is influenced by a variety of ultimate and proximate factors such as migration strategy (e.g., long-distance, short-distance), weather, food availability, predation risk, endogenous cycles, and physiological state (Jenni and Schaub, 2003; Fusani et al., 2009; Goymann et al., 2010; Guillemette et al., 2012; Hou and Welch, 2016). For many species, the total duration of migration is composed mostly of time spent at stopovers and not in flight itself (Wikelski et al., 2003). Thus, much of the hyperphagic periods of most birds are at stopover sites. For several species of dabbling ducks, for example, the average stopover duration was 28 days and was heavily correlated with habitat quality and the availability of food (O'neal et al., 2018). In contrast, the primary predictor of stopover duration in several species of songbirds was dependent upon the amount of fat reserves when all other factors such as weather, predation, and food availability were equal or controlled (Fusani et al., 2009; Goymann et al., 2010; Smith and McWilliams, 2014) although this generalization is based almost entirely on correlational rather than empirical experiments (Smith and McWilliams, 2014).

47.4.2.2 Balancing the energy costs of hyperphagia

Hyperphagia can inherently increase daily energy expenditure (DEE) due to the additional time required to search for and process food as well as maintain more metabolically active tissue (reviewed in Lindström, 2003). Hyperphagic birds must compensate for increased foraging costs in order to rapidly gain body stores. Thus, migratory birds exhibit behavioral and physiological adjustments during hyperphagia that help to promote fattening while keeping their DEE similar to or below nonhyperphagic periods. For example, premigratory common eiders, *Somateria mollissima*, foraged three times more than postmigration periods yet their DEE remained the same because they reduced their heart rate during inactive times and decreased their time spent flying (Guillemette et al., 2012). Several species of migratory birds ranging in size from hummingbirds (Carpenter and Hixon, 1988) to small passerines (Wojciechowski and Pinshow, 2009) to large geese (Butler and Woakes, 2001) reduce their body temperature and so reduce energy expenditure prior to migratory flight regardless of food availability, weather conditions, or degree of fat storage.

47.4.2.3 Fasting and refeeding during migration

During migration, many birds alternate between short-term fasting while flying and intense refeeding at stop over sites. This cycle of alternating feeding and fasting influences gut morphometrics, fattening rates, and subsequently the pace of migration (Karasov and McWilliams, 2005). It is well established that the guts of migrating birds atrophy after just 1 or 2 days of fasting, and this decreased digestive capacity influences the rate at which birds can increase feeding rate and uptake of nutrients upon arrival at stopover sites (Diamond et al., 1986; Karasov and Pinshow, 2000; McWilliams and Karasov, 2005). Thus, the phenotypic flexibility in the gut of migratory birds plays a significant role in their ability to immediately refeed and fatten. Several species of migratory birds increase gut length, mass, and volume in response to increases in food intake in preparation for migratory flight (Dykstra and Karasov, 1992; McWilliams et al., 1999; McWilliams and Karasov, 2001, McWilliams and Karasov, 2005). However, digestive enzyme activity and nutrient uptake per unit of tissue did not change with an increase in food intake in several species of fasted passerines (reviewed in McWilliams and Karasov, 2005). Thus, the relevant phenotypic flexibility seems to be primarily in the size of the gut and not the chemical aspects of digestive efficiency. The digestive organ sizes of fasted birds appear to increase within one to six days upon increasing food intake (Dekinga et al., 2001; McWilliams and Karasov, 2001) and the activity of digestive enzymes, nutrient transporters, and absorption rates take 2–3 days to recover after fasting (Karasov and Hume, 1997; Karasov and Pinshow, 2000). This delay in recovery can impact the overall time it takes for a bird to become ready to migrate and thus slow the overall pace of migration.

47.4.2.4 Diet selection during migration

Many migratory bird species display seasonal shifts in diets associated with migration. For example, several passerines switch from a primarily insectivorous diet to a more frugivorous diet (Herrera, 1984; Bairlein and Gwinner, 1994; Parrish, 1997, 2000), and some artic nesting

shorebirds switch from a diet of primarily terrestrial invertebrates to aquatic invertebrates during fall migration (Schwemmer et al., 2016). This dietary flexibility has been attributed in part to the changes in food availability linked with season (Martin and Karr, 1986; Tsipoura and Burger, 1999). For example, migratory songbirds locally congregated where fruit abundance was high (Smith and McWilliams, 2014), they consistently chose foraging sites with higher fruit availability than insect availability during migration (Martin and Karr, 1986), and migrating shorebirds chose stopover sites along the shores of the eastern United States in conjunction with horseshoe crab spawning (Tsipoura and Berger, 1999). However, food abundance does not entirely explain diet switching in birds during migration as a multitude of factors play into diet choice (see Murphy, 1994 for complete review) including the need to rapidly satisfy the elevated daily energy and nutrient demands associated with migration while eating foods that are typically nutritionally unbalanced.

Birds seem capable of discriminating between foods based on relatively small differences in key nutrients, and these nutrient-based preferences may change with nutrient demands although the evidence for this is less convincing. As an example, four species of tanagers, Blue Dacnis, *Dacnis cayana*, Flame-crested tanager, *Tachyphonus cristatus*, Green Honeycreeper, *Chlorophanes spiza,* and Short-billed tanager, *Cyanerpes nitidus*, were shown to detect differences of 1% in sugar concentration and 2% in lipid concentration in available diets (Schaefer et al., 2003). In addition, these tanagers were able to distinguish between diets that differed in protein type (casein vs. bovine serum albumin) while protein concentration remained constant (Schaefer et al., 2003). Furthermore, white-crowned sparrows preferred semisynthetic diets that differed only in certain amino acids, and their preferences for sulfur amino acids needed for feather growth increased during times of molt (Murphy and King, 1987). Yellow-rumped warblers offered several diets that varied in nutrient and energy content ate a combination of available diets that allowed them to satisfy both their energy and protein demands during nonmigratory as well as migratory periods (Marshall et al., 2016). Whether or not birds have preferences for specific amino acids during the migratory period has not yet been determined. Likewise, many species of migratory birds prefer diets containing certain types of fats (i.e., unsaturated over saturated) and certain amounts or ratios of fatty acids in their diets (Pierce and McWilliams, 2014). There is some evidence that these bird preferences for specific fats remain similar across seasons. For example, red-eyed vireos, *Vireo olivaceous*, preferred diets with more 18:1n9 than diets with more 18:0 or 16:0, and this diet preference did not change between nonmigratory and migratory periods (Pierce and McWilliams, 2005). In sum, migratory birds can discriminate between diets based on certain nutritionally relevant components such as carbohydrates, amino acids, and fatty acids, although whether these nutrient preferences change with nutrient demands is not well documented.

Plant secondary metabolites (PSMs) may influence diet choice in migratory birds somewhat independently of the nutrient composition of foods. PSMs have been shown to increase fruit consumption in some passerines (Cipollini and Stiles, 1993; Bairlein and Simons, 1995) while decreasing consumption in others (Cipollini and Levey, 1997; Levey and Cipollini, 1998). Cedar waxwings, *Bombycilla cedrorum*, chose to eat the energy-rich fruit of *Viburnum opulus*, only when catkin proteins were simultaneously available as a protein source to help produce buffers against the acidic high-PSM fruits (Witmer, 2001). In addition, dietary PSM increased energy intake, intestinal mass, and BMR of rufous-collard sparrows, *Zonotrichia capensis*, but not the common diuca-finch, *Diuca diuca* (Barceló et al., 2016). The impact of the wide diversity of PSM on the diet choices of birds during migration and their ability to regain fuel stores remains a fruitful but largely unexplored question.

47.4.3 Fuel storage

47.4.3.1 Fats are the primary fuel

Birds fuel their high-intensity endurance exercise such as migratory flights primarily by metabolizing fat along with a small amount of protein (McWilliams et al., 2004; Guglielmo, 2010, 2018; Jenni-Eiermann, 2017). Migratory birds use primarily fat to fuel their long-duration flights because fat provides substantially more energy than an equal mass of either carbohydrate or protein (Blem, 1990) which makes it an ideal fuel for weight-economizing migratory birds (Bishop and Butler, 2015; Braun, 2015). Thus, in preparation for long-duration flights birds store appreciable energy mostly as fat (90+% of body mass increase) as well as key nutrients including protein (Jenni and Jenni-Eiermann, 1998; McWilliams et al., 2004; Bishop and Butler, 2015; Guglielmo, 2018) and antioxidants (Skrip et al., 2015a; Cooper-Mullin and McWilliams, 2016). The resulting hypertrophy of muscles and accumulation of substantial visceral, subcutaneous, and intramuscular fat stores has been long-known and well-studied (Blem, 1976, 1990; Bishop and Butler, 2015).

Given that storage of energy and key nutrients is necessary for all migratory birds, and especially those that travel long distances without the opportunity to stopover (Piersma, 1998), there is a type of "limiting factor" worth mentioning here—there are clear limits to how much storage mass can be carried for birds that also must fly. In general, the scaling of energy required to fly to that available from the muscles given their size declines as body size

increases (Pennycuick, 1975). This means that birds as heavy as ostriches cannot become airborne even if they had the largest of wings (Norberg, 1990; Marden, 1994). Such biomechanical constraints (i.e., high-wing loading expressed as grams body mass/cm^2 wing area) associated with flight have been invoked to explain why, for example, swans and ducks require a running takeoff to become airborne and fly (Lovvorn and Jones, 1994), the flightlessness of steamer ducks (Livezey and Humphrey, 1986), and why there are relatively few bird species that fly and eat only plants due to gut size limitations of herbivory (Dudley and Vermeij, 1992; McWilliams, 1999). However, such biomechanical constraints also apply to individuals that dramatically increase their energy and nutrient reserves or gut mass during key times of the annual cycle such as migration (Guillemette, 1994; Piersma, 1998; McWilliams, 1999), while not changing the size of their flight apparatus. For example, the accumulation of large body reserves during the prelaying period results in some female common eider unable to take off (Guillemette and Ouellet, 2005). Such thresholds for flightlessness seem best explained by biomechanical models that integrate wing morphology, muscle mass, and maximum power output required for take off (Marden, 1994). Thus, limitations associated with the power requirements of flapping flight constrain the extent of energy and nutrient storage that can be accumulated especially for larger birds.

47.4.3.2 Physiological challenges associated with fatty acids as fuels

Fats may be ideal fuels for weight-economizing migratory birds because of their high-energy density; however, the metabolism of stored fats requires protein-mediated transport at most every step of the way from adipocyte to mitochondria (Figure 47.5) which can inhibit the very high rates of fat metabolism required for flight (McWilliams et al., 2004; Guglielmo, 2018). Birds are able to enhance their use of stored fats during migratory flights in several important ways (McWilliams et al., 2004; Price, 2010; Guglielmo, 2018). First, they may change the "quality" of their fat stores to enhance the rate of mobilization and oxidation. Fatty acid composition of stored fat changes in birds during migration primarily in response to diet and to preferential metabolism of certain fatty acids (Pierce and McWilliams, 2005; Pierce and McWilliams, 2014) and such changes in fat quality can affect flight performance during long-duration flights (Price, 2010; Guglielmo, 2018; Carter et al., 2020; McWilliams et al., 2020). Second, birds may increase the membrane proteins involved in transporting lipids into cells from the carriers in the blood plasma and the activity of cellular enzymes and so increase the oxidative capacity to use fatty acids (Guglielmo, 2010, 2018). Third, the acquisition of fat stores in birds during migration is associated with a coincident increase in antioxidant capacity to protect against oxidative damage caused by fat storage and use during long-duration flights (Skrip et al., 2015a; Cooper-Mullin and McWilliams, 2016; Skrip and McWilliams, 2016).

47.4.3.3 Fat quality is dynamic, affected mostly by diet, and changes seasonally during migration

The fatty acid composition of natural foods eaten by birds in migration can be quite variable (Pierce and McWilliams, 2014), migratory birds discriminate between foods based

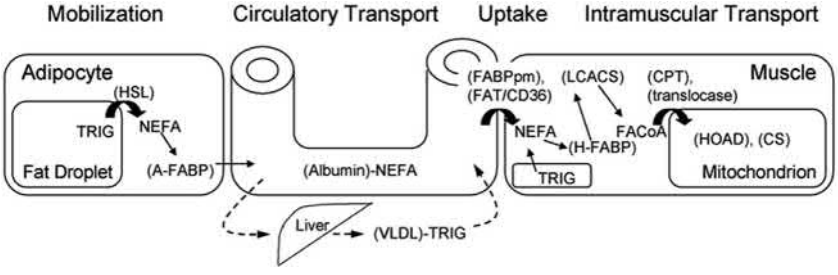

FIGURE 47.5 Lipid transport and oxidation in a bird during exercise while postabsorptive (from Price, 2010). Adipocyte triacylglycerol (TRIG) is hydrolyzed to nonesterified fatty acids (NEFAs) and glycerol through the action of hormone sensitive lipase (HSL). The extremely low-aqueous solubility of fatty acids requires the action of soluble protein carriers at every step of transport. These lipid transporters as well as key enzymes are shown in parentheses. Transport of NEFA within the adipocyte is accomplished by adipocyte fatty acid binding protein (A-FABP). Once exported from the adipocyte, NEFA are bound by plasma albumin and carried to the muscles. In addition to using fat stores as a source of fatty acids, the liver can synthesize many fatty acids de novo or use plasma NEFA to, by esterification to glycerol, produce TRIG packaged into very low-density lipoprotein (VLDL) for release into circulation. Note that the use of plasma VLDL as a source of fatty acids for working muscles requires hydrolysis by lipoprotein lipase (LPL, not shown) at the capillary endothelium (Ramenofsky, 1990; McWilliams et al., 2004). Uptake of fatty acids from circulation into muscle is facilitated by two important fatty acid transport proteins, fatty acid translocase (FAT/CD36) and a plasma membrane fatty acid binding protein (FABPpm). Once in the muscle cells, NEFAs are bound and intracellularly transported by heart-type fatty acid binding protein (H- FABP) which also serves to increase the rate of removal of NEFA from the membrane surface. In addition to these fatty acids sourced from adipocytes and liver, TRIG can also be directly stored within muscle and be hydrolyzed to NEFA and glycerol. Intracellular NEFA are converted by long chain acyl-CoA synthetase (LCACS) to acyl Co-A (FACoA). Uptake of FACoA into the muscle mitochondrion requires several biochemical conversions carried out by two forms of carnitine palmitoyltransferase (CPT) as well as a translocase. Once in the mitochondrial matrix, FACoA enters the β-oxidation pathway and citric acid cycle where key enzymes, including 3-hydroxyacyl-CoA dehydrogenase (HOAD) and citrate synthase (CS), lead to the aerobic production of CO_2, H_2O, and ATP.

on fatty acid composition (Bairlein, 1991; Zurovchak, 1997; Boyles, 2011; Pierce and McWilliams, 2014; Rios et al., 2014), and fatty acid composition of diet primarily determines that of stored fat at least for the mid-chain length fatty acids (e.g., 16:1 and 18:1, no. carbons:no. double bonds) and the essential fatty acids (e.g., 18:2n-6, 18:3n-3 along with their dominate elongation products, 20:4n-6 and 22:6n-3, respectively) with selective metabolism of certain fatty acids playing a possibly important but minor role (Blem, 1976; Pierce et al., 2005; Price and Guglielmo, 2009; Price, 2010). Note that conventional fatty acid nomenclature includes reference to the position of the double bonds relative to the methyl end of the molecule (e.g., n-6 refers to the first double bond at the sixth carbon from this end; n-6 is also referred to as omega-6 or ω-6) because the methyl end is not subject to elongation and desaturation and determines nutritional essentiality (Klasing, 1998). The implication is that migratory birds can select diets so as to achieve a certain fatty acid composition of their stored fat and muscle membranes and thereby satisfy the changing energy and nutritional demands across seasons, including that associated with endurance exercise during migration (Heitmeyer and Fredrickson, 1990; Conway et al., 1994; Bairlein, 1996; Maillet and Weber, 2006; Weber, 2009). Interestingly, behavioral preferences for certain dietary fatty acids (i.e., 18:1 and 18:2 over 18:0) were consistent across migration and nonmigration periods of the annual cycle (Pierce et al., 2004) and more recent studies suggest that migratory birds consistently prefer a 2:1 ratio of 18:1 to 18:2 (Boyles, 2011; Pierce and McWilliams, 2014). In sum, any observed seasonal changes in fatty acid composition of migratory birds are likely due primarily to diet and not to some endogenous seasonal change in diet preference for certain fatty acids or selective metabolism, although many more such studies are clearly needed.

In contrast to the composition of fat stores, the fatty acid composition of muscle and mitochondrial membranes is less affected by diet (Abbott et al., 2012). However, the apparently more consistent membrane composition conceals the fact that 95% of relevant membrane-bound fatty acids (i.e., 16:0, 18:2n-6) turn over on average every 10−17 days in volant birds, and at a faster rate than those in fat stores (Carter et al., 2019). Some studies have measured fatty acid composition of whole plasma [e.g., (Jensen et al., 2020)] or plasma fractions [i.e., NEFA, neutral lipids, phospholipids (Guglielmo et al., 2002c)] although we ignore such information here because seasonal changes in fatty acid composition of circulating lipids primarily reflect changes in feeding rate and diet composition rather than what is necessarily used during migratory flights when birds are fasting and must rely on stored fats (Guglielmo et al., 2002b, 2002c).

Seasonal changes in the fatty acid composition of fat stores in free-living migratory birds suggest that only a few fatty acids may be ecologically relevant and affect exercise performance (Pierce and McWilliams, 2014; Guglielmo, 2018), although given the wide variety of diets eaten by free-living birds during migration, and the relatively few such studies, such interspecific comparisons produce somewhat complicated trends (Table 47.1). In general, the 16- and 18-carbon fatty acids predominate (usually >75% of lipid stores) and the most common forms are usually the saturated 16:0 (no double bonds) and the monounsaturated 18:1n-9. During migration, 16:0 and 18:1n-9 still predominate although 16:1n-7 and two polyunsaturated fatty acids (PUFAs) considered essential for birds, mostly linoleic acid (18:2n-6) and small amounts of alpha-linolenic acid (18:3n-3), are often moderately abundant (up to 40%, but usually <20%) in the fat stores of landbirds. The fatty acid composition of fat stores of marine birds, mostly shorebirds (Napolitano and Ackman, 1990; Egeler and Williams, 2000; Maillet and Weber, 2006; Guglielmo, 2018) and waterfowl (Thomas and George, 1975; Heitmeyer and Fredrickson, 1990) studied to date, also includes much 16:0 and 18:1n-9 but can include up to ca. 20% of longer-chain 18:2n-6 and smaller amounts of 18:3n-3 PUFA (Table 47.1).

Seasonal changes in the fatty acid composition of flight muscle membrane phospholipids in free-living migratory birds confirm that only a few fatty acids may be ecologically relevant and affect exercise performance although much more information is needed (Pierce and McWilliams, 2005; Price, 2010; Guglielmo, 2018). Muscle membrane phospholipids are usually comprised of more saturated fatty acids (notably 16:0 and 18:0), less long-chain monounsaturated fatty acids (notably 18:1n-9), and more longer-chain PUFA (notably 18:2n-6, 20:4n-6, and 20:5n-3, 22:6n-3) compared to the fatty acid composition of fat stores (e.g., western sandpipers *Calidris mauri* (Egeler and Williams, 2000; Guglielmo et al., 2002c), white-throated sparrows (Klaiman et al., 2009), and semipalmated sandpipers (Maillet and Weber, 2006). Fatty acid composition of muscle membrane phospholipids changed seasonally in the two species studied to date (Table 47.1) with n-3 PUFAs (mostly 22:6n-3) decreasing and n-6 PUFAs (mostly 20:4n-6) coincidentally increasing in white-throated sparrows (Klaiman et al., 2009), whereas in western sandpipers, the n-3 PUFAs (mostly 22:5n-3 and 22:6n-3) increased and n-6 PUFAs (mostly 20:4n-6) coincidentally decreased (Guglielmo et al., 2002c), and there was a modest increase in 18:0 during migration in both species. Klaiman et al. (2009) suggest that these differences between species in the reciprocal change in long-chain n-3 and n-6 fatty acids in muscle phospholipids during migration were because of diet changes (to more enriched n-3

TABLE 47.1 Fatty acid composition (%) of subcutaneous fat (including neutral lipids) or whole carcass or muscle phospholipids (structural membranes) for migratory birds captured during both the nonmigration (i.e., breeding or winter) and migration (fall or spring migration) period of the annual cycle.

Only studies that measured fatty acid composition in two or more seasons (e.g., migration, nonmigration periods) are included. Fatty acid nomenclature is number of carbon atoms to number of double bonds, and the location of the first double bond from the methyl end of the fatty acid (e.g., 18:2n-6 has 18 carbons in its backbone, two double bonds, and the first double bond is at the sixth carbon from the methyl end). Fatty acids that were sometimes detected but represent <3% across all studies are excluded (i.e., 18:1n-7, 20:0, 20:3n-6, 20:5n-3, 22:5n-3) except where noted. Given the fatty acid composition of tissues, several hypotheses have been proposed to explain the pattern of change in composition during

TABLE 47.1 Fatty acid composition (%) of subcutaneous fat (including neutral lipids) or whole carcass or muscle phospholipids (structural membranes) for migratory birds captured during both the nonmigration (i.e., breeding or winter) and migration (fall or spring migration) period of the annual cycle.—cont'd

migration. Arrows denote significant changes in fatty acid composition during migration as reported by the original authors (lack of an arrow or dash indicates no significant difference between migration vs. nonmigration periods for a given species). Dashes between migration versus nonmigration rows for a given species indicate no statistical comparison was reported in the original study.

[7] Guglielmo et al. (2002a, b, c).
[8] Thomas and George, 1975.
[9] Heitmeyer and Fredrickson, 1990.

[a] Combined n-6 fatty acids (18:2n-6, 20:4n-6) and n-3 fatty acids (18:3n-3, 20:5n-3, 22:5n-3, 22:6n-3).
[b] Proportion of 18:3n-3 was not reported by season.
[c] in addition, 20:4n-6, another long-chain n-6 PUFA, comprised 3.9% and 2.0% of total fatty acid composition in breeding versus fall migration periods, respectively.
[d] Birds were sampled in both a fall and spring migration period, but combined here (average presented) because differences between these migration periods were relatively uncommon (exceptions for common fatty acids (>2% of total lipids): 18:0 and 18:2n-6 in muscle phospholipids, 18:3n-3 in adipose, and 18:2n-6 in intramuscular neutral lipids were different between fall versus spring migration).
[e] In addition, 20:4n-6, another long-chain n-6 PUFA, comprised 8.1% and 7.5% of total fatty acid composition in winter versus migration (fall and spring) periods, respectively.
[f] Proportion of 22:6n-3, another long-chain n-3 PUFA, is presented because 18:3n-3 comprised <0.5% of total fatty acid composition.
[g] Males and females were separately measured during winter (December in Panama), spring migration (May in British Columbia), and fall migration (July in British Columbia), but the sexes were averaged here. Fatty acid composition of stored fat (Egeler and Williams, 2000) and pectoralis muscle phospholipids (Guglielmo et al., 2002a, b, c) during spring and fall migration were not significantly different so only fall migration is presented.
[h] Proportion of 20:4n-6, another long-chain n-6 PUFA, is presented because 18:2n-6 comprised <1.9% of total fatty acid composition and unlike 20:4n-6 did not change seasonally.
[i] proportion of the combined longer-chain n-3 PUFAs (i.e., 20:5 + 22:5 + 22:6) is presented because 18:3n-3 comprised <0.5% of total fatty acid composition. Significant seasonal changes were detected in only 22:5n-3 and 22:6n-3, and not 18:3n-3 or 20:5n-3.
[j] The n-6/n-3 ratio for birds in fall migration was similar to that during spring migration (presented here), but was significantly lower (1.0) than during winter.

marine prey for sandpipers, to more enriched n-6 seeds for sparrows). Clearly more such studies are needed to determine if the general pattern of reciprocal change in long-chain n-3 and n-6 PUFAs in flight muscle membrane phospholipids is robust across birds species with different migration strategies that inhabit terrestrial and/or marine ecosystems.

47.4.3.4 Physiology of protein storage and flight muscle preparation

Lean mass typically accounts for approximately one quarter of the body mass gain in passerine birds prior to migration (Klaassen and Biebach, 1994; Klaassen et al., 1997; Bauchinger and Biebach, 2001) and on average ~50% of body mass gain in several species of waders (reviewed in Lindström and Piersma, 1993). Much of the lean mass gain observed in free-living birds has been attributed to increases in the size of the gut and organs associated with flight, i.e., heart and pectoralis (flight) muscle (Marsh, 1984; Dietz et al., 1999; reviewed in Lindström and Piersma, 1993; McWilliams et al., 2004). Several hypotheses have been put forth to explain the increase in lean mass and muscle hypertrophy prior to migration including the increased power needed for flight with a larger body mass (Marsh, 1984), as a source for gluconeogenesis (Jenni and Jenni-Eiermann, 1998; Guglielmo et al., 2017) and a storage mechanism for water (Gerson and Guglielmo, 2011) (see Protein Use section below). For pectoralis (flight) muscle in particular, studies suggest the increase in size of the pectoralis muscle is the result of a concomitant increase in body size (Marsh, 1981), a result of power training before flight (Marsh and Storer, 1981), or of an endogenously regulated process that occurs independent of training or size changes (Evans et al., 1992; Bishop et al., 1998; Dietz et al., 1999).

In addition to an overall mass increase in flight muscle, the mass-specific activities of key catabolic enzymes related to the oxidation of fatty acids, overall aerobic/anaerobic capacity, burst power, and glycolytic capacity increase in flight muscle prior to migration (Marsh, 1981; Lundgren and Kiessling, 1985; Banerjee and Chaturvedi, 2016). For example, hydroxyacyl-CoA-dehydrogenase (HOAD) concentration almost doubles in the flight muscle of gray catbirds (Marsh, 1981), and CS and HOAD activity increases in reed warblers, *Acrocephalus scirpaceus*, during fattening prior to migration (Lundgren and Kiessling, 1985). Additionally, Evans et al. (1992) showed that the percentage volume of mitochondria in muscle fibers in Dunlin, *Calidris alpina*, and Sanderlings, *Calidris alba*, increased from winter to spring migration suggesting an increased aerobic capacity of the flight muscle in preparation for migration. Banerjee and Chaturvedi (2016) concluded that the pectoral muscle of premigratory, red-headed buntings, *Emberiza bruniceps*, showed significant increases in aerobic and anaerobic capacity (CS, CCO, and MDH activity), increased fatty acid oxidation capacity [increased carnitine palmitoyltransferase (CPT) and HOAD activity], increased glycolytic capacity (increased PFK and PK activity), and increased burst power (CK activity) compared to nonmigratory buntings (Banerjee and Chaturvedi, 2016). Thus, although the dynamics of fat stores are more extreme than that of body protein, the turnover and dynamics of body protein has important functional significance (Bauchinger and McWilliams, 2012; Bauchinger and McWilliams, 2010; Carter et al., 2019).

47.4.4 Fuel use

47.4.4.1 Patterns of change in fatty acid composition of birds during migratory stage: proposed hypotheses

Understanding how the fatty acid composition of fat stores in free-living birds changes during migration periods provides a foundation upon which to generate ecologically relevant hypotheses, informed by comparative physiology, about how fatty acid composition can affect exercise performance of migratory birds. Given that specific unsaturated fatty acids are preferentially used and more rapidly mobilized during metabolism over saturated fatty acids (Leyton et al., 1987; Raclot and Groscolas, 1995; McKenzie et al., 1998; McKenzie, 2001; Raclot, 2003; Price et al., 2008), which compensates for their relatively lower energy content and potential for ATP production (Weber, 2009; Price, 2010), one proposed hypothesis is that the proportion of unsaturated fatty acids in fat stores will increase during migration. Both studies that directly tested this hypothesis (Table 47.1) found the predicted increase in unsaturation of fat stores (Egeler and Williams, 2000; Klaiman et al., 2009), and three of the other six species studied (wood thrush, *Hylocichla mustelina*, red-eyed vireos, and mallard, *Anas platyrhynchos*) support this hypothesis. Two of the three species (slate-colored junco, *Junco hyemalis*, Canada goose, *Branta canadensis*) had a relatively similar proportion of unsaturated fatty acids in their fat stores (Table 47.1) which led Guglielmo (2018) to conclude that the most general pattern observed to date was that the proportion of unsaturated fatty acids in fat stores of migratory birds increased or stayed the same during migration (the only exception thus far is the white-crowned sparrow which had unusually high proportions of 14:0 in its fat stores during migration).

The other alternative hypotheses that have been proposed to explain the patterns in the fatty acid composition of birds during migration have focused on the essential fatty acids (18:2n-6 and 18:3n-3) and their elongation products (e.g., 20:4n-6 and 22:6n-3,

respectively). Blem (1980) suggested that the ratio of 18:1 to 18:2 was higher in migratory birds. Results from five of the eight species studied to date (slate-colored junco, white-crowned sparrow, wood thrush, western sandpiper, and mallard) support this alternative hypothesis (Table 47.1). Pierce and McWilliams (2005) noted that the ratio of long-chain monounsaturated fatty acids (16:1, 18:1) to an essential long-chain PUFA (18:2) increased during migratory periods for most of the six species studied up to that point in time. Results from six of the eight species presented in Table 47.1 support this alternative hypothesis (Canada goose and white-throated sparrows were the exceptions). The potential importance of a certain ratio of n-3 and n-6 PUFAs to physiological function is long standing and is known to be strongly influenced by diet (Hulbert et al., 2005). For four of the species studied, n-3 PUFAs during both migration and nonmigration periods were <2% of all fatty acids in the whole animal (junco, white-crowned sparrow) or in separated fat stores (western sandpiper, Canada goose), and none of these four species showed the expected increase in n-6/n-3 ratio during the migration period (Table 47.1). For the other four species with more substantial n-3 fatty acids in their tissues (whole animal for wood thrush, fat stores for red-eyed vireo, white-throated sparrow, and mallard), the ratio of n-6/n-3 PUFAs consistently increased during migration compared to nonmigration periods (Table 47.1). As noted above, the changes in muscle phospholipids of birds during migration are modest compared to those observed in fat stores. The general pattern from the two studies conducted to date of reciprocal change between n-6 and n-3 PUFAs in muscle phospholipids and to a lesser extent 18:0 and 16:0 (but not fat stores; Table 47.1), provides little to no consistent support for any of the proposed hypotheses above.

Thus, the principle pattern that emerges from these few studies (Table 47.1) is that (1) there are seasonal changes in fatty acid composition of fat stores and muscle phospholipids that are associated with migration. For fat stores, the observed changes include (a) the proportion of unsaturated fatty acids either remain the same or increase during migration and (b) in particular, the relative amounts of the n-6 and n-3 PUFAs increase during migration (at least for those bird species with >2% n-3 PUFAs in their fat stores). For muscle phospholipids, reciprocal changes between primarily n-6 and n-3 PUFAs occur during migration although the direction of change differs between the two species studied to date. (2) These seasonal changes in fatty acid composition of fat stores and muscle phospholipids seem primarily driven by seasonal changes in diet, and the extent to which diet affects membrane composition is more modest than that of fat stores. Clearly, more studies are needed that systematically measure fatty acid composition of both fat stores (neutral lipids) and membranes (phospholipids) in several tissues [e.g., (McCue et al., 2009)] in a wide variety of migratory birds during migratory and nonmigratory seasons before these trends are confirmed and considered broadly applicable.

47.4.4.2 The oxidative costs of burning fat as fuel

Regulating oxidative balance is important for all air-breathing organisms such as birds because reactive prooxidant molecules can cause considerable cellular damage and affect health, longevity, and performance (Halliwell and Gutteridge, 1999), and PUFAs are especially susceptible to lipid peroxidation (Hulbert et al., 2007; Montgomery et al., 2012). This has led to a rich literature relating variation in membrane fatty acid composition to size-related variation in metabolic rate in mammals and birds (Hulbert and Else, 1999, 2000) and in turn to variation in reactive species (RS) production, life span, and aging (Harman, 1956; Speakman, 2005; Speakman and Selman, 2011; Speakman and Garratt, 2013; Herborn et al., 2016). In this context, birds have often been portrayed as exceptional vertebrates in that they display relatively high-metabolic rates, with the associated increased RS production, yet they are remarkably long-lived compared to mammals (Buttemer et al., 2010; Munshi-South and Wilkinson, 2010; Barja, 2014; Jimenez et al., 2019). Furthermore, birds use of fats as their primary fuel during high-intensity endurance exercise such as migratory flights (Jenni and Jenni-Eiermann, 1998; Guglielmo, 2010) has potential acute oxidative costs because fats, and especially PUFAs, are highly susceptible to oxidative damage (Cooper-Mullin and McWilliams, 2016; Skrip and McWilliams, 2016). As noted earlier, an important adaptation in Neoaves has led to the constitutive activation of the NRF2 master antioxidant response which lowers the risk of macromolecular oxidative damage in birds other than the fowl (e.g., chicken, ducks, geese (Castiglione et al., 2020). This constitutive activation of the antioxidant response may require birds to maintain a more robust and costly endogenous antioxidant system, although consumption of dietary antioxidants could reduce or alleviate these costs.

One of the challenges of studying how the antioxidant system of birds responds to the physiological challenges of migration is that the primary instigator of the oxidative challenge, increased RS production with increased metabolism, is not yet measurable in whole organisms (Costantini, 2014; Cooper-Mullin and McWilliams, 2016; Skrip and McWilliams, 2016). This must be inferred from measurements of key components of the antioxidant system (e.g., upregulation of antioxidant enzymes implies a response to increased RS production) and ideally simultaneous measures of RS-associated damage (e.g., upregulation

of lipid peroxidation products implies increased RS production that are insufficiently quenched by the antioxidant system). Another challenge of studying phenotypic flexibility in the antioxidant system of migratory birds is that the major site for generation of RS is the mitochondria which will vary in density and activity across tissues (Costantini, 2019) as well as with exercise and age (Cooper-Mullin and McWilliams, 2016). In addition, RS can act as both damaging molecules, as discussed above, and also as signaling molecules that can stimulate the endogenous antioxidant system (Halliwell and Gutteridge, 1999; Costantini, 2014, 2019). There are also a multitude of tests available to probe the response of the antioxidant system to ecologically relevant challenges which too often complicates comparisons across studies (Costantini, 2016, 2019; Skrip and McWilliams, 2016). Consequently, integrative studies (from mitochondria to cells to tissues to whole organism) that are also comparative (e.g., multiple tissues within the same individuals, migration state vs. nonmigration periods, multiple species that differ in migration strategy) are required to fully understand the antioxidant system of migratory birds within an ecological context. Given such integrative and comparative studies of migratory birds are largely lacking, evidence to date provides a more piecemeal view of how the antioxidant system of migratory birds changes during migration.

Does fattening and storage of oxidatively vulnerable PUFAs in preparation for migration increase RS production and an associated antioxidant response? Blackpoll warblers, *Dendroica striata*, and red-eyed vireos at a New England stopover site during fall migration (Skrip et al., 2015a), and garden warblers and barn swallows at a Mediterranean coastal stopover site during spring migration (Costantini et al., 2007), simultaneously increased their fat stores, nonenzymatic antioxidant capacity (plasma OXY), and oxidative damage (plasma d-ROMs) suggesting that fattening may incur oxidative costs and that the balance of capacity and damage may be condition-dependent. Captive-reared Northern wheatears, *Oenanthe pileata*, that were photostimulated into "migration state" in fall and that were rapidly refueling and hyperphagic increased their nonenzymatic antioxidant capacity (plasma OXY), consistent with the field studies described above, but not lipid peroxidation (red blood cell MDA) compared to control (*ad libitum*-fed) birds (Eikenaar et al., 2016). Several experimental and field studies suggest that the quality of fats consumed and stored in migratory birds affects circulating markers of oxidative damage. For example, European starlings, *Sturnus vulgaris*, fed for many months on diets with more or less n-6 PUFA had fuel stores composed of more or less n-6 PUFA, and those composed of more n-6 PUFA had consistently higher levels of plasma markers of oxidative damage (McWilliams et al., 2020). White-throated sparrows that consumed diets with more PUFA had increased circulating oxidative damage (d-ROMs) although when given choices between diets that differed only in available antioxidants (vitamin E) these birds did not prefer antioxidant-rich diets when consuming more dietary PUFA (Alan and McWilliams, 2013). Common blackbirds captured at a stopover site in northern Germany had a higher plasma fatty acid peroxidation index, higher nonenzymatic antioxidant capacity (OXY), but similar lipid peroxidation compared to sympatric resident blackbirds (Eikenaar et al., 2017a). The lack of correspondence between plasma fatty acid composition and that of fat stores and cell membranes in the same individuals (as described earlier) may explain why oxidative damage did not change with plasma peroxidation index in this latter study. Hudsonian godwits, *Limosa haemastica*, preparing for a very long-duration migratory flight increased total antioxidant capacity and reduced oxidative damage (TBARS) but did not change metabolic enzyme activity (Gutiérrez et al., 2019). In sum, migratory birds seem to build some component of their antioxidant capacity concomitantly with fat stores and increased oxidative damage may be an inevitable consequence of increasing (or maintaining more) fat stores, especially if they are composed of mostly PUFA.

During migratory flight, do birds upregulate antioxidant capacity and thus avoid the energetically expensive repair of damaged structures? In two recent reviews, Cooper-Mullin and McWilliams, 2016 and Skrip and McWilliams, 2016 reported that free-living birds during migration, or captive birds that flew for certain periods of time, often exhibit an increase in damage to lipids and/or proteins despite an often upregulated antioxidant system composed of antioxidant enzymes, nonenzymatic sacrificial molecules, and dietary antioxidants. For example, homing pigeons, *Columba livia*, that flew further (200 km) had more oxidative damage and less serum nonenzymatic antioxidant capacity than those that flew less far (60 km) when blood was sampled w/in 15 min of returning to the roost (Costantini et al., 2008). European robins, *Erithacus rubecula,* caught during nocturnal migratory flight had elevated markers of circulating oxidative damage to proteins (protein carbonyls) compared to resting robins even though the former also had higher circulating levels of glutathione peroxidase (GPx), an enzymatic antioxidant (Jenni-Eiermann and Jenni, 1991; Jenni-Eiermann et al., 2014). In contrast, migratory common blackbirds had higher nonenzymatic antioxidant capacity (OXY) but similar lipid peroxidation compared to sympatric resident blackbirds (Eikenaar et al., 2017a). Captive zebra finches, *Taeniopygia guttata*, flown for 2 h/day for many weeks increased the coordination between the enzymatic (GPx) and nonenzymatic (OXY) components of the antioxidant system while oxidative damage remained low and similar to sedentary finches (Cooper-Mullin et al., 2019). Plasma

markers of oxidative damage did not change in European starlings over the course of daily flying for several weeks, nor before and after a single long flight, in part because of upregulation of components of their antioxidant system (Frawley et al., 2021; McWilliams et al., 2020). Thus, upregulation of the antioxidant system and, at least in one case, increased coordination of key components of the antioxidant system occurs during repeated long-duration flights, and in some but not all cases, this seems to avoid the potential increase in oxidative damage with exercise. These studies also provide an important reminder that the response of individuals to an oxidative challenge involves an interacting, multicomponent antioxidant system (Costantini, 2019).

Given that some oxidative damage may occur during a migratory flight or enforced exercise, are migratory birds able to recover from this damage in an appropriately short period of time? Migratory birds at stopover sites seem to be able to in part recover from any oxidative damage that may have occurred during migration. For example, European robins that rested during the day had lower protein damage levels (protein carbonyls) than those caught during active nocturnal flight presumably because they had time to remove or repair damaged proteins (Jenni-Eiermann and Jenni, 1991). Individual Garden Warblers sampled repeatedly at a spring stopover reduced circulating lipid peroxidation levels over time (Skrip et al., 2015a). Thus, if oxidative damage occurs, then migratory birds seem capable of repairing this damage in a relatively reasonable amount of time (i.e., days not weeks) given their usual stopover durations, although many more such studies are needed that track recovery of individuals after long-duration flights.

Does consumption of dietary antioxidants affect the upregulation of the endogenous antioxidant system associated with migratory flights? In theory, the costs of upregulating the endogenous antioxidant system could be reduced if dietary antioxidants could quench RS producing during flight (Costantini et al., 2010a; Pamplona and Costantini, 2011; Costantini, 2014). Recent experimental evidence demonstrated for the first time that an ingested fat-soluble dietary antioxidant (Vitamin E) was absorbed and transported to the mitochondria in the flight muscles of a songbird within 22.5 h, but only if the birds were regularly flying each day (Cooper-Mullin et al., 2021). Thus, actively migrating songbirds that ingest dietary antioxidants during the day at a stopover, in this case fat-soluble antioxidants, would have these available in their mitochondria to protect against RS produced during subsequent nocturnal flight(s). Several experimental studies have directly manipulated the amount and type of dietary antioxidant(s) available to migratory birds, or captive birds exposed to regular exercise, and then measured the response of the antioxidant system often in relation to some ecologically relevant challenge (e.g., flight, high-PUFA diets). For example, European starlings fed diets supplemented or not with anthocyanins had similar plasma nonenzymatic antioxidant capacity (OXY) and oxidative damage (d-ROMs), but circulating uric acid was higher in individuals fed the low-antioxidant diet (Frawley et al., 2021). Likewise, zebra finches fed more or less anthocyanins and exercised (daily 2-h flying for months) or not had similar plasma nonenzymatic antioxidant capacity (OXY), antioxidant enzyme activity in liver (GPx, catalase, superoxide dismutase) and oxidative damage (d-ROMs); plasma uric acid was not measured in this study (Skrip et al., 2016). The suggestion from these studies is that when birds consume too little dietary antioxidants, this may not directly affect upregulation of antioxidant enzymes but may increase protein catabolism and thus circulating uric acid when flying for long durations and/or consuming high-PUFA diets. There is also evidence that consumption and physiological use of dietary antioxidants in birds may depend on their nutritional needs, energy demands, and type of dietary antioxidant (Costantini et al., 2010b; Beaulieu and Schaefer, 2013). Clearly, much more work is needed to adequately understand the role of dietary antioxidants in enabling migratory birds to maintain oxidative balance.

47.4.4.3 Carry over effects from winter to breeding

For the many birds that breed in seasonal environments, migration to more benign areas during winter has evolved along with the need to acquire energy and nutrient stores to fuel migration and, in the spring, also prepare for breeding. Life-history theory predicts that major annual cycle events such as breeding and migration are separated in time (and often space) to effectively distribute the total costs over time and to maximize the benefit-to-cost ratio given seasonal changes in resources (Lack, 1954; Dingle, 1996). However, such temporally separated events are not thereby independent in that, for example, condition of animals during one annual cycle event (e.g., in winter or on migration) can affect subsequent events (e.g., migration, reproduction). These so-called carry-over effects (Marra et al., 1998; Holmes, 2007; Harrison et al., 2011; Mitchell et al., 2011; Drake et al., 2013; Paxton and Moore, 2015) reveal links between annual cycle events that affect populations and individual fitness (Harrison et al., 2011). It has long been recognized that the extent of nutrient acquisition during spring, often prior to initiating migration, largely determines reproductive success in many waterfowl species (Ryder, 1970; Drent and Daan, 1980; Alisauskas and Ankney, 1992). As such, waterfowl provide many examples of the importance of carry-over effects (Harrison et al., 2011), the acquisition and storage of nutrient reserves at

one time or place (e.g., during the nonbreeding period) that are then used as resources at a later time and place (e.g., for breeding) (Warren et al., 2013; Sedinger and Alisauskas, 2014). Knowing the location and timing of nutrient storage during the nonbreeding period often has important conservation implications (Raveling and Heitmeyer, 1989; Abraham et al., 2005; Stafford et al., 2014; Alisauskas and Devink, 2015). Despite the importance of carry-over effects especially in migratory animals, a major gap in our understanding of these effects involves identifying the proximate causal links. All previous work has focused on how energy in the form of fat, protein, or carbohydrate stores may provide such linkages, whereas no previous studies have focused on antioxidants even though they have been proposed as an important currency that underpins life history tradeoffs (Catoni et al., 2008; Alonso-Alvarez et al., 2010) and potentially carry-over effects (Harrison et al., 2011).

Dietary antioxidants are likely an important, yet understudied, currency for carry-over effects in birds especially during spring migration for primarily three reasons. First, dietary antioxidants play important roles during the reproductive season in that breeding effort of birds promotes oxidative damage (Alonso-Alvarez et al., 2010) and domestic fowl supplemented with dietary fat-soluble antioxidants gain fitness advantages (Koutsos et al., 2003; Royle et al., 2003; McGraw et al., 2005; Williamson et al., 2006). Additionally, developing egg embryos are protected from external oxidative challenges if the females are able to deposit antioxidants in the yolk (Watson et al., 2018). Consistent with this important role of dietary antioxidants during reproduction, European starlings fed high-anthocyanin diets during spring had more elevated testosterone and more sustained breeding behaviors compared to individuals fed less antioxidants (Carbeck et al., 2018). Second, the increased metabolic rate associated with long-duration migratory flights produces pro-oxidants that must be quenched to avoid damage (Costantini, 2008; Costantini et al., 2007, 2008), and for spring migrating birds, this may reduce the antioxidant capacity available for subsequent reproduction. Importantly, dietary anthocyanins can support the metabolic function of glucocorticoids (corticosterone) and so control potential negative effects of excessive secretion of these hormones especially during long-duration flights (Casagrande et al., 2020). Third, fat-soluble antioxidants can be deposited in fat stores and so migratory birds could strategically store antioxidants prior to departure (Costantini et al., 2007), and balance their use during migratory flights so as to retain enough for investment into eggs that can subsequently enhance offspring survival and fitness (Blount et al., 2003; McGraw et al., 2005; Skrip et al., 2016). Clearly, much more study is needed to determine how female migratory birds contend with the oxidative costs of migratory flights in spring while also preparing for subsequent breeding and egg laying.

47.4.4.4 Fat quality matters

In theory, selectively eating and hence storing certain long-chain unsaturated fatty acids may be advantageous because (1) such fatty acids may be preferentially mobilized and metabolized more quickly (fuel hypothesis); (2) such fatty acids may affect composition and key functions of lipid-rich cell membranes (membrane hypothesis); and (3) such fatty acids may stimulate key facets of aerobic metabolism such as stimulating expression of genes involved in fatty acid oxidation (signal hypothesis) (Figure 47.6). Below we briefly discuss aspects of each of these hypotheses and how they may relate to the observed effect on exercise performance of migratory birds. Other reviews should be consulted for more thorough discussion of these hypotheses and the evidence (Weber, 2009; Guglielmo, 2010; Price, 2010; Pierce and McWilliams, 2014; Guglielmo, 2018). Although we separately describe these three hypotheses for convenience, they are not mutually exclusive.

The fuel hypothesis states that enhanced exercise performance occurs because certain fatty acids are more quickly mobilized and metabolized, and this can occur in several ways (Figure 47.5): selective mobilization from adipocytes, enhanced transport to target tissues, selective uptake by and transport within muscle cells, and/or enhanced oxidation and production of ATP (McWilliams et al., 2004, Price, 2010; Guglielmo, 2018). Several studies across taxa have shown that mobilization of shorter chain SFAs and fatty acids with more double bonds (e.g., 18:2n-6) was more rapid from fat stores in rats, fish, and birds (Raclot and Groscolas, 1995; Sidell et al., 1995; Hulbert et al., 2005; Price et al., 2008; Guglielmo, 2018). Isotope tracer studies that track ingested nutrients to breath CO_2 confirm that long-chain unsaturated fatty acids are oxidized more rapidly than their saturated counterparts (e.g., 18:1 vs. 18:0) (McCue et al., 2010). Once mobilized from fat stores, fatty acids require solubilization and intracellular translocation by the family of fatty acid binding proteins (FABPs) such that an increase in the number and action of FABPs present in the cell membranes and cytosols of muscle cells increases oxidative capacity (Guglielmo et al., 1998, Guglielmo et al., 2002a; McFarlan et al., 2009; Guglielmo, 2010, 2018). Furthermore, within flight muscle cells, the rate of CPT catalysis (Figure 47.5) was relatively higher for fatty acids with more double bonds compared to their saturated forms (e.g., 18:2 and 18:3 vs. 18:0) (Price et al., 2011; Guglielmo, 2018). This evidence supports the fuel hypothesis in that certain fatty acids such as 18:2n-6

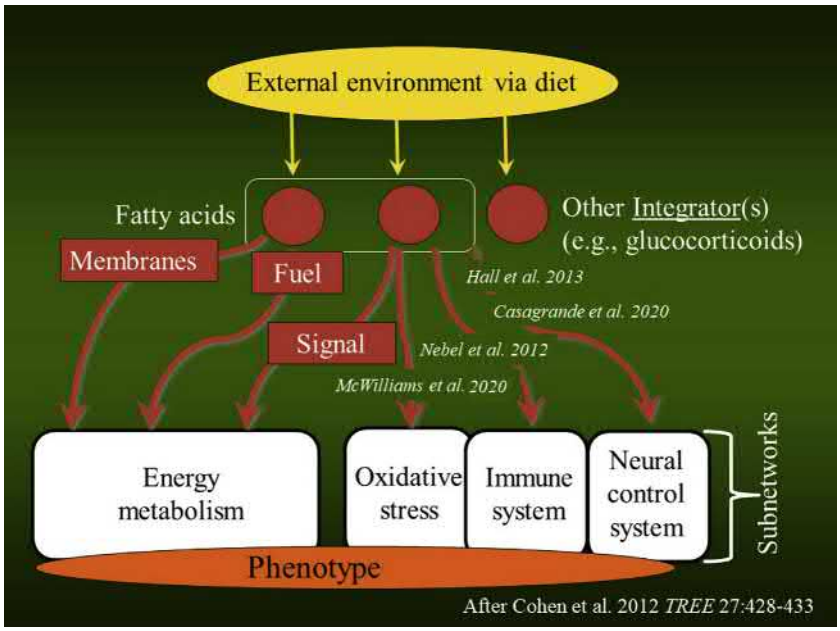

FIGURE 47.6 A simplified schematic of a physiological regulatory network that indicates how certain dietary fatty acids serve as key "integrators" that interact with multiple systems (subnetworks) and each other, thereby ensuring an appropriate match between phenotype and environmental conditions. Dietary fatty acids have been shown to influence the immune system (Nebel et al., 2012), neurogenesis (Hall et al., 2013), and neuroendocrine control of metabolism (Casagrande et al., 2020), and oxidative status (McWilliams et al., 2020). The three hypotheses (membrane, fuel, and signal), and the evidence that supports or refutes them are described in the text. *After Cohen et al. (2012).*

are metabolized more quickly at many steps of fatty acid oxidation although whether this is primarily responsible for enhanced exercise performance during migration periods is not yet clear (Guglielmo, 2010; Price, 2010) and discussed in the next section.

The membrane hypothesis states that the fatty acid composition of membrane phospholipids can effect key aspects of membrane structure and function (Hulbert and Else, 1999; 2000; Hulbert et al., 2005) and thus exercise performance of an organism (Valencak et al., 2003; Maillet and Weber, 2006; Maillet and Weber, 2007; Weber, 2009; Price, 2010). As described above, fatty acid composition of diet influences the phospholipid composition of muscle membranes in vertebrates, and this effect of diet on membrane composition is especially strong for dietary n-3 and n-6 compared to other fatty acids (e.g., shorter-chained saturated fatty acids (Hulbert et al., 2005; Maillet and Weber, 2006; 2007). Accordingly, the fatty acid composition of cell and subcellular membrane phospholipids converged with that of diet in migrating shorebirds that consumed marine invertebrates laden with n-3 PUFAs (Maillet and Weber, 2006, 2007). An increase in membrane PUFAs has potential functional importance for exercising animals in that (1) n-3 and/or n-6 PUFAs increase the fluidity and permeability of cell membranes (Stillwell and Wassall, 2003; Weber, 2009) and (2) n-3 and/or n-6 PUFAs are known to influence the activity of membrane-bound proteins and enzymes (e.g., UCP and -ATPases) which could affect efficiency of aerobic respiration (Hulbert and Else, 2000; Infante et al., 2001; Hulbert et al., 2005; Maillet and Weber, 2006, 2007; Gerson et al., 2008).

The signal hypothesis states that certain dietary fatty acids (most notably the n-3 and n-6 PUFAs) directly act as natural ligands for receptors that regulate the expression of genes associated with lipid metabolism (McClelland, 2004; Bordoni et al., 2006; Maillet and Weber, 2006; 2007; Weber, 2009). In particular, PUFA directly bind to and regulate the activity of peroxisome proliferator-activated nuclear receptors (PPARs) which are well known to stimulate expression of genes involved in fatty acid oxidation (Hochachka and Somero, 2002; Pawar et al., 2002; Zhang et al., 2004; Narkar et al., 2008; Weber, 2009), although the specific mechanism of action depends on the type of PPAR (Feige et al., 2006). PPAR α and β stimulate fatty acid oxidation and transport whereas PPAR γ is involved in lipid storage and adipocyte differentiation (Desvergne and Wahli, 1999; Nagahuedi et al., 2009). PPARs exhibit high affinity for n-3 PUFAs (Bordoni et al., 2006) and the upregulation of rate-limiting enzymes involved in aerobic metabolism by certain fatty acids such as 18:2n-6 (Sidell et al., 1995; Egginton, 1996; McKenzie, 2001) enables more rapid production of ATP during exercise (Guglielmo et al., 1998, 2002a; McWilliams et al., 2004). The effects of PUFAs on gene expression depend largely on the cellular concentration of PUFA, although it is not yet clear if a specific amount or ratio of dietary n-3 and n-6 fatty acids is optimal (Bordoni et al., 2006). The direct binding of certain dietary PUFAs to PPARs that then activate genes regulating lipid metabolism provides an example of "natural doping" whereby exercising animals can eat certain PUFAs, upregulate key aspects of lipid metabolism, and so enhance their exercise performance (Maillet and Weber, 2006, 2007, Weber, 2009). Such natural doping on n-3

PUFAs has been proposed for semipalmated sandpipers as they pause at key stopover sites during fall migration (Maillet and Weber, 2007). Whether this is a most interesting but unusual case in migratory birds deserves further investigations. In addition, these same essential PUFAs are used to build eicosanoids (e.g., prostaglandins, thromboxanes, leukotrienes, and lipoxins) that act locally on the cells that produce them or are nearby, and in this sense they are classified as hormones with signaling properties. At present, the importance of eicosanoids in birds during migration has not been directly studied and only proposed as an explanation (Klaiman et al., 2009; Carter et al., 2020), although their involvement in regulating a wide variety of physiological systems (e.g., immunity, development and growth, thermoregulation, and oviposition) suggests some attention may be worthwhile.

47.4.4.5 Testing the fuel, membrane, and signal hypotheses

Empirical evidence somewhat supports all of these alternative hypotheses although the weight of evidence to date seems to favor the fuel or signal hypotheses. The fuel hypothesis has been invoked to explain how fatty acid composition affects performance in rats, lizards, fish, and more recently migratory birds (Leyton et al., 1987; Geiser and Learmonth, 1994; Raclot and Groscolas, 1995; McKenzie et al., 1998; Wagner et al., 2004; Pierce et al., 2005; Price et al., 2008; Price and Guglielmo, 2009; Petersson et al., 2010). Our own recent work and that of colleagues has confirmed that songbirds with stored fat composed of more n-6 PUFA have improved exercise performance during short-term intense exercise (Pierce et al., 2005; Price and Guglielmo, 2009; Price, 2010). Price and Guglielmo (2009) used a cleverly designed sequence of feeding and fasting protocols to produce white-throated sparrows with fat stores and muscle membranes composed of different fatty acids. Consequently, they were able to demonstrate that the enhanced exercise performance of sparrows was associated with the fatty acid composition of fat stores rather than muscle membranes. The implied mechanism for the enhanced performance, in this case higher peak metabolic rates, included both faster mobilization rates of n-6 fatty acids from adipose as well as selective uptake of fatty acids into muscle cells and intramyocyte transport (Price and Guglielmo, 2009; Price, 2010). As correctly pointed out by Price (2010), a crucial untested assumption of this proposed mechanism for producing higher peak metabolic rates is that rate of fatty acid supply, and not some other factor such as oxygen supply or oxidative capacity, is the physiological limitation responsible for these whole-animal changes in exercise performance. In vivo studies that examine *selective* uptake and intracellular transport rates of certain fatty acids in muscle cells during exercise would be quite informative, especially if combined with diet and feeding regime manipulations that allow the effect of fatty acid composition of fat stores to be isolated from that of the other mechanisms.

Birds during migration, however, may be optimizing energy efficiency rather than maximizing metabolic rate and so may not need to maximize rate of fatty acid supply, as is often assumed. Energy efficiency in this case refers to flying further for a given amount of fuel energy or flying as far but expending less fuel energy. A possible mechanism for such enhanced efficiency that is consistent with the fuel hypothesis includes, for example, the documented higher transport rates of unsaturated fatty acids reducing the energy needed for transport of fatty acids (Price, 2010). Evidence in support of this enhanced flight efficiency idea comes from a study of European starlings from a migratory population in southern Germany that were fed for many months specially formulated diets that differed only in the amount of n-6 and n-3 fatty acids—the fatty acid composition of their fat stores was likewise different as expected. During the fall migration period, and after several weeks of flight-training in a wind tunnel, starlings composed of more n-6 (and n-3) PUFA used substantially less energy (ca. 11%) to fly the same distance (260 km) and duration (6 h) than those composed of more monounsaturated fatty acids (McWilliams and Pierce, 2006; McWilliams et al., 2020). This experimentally demonstrated that migratory birds can enhance fuel economy when composed of more n-6 PUFAs, a result consistent with the fuel hypothesis although it does not by itself definitively refute the other proposed hypotheses. As discussed further below, this energy savings gained during a long flight by starlings composed of more n-6 PUFA came at the long-term cost of higher oxidative damage in the n-6 PUFA-fed birds (McWilliams et al., 2020). This may explain why migratory birds seasonally shift their diet to increase consumption of n-3 and/or n-6 PUFAs during migration but then reduce their consumption of long-chain PUFAs during nonmigration periods.

Several lines of evidence suggest a link between the n-3 and/or n-6 PUFA content in membrane phospholipids and exercise performance. For example, maximal running speed in 36 species of mammal was strongly related to the n-6 PUFA content of their muscle membrane phospholipids (Ruf et al., 2006), n-6 PUFA in muscle membranes of rats was positively associated with their exercise performance (Ayre and Hulbert, 1997), and regular exercise increased PUFA content of muscle membranes in humans (Andersson et al., 2000). Also, PUFA-rich membranes have been found in various muscle types having high-aerobic capacity such as the pectoralis muscle in hummingbirds and the shaker muscle in rattlesnakes (Infante et al., 2001). Along with high levels of n-3 PUFAs, these muscle membranes had increased Ca^{2+}-ATPase activity

which may play a significant role in metabolism during exercise (Infante et al., 2001; Ruf et al., 2006). Furthermore, the activity of Na+/K+ -ATPase enzyme in the tissue membranes of birds and mammals has been correlated with the amount of 22:6n-3 in the membrane suggesting a causal link between certain types of PUFA and metabolic rate (Wu et al., 2001, 2004; Turner et al., 2003).

Studies of migratory birds provide some evidence in support of the membrane hypothesis in terms of effects of diet composition on membrane composition and in turn on cellular-level fat metabolism, although the evidence was not consistent (e.g., Maillet and Weber, 2007; Nagahuedi et al., 2009; Guglielmo, 2010; Dick and Guglielmo, 2019). Most studies to date that related membrane composition to whole-animal performance refuted the membrane hypothesis. For example, as discussed above, when Price and Guglielmo (2009) used a sequence of feeding and fasting protocols to produce white-throated sparrows with fat stores and muscle membranes composed of different fatty acids, they found that the enhanced performance (i.e., peak metabolic rate) was associated with the fatty acid composition of fat stores rather than muscle membranes. Dick and Guglielmo (2019) used diet manipulations to produce groups of yellow-rumped warblers that differed in the MUFA, n-3, and n-6 composition of flight muscle membranes. They found effects of membrane composition on activity of several flight muscle oxidative enzymes in warblers but not on multiple whole-animal performance measures including BMR, peak metabolic rate, and energy expenditure and duration of wind tunnel flights. Carter et al. (2020) fed European Starlings one of two diets that differed primarily in 18:2n-6 (reciprocally replaced with 16:0) and this in turn produced starlings with corresponding differences in fatty acid composition of fat stores and muscle membranes that were consistent over the 4-month experiment (Carter et al., 2020). Carter et al. (2020) found effects of membrane composition on activity of several flight muscle oxidative enzymes (Carter et al., 2021) but also on multiple whole-animal performance measures including BMR, peak metabolic rate, and rate of energy expenditure during >2-h wind tunnel flights. Specifically, birds with higher concentrations of 18:2n-6 in membranes and fat stores had higher BMR and peak metabolic rates, although this pattern was evident early in the fall and not later in the fall experiment. The change through time in performance measures but not membrane composition led Carter et al. (2020) to conclude that their results were most consistent with the signal hypothesis rather than the membrane hypothesis. Thus, evidence to date supports the membrane hypothesis in the sense that key metabolic enzymes and other suborganismal measures are affected by fatty acid composition of membranes; however, these studies have not consistently found the predicted effects on whole-animal exercise performance given differences in membrane composition alone.

The natural doping hypothesis proposes that birds (in this case shorebirds) during migration enhance their exercise performance by selecting high n-3 diets (marine prey such as *Corophium volutator* in the case of semipalmated sandpipers) and thereby (a) incorporate these PUFAs into membrane phospholipids and affect membrane function (membrane hypothesis), and (b) (signal hypothesis) binding of n-3 PUFAs to PPARs that then activate the expression and activity of key genes and enzymes that instigate the metabolic pathways involved in enhancing the oxidative metabolism of fatty acids (Maillet and Weber, 2006, 2007, Weber, 2009). Some support for the mechanisms proposed by the signal hypothesis comes from recent studies of Gray catbirds sampled throughout their annual cycle. During premigratory fattening periods, catbirds had increased mRNA expression of certain PPARs and key target genes (Corder et al., 2016; DeMoranville et al., 2019), and these PPAR isoforms from catbirds were activated by certain fatty acids (i.e., 18:1, 20:5n-3) tested on mammal cell lines (Hamiliton et al., 2018). Whether dietary n-3 fatty acids (and n-6 PUFA) act as important natural ligands and so determine these seasonal changes in PPAR expression in migratory catbirds remains unknown (Corder et al., 2016; DeMoranville et al., 2019). In one of the most comprehensive and relevant tissue-to-whole animal experimental studies of migratory birds to date, yellow-rumped warblers fed more n-3 PUFAs and that had membranes composed of more n-3 PUFA *decreased* PPAR-β mRNA abundance, activity of muscle oxidative enzymes, and overall oxidative capacity, and this was not associated with any whole-animal performance effects, in direct opposition to the natural doping, signal hypothesis (Dick and Guglielmo, 2019). The potential to enhance whole-animal performance as proposed by the signal hypothesis may also pertain to the essential n-6 PUFAs. As noted earlier, Carter et al. (2020) concluded that the results from their study of European starlings that were fed and composed of more n-6 PUFAs, and then flown for long durations in a wind tunnel, were most consistent with the signal hypothesis. These same starlings composed of more 18:2n-6 increased the expression of PPARα in the liver and LPL in the pectoralis; however, this occurred only in starlings that flew daily for 2 weeks in the wind tunnel and not untrained birds fed the same diet, and no such effect of diet was observed on the expression of other PPAR transcription factors, PGC-1 coactivators, and key metabolic genes (i.e., CD36, MCAD, CS, PLIN2, and avUCP) in the pectoralis muscle and the liver (DeMoranville et al., 2020). The dependency of the signaling effect of n-6 PUFA on flight training suggests something more complex than a simple direct diet influence.

The three proposed hypotheses (fuel, membrane, and signal) are not mutually exclusive, and each has garnered some support. Given that the use of fats as fuel requires storage, protein transport at many steps of the ways, up- and downregulation of metabolic enzymes (Figure 47.5), and that dietary fatty acids affect the composition of stored fat as well as membranes and can act as signaling molecules, we should not be surprised that this multifaceted fat metabolism system can be affected by diet and exercise in multiple ways. We know from both experimental and correlative studies that the fatty acid composition of diet largely determines that of fat stores and muscle membranes and that there is seasonal variation in the composition of the fat stores and membranes. Thus, the study of how dietary fatty acids affect fat metabolism at large as well as exercise performance in birds during migration presents a very tractable and ecologically relevant opportunity to test these various hypotheses. Especially intriguing and potentially informative are recent transcriptomic analyses (Dick, 2017) that revealed upregulation of key fatty acid metabolism pathways in captive yellow-rumped warblers in fall (vs. winter) while 45 other metabolic pathways were downregulated including those related to muscle growth, inflammation and immune function, and hormone signaling. The extreme challenges of migration may require such metabolic tradeoffs (Guglielmo, 2018), as has also been suggested in terms of an energy savings-oxidative cost tradeoff for birds during migration (McWilliams et al., 2020).

47.4.4.6 Fatty acid transport really matters

Metabolizing fatty acids at very high rates is quite difficult compared to the alternative, more soluble, carbohydrate and protein fuels used predominately by mammals during exercise (Guglielmo, 2010, 2018). As discussed in the next section, fatty acid oxidation in the flight muscles of migratory birds is enhanced by increasing the activity of key mitochondrial enzymes (e.g., HOAD and CPT) although the primary metabolic limitation seems more related to fatty acid transport through the circulation and its uptake by muscle cells (Guglielmo, 2010, 2018). The hypothesized mechanisms for effective and adequately rapid transport of fatty acids from fat stores into muscle cells in migratory birds has been extensively discussed elsewhere (McWilliams et al., 2004; Guglielmo, 2018) and above. In brief, migratory birds in general and birds during active migration, in particular, rely somewhat on augmented circulatory pathways to enhance fatty acid utilization, but the more important determinants of fatty acid flux seems to occur at the muscle cell level—specifically, protein-mediated transport of fatty acids across the muscle cell membrane [e.g., fatty acid translocase (FAT/CD36), plasma membrane fatty acid binding protein (FABPpm)] and within cells [e.g., heart-type fatty acid binding protein (H-FABP)] seems most likely to limit the overall rate of fatty acid metabolism in migratory birds (Figure 47.5). See Bishop and Butler (2015) for a more thorough treatment of this topic.

47.4.4.7 Protein use during flight and water balance

It is well established that birds catabolize lean mass as a protein source during flight with significant reductions in pectoralis muscle, leg muscle, digestive organs, and liver masses among other organs (Åkesson et al., 1992; Bauchinger and Biebach, 1998, 2001; Battley et al., 2000). Unlike lipids and carbohydrates, birds have no specific storage form for proteins (except very small endogenous amino acid pools). Proteins are stored in functional tissue such as flight muscle, digestive organs including the liver, and even skin (Marsh, 1984; Bauchinger and Biebach, 1998; Battley et al., 2000). Thus, the use of protein during flight causes a concomitant loss of structure and/or function. In red knots, *Calidris tenuirostris*, all organs (flight muscle, leg muscle, intestines, liver, kidney, stomach, heart, spleen, and skin) except brain and lungs decreased in mass during their long-duration flight from Australia to China (Battley et al., 2000). This lean mass loss in organs coincided with a 40% decrease in mass-specific BMR after migration suggesting a significant functional consequence in the organs contributing to BMR (Battley et al., 2000).

Several hypotheses explain why birds utilize protein during long-duration flights including the need for proteins as an adaptive reduction in muscle mass to conserve energy (Pennycuick, 1998), as intermediaries in the citric acid (Kreb's) cycle (Jenni and Jenni-Eiermann, 1998; Jenni-Eiermann, 2017), in tissue maintenance and repair (Lindström and Piersma, 1993; Guglielmo et al., 2001), and as a water source (Gerson and Guglielmo, 2011; Jenni-Eiermann, 2017; Groom et al., 2019). It is well understood that exercising mammals use proteins as a fuel source for gluconeogenesis and as intermediaries in the citric acid cycle (Aragón, 1981; Dohm, 1986). Jenni and Jenni-Eiermann (1998) concluded that the use of protein for the maintenance of citric acid cycle intermediaries is important in permitting the high rates of fatty acid oxidation required to meet the increased metabolic demands of long-duration flight in migratory birds. Guglielmo et al. (2001) found elevated plasma creatine kinase (CK) in migrating western sandpipers, and bar-tailed godwits as compared to nonmigrants in the same year suggesting that birds undergo a moderate amount of flight-induced muscle damage during migration and therefore must repair this damage before continuing their migration. However, the extent to which this damage impacts the recovery time at stopover sites and ultimately the pace of migration is still unclear.

Models of water use during flight suggest that water may be an important factor in limiting flight duration (Carmi et al., 1992; Klaassen, 1996). Protein catabolism provides 5.9 times more water per kilojoule than lipid catabolism (Jenni and Jenni-Eiermann, 1998) and thus can provide an invaluable source of water for fasting, flying birds (Gerson and Guglielmo, 2011; Jenni-Eiermann, 2017; Groom et al., 2019). The rate of protein catabolism during flight has been shown to be directly related to ambient relative humidity. Gerson and Guglielmo (2011) found that Swainson's thrushes *Catharus ustulatus* flown in a wind-tunnel at moderately low-ambient humidity had greater lean mass loss, increased metabolic water production, and higher uric acid levels (indicative of protein catabolism) than birds flown in moderately high humidity. Additionally, Groom et al. (2019) found that lean mass loss in birds exposed to low and high-ambient humidity was independent of metabolic rate in Swainson's thrushes with flown birds having similar protein catabolism as birds at rest. Birds have been shown to be effective at controlling blood plasma volumes regardless of thermal dehydration or dehydration incurred during flight (Carmi et al., 1993). Gerson and Guglielmo (2011) suggest that birds may utilize the protein-for-water strategy in an effort to maintain osmotic homeostasis since the plasma osmolarity of the thrushes was unaffected by ambient humidity during flight.

Although several species of birds have been shown to be sensitive to dehydration in ambient temperatures below 20°C in wind-tunnel studies (Torre-Bueno, 1978; Giladi and Pinshow, 1999; Engel et al., 2006), studies of trans-Saharan migrants suggest that energy savings may supersede any limitations set by water loss as migrants fly at higher ambient temperatures and lower humidity than expected given our current understanding from wind tunnel studies (Schmaljohann et al., 2008, 2009). Notably, access to drinking water may be a factor in a bird's decision to depart a stopover site and continue migration. For example, Garden warblers at a spring migration stopover site in the Mediterranean Sea that were captured with large fat stores and then given no access to water, were more likely to depart that night (i.e., had the greatest zugunruhe activity) compared to warblers with similar fat loads and access to water as well as those with less fat loads regardless of access to water (Skrip et al., 2015b). The degree to which freely available water influences departure of birds from a stopover site deserves further study, especially given the impact of climate change on worldwide water distribution.

The amount of protein used during long flights and the sources of these proteins appears to also be influenced in part by the level of fat storage, at least in passerines. Garden warblers, pied flycatchers *Ficedula hypoleuca*, Willow warblers *Phylloscopus trochilus*, and Barn swallows consumed protein primarily from flight muscle when fat stores comprised greater than 20% of total dry body mass. However, when fat stores reached critically low levels (i.e., 5–10% of total dry body mass), protein catabolism greatly increased and the protein mass of all organs decreased with significant reductions in the digestive organs as well as flight muscle masses (Schwilch et al., 2002). This pattern of protein use suggests an adaptive response in birds to the interaction of fuel use, energy requirements, and flight capability. When fat stores are adequate, reduction in flight muscle coincides with reductions in overall body mass (thus conserving energy) without compromising flight capability. However, when fat stores are nearing depletion, protein requirements increase and so birds rely more heavily on protein stores in nonuse organs such as the digestive tract as well as flight muscle. Although this is an adaptive response to meeting the energetic needs of the bird during flight, it appears to be at the detriment of flight capability.

47.4.4.8 Rebuilding protein stores after flight

The loss of proteins from structural and functional tissue during flight naturally requires that birds replenish what has been lost prior to their next flight. Birds arriving at a stopover site replenish protein reserves first before storing fat (Atkinson et al., 2007). For example, mass gain in red knots at Delaware Bay, USA, comprised ~15% fat when birds were below 133 g and ~84% fat above 133 g suggesting that birds have a critical body mass level where they must first rebuild protein stores before they are able to begin refattening (Atkinson et al., 2007). Since much of the protein used during flight is taken from digestive organs, fasted birds must rebuild their guts before returning to maximum digestive capacity and food intake (McWilliams and Karasov, 2001; Gannes, 2002; Pierce and McWilliams, 2004; Muñoz-Garcia et al., 2012). Passerine birds require 1–3 days for their digestive system to fully recover from fasting (Karasov and Pinshow, 2000; McWilliams and Karasov, 2001; Gannes, 2002) and this recovery may be diet-dependent (Pierce and McWilliams, 2004; Muñoz-Garcia et al., 2012). For example, fasted and food restricted white-throated sparrows fed a fruit diet (low protein) were unable to increase food intake rates to pre-fasted levels and thus regain body stores in three days of refeeding whereas sparrows fed a grain diet (high protein) were able to fully recover food intakes to prefast levels and regain energy stores in 24 h (Pierce and McWilliams, 2004). Munoz-Garcia et al. (2012) fed blackcaps, *Sylvia atricapilla*, diets containing 3% (low) and 20% (high) protein with labeled leucine to determine the extent to which these birds relied on dietary (exogenous) or endogenous sources of protein to rebuild their guts. Blackcaps fed a low-protein diet incorporated less exogenous protein into their tissue than blackcaps fed the high-protein diet. Interestingly, blackcaps incorporated more

exogenous protein into their gut than their pectoral muscle but were unable to rebuild their intestines at a similar rate as the blackcaps fed a high-protein diet (Muñoz-Garcia et al., 2012). However, the rate of rebuilding of protein stores (i.e., gut tissue) in migrating blackcaps was influenced by the availability of drinking water when the water content of food was low (Mizrahy et al., 2011). Blackcaps with limited access to drinking water and fed food with low-water content had no increase in lean mass nor fat mass during a simulated stopover period whereas birds provided with unlimited access to drinking water and/or food with high-water content were able to gain lean and fat mass (Mizrahy et al., 2011). This finding, along with that of Skrip et al. (2015) discussed above, suggests that freely available water at stopover sites may play a much larger role than previously thought in enabling birds to rebuild energy and protein stores and complete migration. A full understanding of the interaction between the protein-for-water strategy and the availability of drinking water at stopover sites deserves further investigation.

47.4.5 Temperature regulation during flight

Much of what is known about the body temperature fluctuations of birds during flight has been from wind tunnel studies of captive birds in short duration flights (Aulie, 1971; Torre-Bueno, 1976; Hudson and Bernstein, 1981). For example, pigeons increase their core body temperature (hyperthermia) during short-duration wind tunnel flights at ambient temperatures between 25 and 29C (Aulie, 1971), and this hyperthermia seems to limit the length of flight bouts in pigeons and European starlings (Aulie, 1971; Torre-Bueno, 1976). More recently, studies on wild birds using implanted data loggers have found that hyperthermia may play a much greater role in limiting the duration of migratory flights than previously assumed (Guillemette et al., 2016, 2017); however, this may only be relevant for the larger aquatic species with continuous, fast-flapping flight (Guillemette et al., 2017). Common eiders allow their body temperatures to rise on average 1C by the end of a typical flight and spend a significant portion (36%) of their daily time budget behaviorally cooling their body temperatures from previous flight bouts (Guillemette et al., 2017). Thus, eiders are heat dumping in between migratory flights. Less is known about temperature regulation to avoid hyperthermia during migratory flight in passerines as there are no studies to our knowledge that have used data loggers to track migratory temperature fluctuations in songbirds. Given the few studies to date on free-living birds, it would be beneficial to investigate the role of hyperthermia in regulating the duration of flight in migratory birds, especially in light of climate change.

47.4.6 Flight at high altitude

Birds are preadapted to low-oxygen conditions since the design of their respiratory and circulatory systems makes their oxygen uptake highly efficient, although several aspects of their physiology enable regular flying at high altitude during migration (see Bishop and Butler, 2015 for a thorough treatment of this topic). For example, birds such as bar-headed geese, *Anser indicus*, that fly regularly at high altitudes produce more hemoglobin, more red blood cells, and more myoglobin (the hemoglobin equivalent in muscle cells) as they prepare for migration which enhances their blood's capacity to bind and transport oxygen (Scott and Milsom, 2006). In addition, relatively larger lungs, and more and deeper penetrating blood capillaries in their heart and flight muscles compared to other geese further facilitates oxygen transport. Bar-headed geese also have a special form of an enzyme (nicknamed COX) involved in energy production within their muscle cells (Scott et al., 2011).

47.5 Beyond systems

Migration is one of the most complicated life history stages given the diverse habitats traversed, distances covered, multiple routes, and daily fluctuations of climatic conditions to which birds are exposed in vernal and autumnal stages. To be successful, this life history stage requires flexibility of morphology, physiology, and behavior in tight coordination with environmental information that initially regulates preparation for the stage and subsequently influences the timing, duration, and amplitude or intensity of the response throughout the fueling and flight cycle and eventually termination. The endocrine system plays major roles integrating environmental information with the molecular and cellular physiology as presented here. But, questions remain including: (1) how does seasonal variation of resources and routes affect fueling and flight, (2) does the endocrine status of vernal and autumnal migrants affect their responses to the conditions of specific habitats *en route*, and (3) are the apparent seasonal differences in the endocrine pathways exerting similar effects on fueling or are there multiple ways in which such regulatory systems have evolved?

A fundamental aspect of the life history of migratory birds is the ability to flexibly modify their physiology to satisfy the changing demands associated with migration. Such physiological flexibility is possible only because the network structure of molecules and regulatory relationships that maintain and adjust homeostasis (i.e., the Physiological Regulatory Network, PRN *structure*) can remain the same while the concentrations and relative strengths of the

relationships (i.e., the PRN *state*) can change depending on conditions (e.g., age, seasons, and migration; Cohen et al., 2012). In this chapter, we have outlined key components of the PRN *structure* (e.g., Figure 47.6) and how the PRN *state* is adjusted within individuals during migration. However, our review also makes clear that there remain major gaps in our understanding of both (a) the network of specific molecules and regulatory relationships that maintain and adjust homeostasis (i.e., PRN *structure*) and especially (b) how the concentrations of key molecules and the relative strengths of certain regulatory relationships change with the context and the conditions of vernal and autumnal migration (i.e., PRN *states*). For example, the biochemical mechanisms involved in using fats as fuel, or those responsible for maintaining redox homeostasis and limiting oxidative damage, are usually considered distinct physiological systems (i.e., separate PRN *structures*) that dynamically respond to changing conditions. However, we have emphasized here that there are physiological linkages between fat metabolism and oxidative status that require a more systems-level, integrative approach to fully understand how migratory birds respond to their changing environment(s), and the conditions of vernal and autumnal migration. Furthermore, phenotypic flexibility of physiological traits requires that the capacity of a physiological system is matched to the prevailing demand but can be modulated in response to changes in demand as to provide some limited excess capacity ("enough but not too much") (Diamond, 1991; Hammond and Diamond, 1997; McWilliams and Karasov, 2014). The level of so-called "spare capacity" and the full extent of phenotypic flexibility and its required time course provide important insights into constraints on whole-animal performance, diet diversity, and ecological niche (Piersma and Gils, 2011; McWilliams and Karasov, 2014). Given this systems-level perspective, the following related questions remain outstanding: (1) for a given physiological system (e.g., fat metabolism, oxidative status, and immune function), what is the PRN *structure* for migratory birds and how does PRN *state* change within individuals during migration, (2) what are the key physiological linkages between these systems that influence the limits to animal performance, and (3) what is the time course for such phenotypic flexibility of key physiological traits given that birds during migration are often time-limited?

48.1 Introduction

The use of chemicals has been critical in crop production, pest control, health and beauty products, and industrial systems crucial in our global economies. Nonrenewable energy sources, plastics, and industrially produced compounds have been essential to our lifestyle and are key in the efficiency of production systems, packaging, and storage. Not surprisingly, as we learn more about the chemical components used in many of these processes, in storage and production, and for control of pests and our environment, adverse effects have come to light. One of the earliest findings indicative of potential adverse effects of industrial chemicals and pesticides was the thinning of eggs in bald eagles in response to exposure to dichlorodiphenyltrichloroethane (DDT), which dramatically illustrates the potency of these chemicals in wild birds (Felton et al., 2015). Since that time, there has been extensive research aimed at assessing the actions and risks associated with exposure to environmental chemicals across vertebrate and invertebrate species. Workshops, including the Wingspread Meetings and research publications have documented a range of impacts of endocrine disruptors and other toxicants in laboratory studies and in field populations of avian species (Basu, 2015; Berg et al., 1999; Bowerman et al., 2007; Brunstrom et al., 1991; Cesh et al., 2010; Cohen-Barnhouse et al., 2011; Corbitt et al., 2007; Custer et al., 2010a, 2012b; Custer and Read, 2006; Hotchkiss et al., 2008; Kavlock et al., 2005; Rattner, 2009; Rattner et al., 2000, 2001, 2010; Safe et al., 1985; Levengood et al., 2007). Many of these environmental chemicals persist in and move through the environment, with secondary metabolites and degradants that are also

Sturkie's Avian Physiology. https://doi.org/10.1016/B978-0-12-819770-7.00036-0

biologically potent. Further, multiple chemicals generally coexist in the environment, meaning that most vertebrates are exposed to a mixture of chemicals at any point in time (Vermeulen et al., 2020). Exposure to complex mixtures vary in wild populations depending on location; migratory birds also may encounter very different chemical mixtures at their wintering grounds compared to nesting area.

It is important to distinguish between a primary toxic effect from environmental chemicals versus adverse impacts from endocrine disruption, which often is nonlethal (details provided later in this review). Some early studies began to distinguish toxic from endocrine disruption and characterize the actions as well as physiological targets of EDCs. Although the characterization of exposure effects has focused on single compounds, it is also clear that wild birds are exposed to a complex mixture of environmental chemicals, which often include toxic compounds, metals, and EDCs. Research is needed to understand possible synergisms of the compounds in these complex mixtures. The potential for deleterious results has been supported by observations of endocrine related effects to organisms in areas in which dioxin, PCB, or other chemicals occurred. Furthermore, the exposure of wildlife to environmentally relevant levels is often at sublethal concentrations, making the determination of effects of EDCs a challenge, especially when attempting to separate other interacting factors in the animal's environment that also impact fitness and overall health. Additional environmental factors impacting wild populations include environmental conditions, habitat loss, food availability, disease, or exposure to complex mixtures of chemicals.

It is therefore important to develop reliable and sensitive measures that are appropriate for the endocrine or organ system that are the targets of the EDCs. This chapter will consider EDCs and their actions target physiological systems, particularly reproductive and metabolic endocrine systems of birds. In addition to physiological targets of EDCs that are found across vertebrates, termed conserved mechanisms, birds also have unique adaptations for migration, flight, and reproductive strategies, such as precocial or altricial developmental stages in chicks at hatch. Further, birds living in varied habitats, climates, and resources have developed a range of reproductive strategies, as well as other adaptations for flight, migration; all with associated metabolic and reproductive modifications. Some of these unique characteristics of birds may also affect their vulnerability to exposure to environmental chemicals. It is important to identify specific physiological measures that reflect EDC exposure and utilize these measurement end points as metrics to assess effects. Testing provides the basis for risk assessment and injury quantification criteria that take these unique characteristics of birds into consideration. As more compounds are characterized as endocrine disruptors, it has become clear that there are thousands of these chemicals in the environment. As such, these chemicals have been considered in terms of broad categories, often with studies conducted on representative chemicals for a category. Influence diagrams, AOPs, and the one health framework help to describe molecular/cellular mechanisms of action and relate these adverse impacts to effects of exposure for the organism and potentially to the population. Compiling this information becomes essential in developing reliable testing paradigms for the commercial, industrial, and personal applications of chemicals that migrate into the environment.

48.2 Environmental chemicals: utilities and hazards?

48.2.1 Chemical sources and production

A number of factors must be considered when evaluating the cost/benefit for production and use of environmental chemicals. The productivity of modern agricultural systems is outstanding, in part due to the use of chemical treatments that limit pests and make applications, storage, and preparation more efficient. The use of chemicals has dramatically increased as our knowledge of chemistry and biochemistry has enabled the development of designer chemicals for specific applications. In recent years as we have become more aware of the adverse impacts of some of these chemicals on nontarget species or systems, we have seen the emergence of "green chemicals" (see https://www.epa.gov/greenchemistry), designed with the intent of lessened adverse impacts on nontarget organisms and attenuated presence in the environment. However, many of these chemicals are effective because they specifically interact with endocrine-related processes or other physiological functions in pest species. For example, an effective pesticide for gypsy moths is tebufenozide, which is an ecdysone inhibitor that acts on the timing of molting in larvae. Because these compounds were developed specifically to act on physiological targets in insects, coincident effects on other vertebrate classes are generally regarded as minimal risk compared to the benefit of pest management. However, as we have seen in the past, there are sometimes unexpected adverse impacts due to spills, or chemical overuse resulting from chemical resistance by the target pest species. One of the challenges of characterizing the potential risk and impacts of environmental chemicals to wildlife, and birds in particular distinguishing between toxic physiological effects and endocrine disruption. Moreover, wildlife populations are generally exposed to multiple chemicals that exist in the environment that may also include metals and other contaminants. These complex mixtures will also be discussed in the context of physiological targets of single compounds and

actions of simultaneous exposure to a suite of chemicals. Additionally, the assessment of adverse effects of EDCs has presented some unique challenges as discussed below.

48.2.2 Assessing the safety of chemicals

The US Environmental Protection Agency formed the Endocrine Disruptor Screening and Testing Advisory Committee (EDSTAC), a committee of scientists and stakeholders that was charged by the EPA to provide recommendations on how to implement its Endocrine Disruptor Screening Program (EDSP). The EDSP is critical for assessing the potential for EDCs to impact vertebrate species with the added benefit that identifying EDCs with adverse effects in vertebrates and banning them from use would then prevent human exposure. Upon recommendations from the EDSTAC (Harvey and Everett, 2006), the EPA expanded the EDSP using the Administrator's discretionary authority to include the androgen and thyroid hormonal systems as well as the reproductive endocrine systems of wildlife (see http://www.epa.gov/endo/pubs/edspoverview/edstac.htm). Following broader international concerns and the creation of similar programs in other countries, the Organization for Economic Cooperation and Development established the Endocrine Disrupters Testing and Assessment Task Force in 1998 within its Test Guidelines Program, with the charge of developing an internationally harmonized testing strategy for the screening and testing of EDCs. Additional international collaborative efforts have been initiated through professional societies and workshops focused on the effects of exposure to environmental chemicals across vertebrates.

48.2.2.1 Assessing multigenerational impacts in the Japanese quail model

To address possible effects specifically due to EDC exposure in birds, the Japanese Quail (*Coturnix japonica*) Two Generation Test was developed to detect potential disruption of the endocrine system by EDCs at varied stages of the lifecycle; this and other tests will be reviewed later in this chapter. One of the primary challenges, given the diversity of chemicals considered potential EDCs is to ascertain risk across vertebrate classes. Additionally, the incidence of EDCs is global, including areas that have been considered relatively pristine (Kakimoto et al., 2018; Santamans et al., 2017). Because birds have a broad range of life histories and unique developmental characteristics, there are differential sensitivities across avian species with changing lifetime vulnerability. Further, migratory birds have enormous metabolic demands (Seegar et al., 2015). As such, EDCs that impact metabolic and in particular the thyroid systems pose risk to migratory avian species. Not only to ensure adequate growth and fattening before migration but also adequate feather replacement or development of subadult or adult plumage for young-of-the-year prior to migration. Furthermore, sexual differentiation of reproductive and other endocrine systems is unique to birds, being driven by primarily estradiol-mediated mechanisms. Migratory birds are once again subject to particular stressors during reproductive periods, such as switching rapid from physiology and energetics associated with long-distance flight to egg production, song production, nest building, territorial defenses, and parental behavior, all of which rely on functioning endocrine pathways and feedback loops. Developmentally, songbirds and other passerine species are altricial, while ducks, quail, and other ground dwelling species are generally precocial. This developmental difference appears to relate to the extent and timing of sensitivity to EDCs because precocial species are fully functional and relatively independent at hatch. They undergo sexual differentiation in ovo; similarly, other physiological systems are also well developed at hatch as compared to altricial birds that require intensive parental care. These developmental differences can be greatly impacted by the degree of maternal transfer of environmental toxicants. Lipophilic compounds such as PCBs are primarily sequestered in egg yolk, which is used in the latter part of in ovo development and in the first few days posthatch. The exact timing of the transfer of EDCs into the developing embryo could greatly impact brain, neuroendocrine function, and gonadal development, and this can vary with the degree of development at hatch. Finally, the potential for adverse effects of EDCs on long- or short-lived birds is unknown especially in the context that long-lived birds tend to have small clutches and raise fewer chicks per year compared to short-lived birds (Holmes and Ottinger, 2003; Ottinger et al., 2009a; Ottinger, 2005).

48.2.2.2 Effects of environmental chemical impacts in wild birds

Historically, there are many studies in wild birds that document cases of exposures with higher concentrations of toxicants originating from chemical applications and industrial spills. Often these occurrences were associated with high mortality; thereby prompting federal and regional responses aimed at protecting human and wildlife health. However, less is known about nonlethal impacts of EDCs on wild birds and the potential for adverse effects translating even to the level of a risk to the population. The deleterious effects of DDT were recognized as adverse effects of a pesticide exerting endocrine disruption of an estrogen dependent process in bald eagles, resulting in egg shell thinning (Lundholm, 1997). As a consequence, embryonic eagles failed to develop to hatch. In addition, there are extensively documented cases, such as incidences of avian impacts from the Great Lakes, PCBs released into the

Housatonic and Hudson Rivers and the Gulf of Mexico Macondo Oil Spill that indicate impacts on birds (Best et al., 2010; Bowerman et al., 2007; Burger, 2018; Champoux et al., 2020; Custer et al., 2010a; Darnerud, 2003; Franceschini et al., 2008). Data from some extraordinary datasets are emerging from long-term monitoring and research programs, such as the Great Lakes region, Chesapeake Bay Programs, and The Gulf of Mexico (Gulf of Mexico Avian Monitoring Program https://gomamn.org); many of these studies have considered physiological and reproductive impacts of exposure to chemicals found in those areas (Deepwater Horizon Natural Resource Damage Assessment Trustees, 2016). Laboratory studies have provided additional insights into potential mechanisms of action of EDCs as well as periods of sensitivity throughout the life cycle. Information from many of these studies will be discussed below in order to put the proposed two-generation test into the context of testing in avian species. Furthermore, it is important to consider unique characteristics of the avian physiology with emphasis on sexual differentiation, hormonal modulation of endocrine and behavioral components of reproduction, and functional impacts of EDCs on neuroendocrine regulatory systems, especially considering potential adverse outcomes.

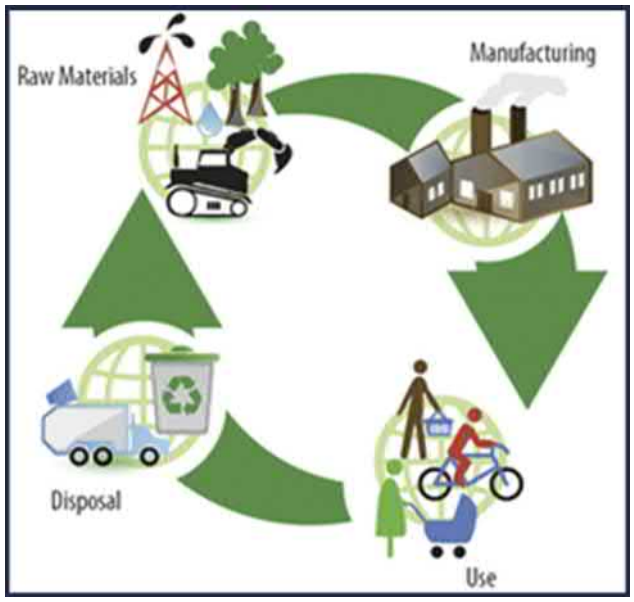

FIGURE 48.1 Diagrammatic representation of the life cycle of industrial compounds; once manufactured, they are used and then disposed allowing reentry into the environment. *From: Environmental Protection Agency "Risk Management Sustainability Technology" http://www.epa.gov/nrmrl/std/lifecycle.html.*

48.3 Life cycle of chemicals: endocrine disrupting chemicals in the environment

48.3.1 Parent compounds and their metabolites in the environment

There are many sources of chemical contaminants, including EDCs in the environment, and there are excellent resources available to search for information and distribution about many of these compounds. For example, the United States Geological Service (USGS) has a Contaminant Exposure and Effects—Terrestrial Vertebrates Database provides a searchable database containing over 20,000 records that provide information on taxonomy and chronology of ecotoxicological exposure and effects as well as geographic location of contaminants (see http://www.pwrc.usgs.gov/contaminants-online/pages/ceetv/ceetvintro.htm). In considering the use and fate of environmental chemicals, it is important to consider the life cycle of a chemical or compound (Figure 48.1). The fate of a compound in the environment relates to both the movement in soil, water, and air as well as the metabolism of the parent or original chemical. Some chemicals enter directly into the air as a consequence of the manufacturing process, such as in the case of airborne chemicals through smoke stacks or steam. Moreover, chemicals in the environment become metabolized with exposure to air, sun, heat, and microbial metabolism. Metabolites of parent compounds are often bioactive and, in some cases, impact different physiological targets with even greater toxicity than the parent compound. Alternatively and more frequently, chemicals are manufactured for a specific purpose such as in the case of DDT, which as an effective insecticide became ubiquitous in the environment with wide use as a pesticide and in the battle against malaria-carrying mosquitos (Asawasinsopon et al., 2006; Borga et al., 2007; Braune et al., 2005; Rattner, 2009). As may be seen in Figure 48.2, DDT applied to fields as an insecticide then migrates into the water via rain events and runoff into waterways and ultimately into the groundwater. In the rivers and streams, DDT becomes part of the food chain by ingestion into invertebrates, which are eaten by fish and eventually by organisms higher on the food chain. This brings to attention the effects, meaning. In this example, effects were observed in bald eagles and more recently in herons at Lake Michigan on egg shell thinning (Lundholm, 1997; Rattner, 2009). The life cycle of DDT also includes metabolism into dichlorodiphenyldichloroethylene (DDE), an antiandrogenic compound in vertebrates (Bowerman et al., 2007; Quinn et al., 2008). Although banned in the United States in 1972 as well as in many parts of the world, significant concentrations of DDT and its metabolites are found in agricultural areas and in wildlife living and breeding in proximity to areas that had wide use of DDT as an insecticide (Weseloh et al., 1990; Mora et al., 2016). Further, the use of DDT continues in some countries battling persistent malaria-carrying mosquitos, including providing mosquito netting impregnated with DDT to families with

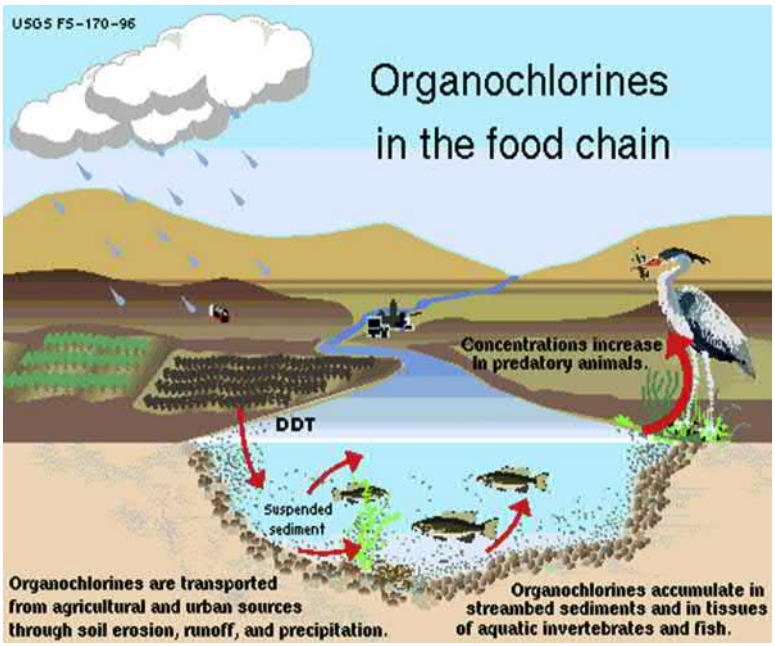

FIGURE 48.2 The life cycle of DDT in the environment from application on fields, transport to aquatic environments, uptake by invertebrates and fish that are eaten by higher vertebrates higher on the food chain. *From U.S. Department of the Interior-USGS Fact Sheet 170–96; https://pubs.usgs.gov/fs/1996/0170/report.pdf.*

young children. Alternative chemicals related to DDT have also been developed to address the need for effective pesticides, including dicofol and methoxychlor, both of which have been linked to adverse impacts in birds and transfer into the eggs of exposed females (Wiemeyer et al., 2001; Kamata et al., 2010).

48.3.2 Environmental contamination by industrial chemicals and mixtures

In the case of industrial compounds, such as crude oil, lubricants, plastics, flame retardants, and nanofibers, there may be purposeful or inadvertent release into the environment, especially at the time of usage or disposal. This is the case with the release of polychlorinated biphenyls (PCBs) into the environment, which occurred both as a consequence of the manufacturing practices for electrical transformers containing Aroclors® and affected the Housatonic River in western Massachusetts (Custer and Read, 2006; Custer et al., 2012a; Barnthouse et al., 2003). Similarly, General Electric's Hudson Falls and Fort Edward plants discharged PCBs into the upper Hudson River from 1947 until 1952 (http://www.darrp.noaa.gov/northeast/hudson/index.html). This, in combination with leakage of these compounds from the manufacturing process for capacitors resulted in long-term contamination of the river and continued persistence of PCBs in the environment (Erickson et al., 2005; Butcher and Garvey, 2004; Cho et al., 2002; Foley, 1992; Man et al., 2011). Not only do PCBs have a very long half-life in the environment, they also remain chemically stable in the sediment and become available when the sediment is disturbed. Further, measurements in tree swallow and sandpiper eggs, respectively, revealed that there were two mixtures present in the Hudson River environs; reflecting both released congeners and other congeners associated with metabolism (Echols et al., 2004; Nichols et al., 2004). As such, there are dynamics in the environment including rainfall events as well as climate change that will impact the movement and potential for exposure across living organisms.

As initially discussed above, it is most common to have mixtures of chemicals occurring in the environment, which in turn become incorporated into the body burden carried by all vertebrates, including humans and wildlife. As such, there is a growing literature focused on understanding exposure and persistence of these chemical mixtures in the environment and retention in the body, generally in the fatty tissue as many of these chemicals are lipophilic compounds. In addition, it is unclear how the compounds that constitute the complex mixture interact, specifically do these compounds have synergistic actions? Further, metals are often in these mixtures but rarely considered as a component; thereby not included in an assessment of risk from exposure.

48.4 Classes of endocrine disrupting chemicals and their physiological actions

As mentioned earlier, the Environmental Protection Agency (EPA) formed a federal advisory committee, the

Endocrine Disruptor Screening and Testing Advisory Committee in 1996 to consider the specific risks from exposure to EDCs and recommend appropriate regulatory measures (see http://www.epa.gov/endo/pubs/edspoverview/edstac.htm). Over two years, EDSTAC considered the complexities of potential and recognized EDCs, risks to vertebrate and invertebrate organisms, and recommended a series of testing paradigms to be developed and verified (see http://www.epa.gov/endo/pubs/edspoverview/finalrpt.htm for EDSTAC final report). These tests would include screening and testing, utilizing cell-based screens and bioassays sensitive to endocrine disruption of the reproductive and thyroid endocrine systems. The tests were separated into Tier 1 containing in vitro high-throughput screens to allow rapid assessment and identification of endocrine active compounds and in vivo specific assays to target known EDC mechanisms of action (Table 48.1) primarily focused on estrogenic, androgenic, or thyroid active compounds (Table 48.2). Tier 1 assays serve to identify compounds for in depth tests in Tier 2 multigenerational tests, to capture periods of vulnerability to EDC effects (Touart, 2004). There are a range of two-generation tests, including the medaka multigeneration test, Japanese quail two-generation test (JQTT), mysid two-generation toxicity test, and larval amphibian growth and development test. All tests are reviewed by expert panels (FIFRA Science Advisory Panels) for use in regulatory oversight of current and emerging chemicals. Further review and updated regulatory guidelines continue as more is learned about the actions, risks, target organisms, and of EDCs.

48.4.1 Categorizing endocrine disruptors according to structure and function

Many factors impact the passage and life cycle of chemicals in the environment and affect the potential for exposure to living organisms. Moreover, individuals are generally exposed to multiple environmental chemicals concurrently and all living organisms carry some chemical contaminant burden within their body. There have been attempts to organize potential and proven EDCs into classes of chemicals, grouped by mechanism of action, physiological target, and relative activity including capacity for toxicity. These groupings are based on

TABLE 48.1 List of assays proposed by the endocrine screening and testing advisory committee.

Assay	Reason for inclusion
Estrogen receptor binding or transcriptional activation assay	An in vitro test to detect chemicals that may affect the endocrine system by binding to the estrogen receptor.
Estrogen receptor transcriptional activation assay	An in vitro test to detect chemicals that may affect the endocrine system by binding to the estrogen receptor.
Androgen receptor binding assay	An in vitro test to detect chemicals that may affect the endocrine system by binding to the androgen receptor.
In vitro steroidogenesis assay	An in vitro test to detect chemicals that interfere with the synthesis of the sex steroid hormones
Placental aromatase assay	An assay to detect interference with aromatase.
Uterotrophic assay	An in vivo assay to detect estrogenic chemicals.
Hershberger assay	An in vivo assay to detect androgenic and antiandrogenic chemicals.
Pubertal male	An in vivo assay to detect chemicals that act on androgen or through the hypothalamic–pituitary–gonadal (HPG) axis that controls the estrogen and androgen hormone systems. It is also enhanced to detect chemicals that interfere with the thyroid system. This assay could in part substitute for the female pubertal assay.
Pubertal female assay	An in vivo assay to detect chemicals that act on estrogen or through the HPG axis that controls the estrogen and androgen hormone systems. It is also enhanced to detect chemicals that interfere with the thyroid system.
Amphibian metamorphosis assay	An in vivo assay for detection of chemicals that interfere with the thyroid hormone system.
Fish screening assay	An in vivo assay for detection chemicals that interfere with the HPG axes.

Assays recommended for consideration for the Tier 1 screening battery.

structure-function relationships and when available, on experimental findings in the literature for a specific or similar compound (Le Page et al., 2011; Newbold et al., 2008; Safe et al., 1998; Watanabe et al., 2002; Zacharewski, 1998; Foster, 1998; Kavlock and Ankley, 1996). A great deal of emphasis has gone into understanding the actions of xenoestrogens because much of the initial recognition of endocrine disruption from antiestrogenic effects of DDT and subsequently compounds and mixtures that are androgen active, either having androgen like activity or antiandrogenic actions. In addition, many compounds including polybrominated biphenyls, triphenyl phosphate, PCBs, and others target the thyroid axis as well as metabolic function; with variable effects in field birds (Marteinson and Fernie, 2019; Nossen et al., 2016; Ruuskanen et al., 2019). The perfluoroalkyls are gaining increasing attention as EDCs and emerging as a contaminant impacting birds (Guigueno and Fernie, 2017; Guigueno et al., 2019; Vorkamp et al., 2019), and evidence that polycyclic aromatic hydrocarbons (PAHs) from crude oil can impact the adrenal axis (Lattin and Romero, 2014; Lattin et al., 2014). Finally, there is increasing recognition that environmental chemicals are inherently stressors, with a wide range of other actions on the immune response, growth, epigenetic actions associated with alterations at the genetic level, and lifetime effects on metabolism and overall fitness. Therefore, it is critical to continue to refine the detection and characterization of environmental chemicals and complex mixtures.

Analysis of the chemical structure of a compound provides valuable insight into the potential actions and physiological targets. In the case of PCBs, there is increasing toxicity associated with the number of and molecular placement of chlorine atoms. Extremely toxic compounds, such as dioxins, particularly 2,3,7,8-tetrachlorodibenzodioxin, provide a "yardstick" for comparison of toxic effects from other toxicants with the same mode of action (activation of the AhR). As pointed out earlier, it is challenging to discern frank toxicity from endocrine disruption, given the complexity of the endocrine systems, variation among individuals and plethora of compensatory physiology mechanism. Therefore, it has become important to utilize approaches, such as AOP (details provided below) that describe the suite of effects associated with exposure to a compound or mixture.

Because the presumed targets of EDCs have been the reproductive axis and more specifically via interaction with steroid hormone receptors, many of the strategies for high-throughput screening have utilized cell-based systems that detect interactions with these steroids (Fisher, 2004; Hartig et al., 2002; Kase et al., 2009; Kusk et al., 2011; D'ursi et al., 2005). However, these in vitro approaches must be integrated with information about physiological and toxicological effects. As a consequence, computer-based predictive models have been developed that provide a rapid method for ascertaining potential endocrine activity based on structure-function and known mechanisms of action (Wambaugh et al., 2013; Knudsen et al., 2013; Kavlock et al., 2012; Martin et al., 2009; Dix et al., 2007; Basu, 2015). As more information becomes available, these approaches provide a powerful technique for assessing the potential for emerging chemicals to be endocrine disruptors.

48.4.2 Mechanisms of action of endocrine disrupting chemicals in vertebrates

There is an extensive literature that clearly demonstrates the interaction of EDCs and steroid hormone receptors, particularly xenoestrogens, androgens, and thyroid hormone active compounds (Kusk et al., 2011; Zhang and Trudeau, 2006; Masuyama et al., 2002). There are conserved mechanisms of action found for birds, mammals, and other vertebrates in response to EDC exposure. In addition to extensive databases and mechanism-based models, a number of investigations have explored the mechanisms of endocrine disrupting activity, in mammals, birds, and other taxa (Stoker et al., 2000; Zacharewski, 1998; Watanabe et al., 2002; Le Page et al., 2011; Janer et al., 2005; Gore, 2010; Harvey and Everett, 2006). A number of EDCs are estrogen mimics, interacting with estradiol receptors and/or with estrogen responsive systems as agonists or antagonists (Watson et al., 2014; Hall and Korach, 2002; Marino et al., 2012; Felton et al., 2015; Jimenez et al., 2007). Conversely, DDE, trenbolone, and others having potent androgenic or antiandrogenic actions (Hartig et al., 2007; Manikkam et al., 2013; Soto and Sonnenschein, 2010; Guerrero-Bosagna and Skinner, 2009; Prins, 2008; Skinner, 2007; Maffini et al., 2006; Bigsby et al., 1999; Santti et al., 1998; Quinn et al., 2007a,b). Many of the assays developed have taken advantage of the mechanisms revealed by these studies, as for example, the vitellogenic effects of EDCs in fish (Wang et al., 2011; Larkin et al., 2002). It is also important to recognize that there are effects of EDC exposure, which may reflect some direct toxicological effects of these compounds in addition to endocrine effects (Fucic et al., 2012; Carro et al., 2013a,b; Quinn et al., 2007b). Furthermore, induction of cancer in reproductive organs has also been linked to EDC exposure (Ohlson and Hardell, 2000; Fucic et al., 2012). There are additional specific vulnerabilities associated with unique characteristics of birds that must be considered in order to accurately assess potential for adverse outcomes from exposure, which will be discussed in more detail later in this chapter.

48.4.3 Interactions of endocrine disrupting chemicals and specific receptors

Interactions with receptors depend on the structural characteristics of the EDC. In the case of PCBs, the toxicity and relative impacts relate to the number and location of chlorine molecules on the ring structure (Figure 48.3, Fischer et al., 1998; Hennig et al., 2002). Primary effects of EDCs rely on the ability to interact with steroid or thyroid hormone receptors, which then exert competitive inhibition or antagonistic effects; or in some cases may be stimulatory with agonistic effects. The up- or down-regulation of cellular processes via interaction with these receptors then has the capacity to alter a host of physiological functions that are modulated through steroid hormone or thyroid hormones. Although less is known about the potential for EDCs to act on the stress axis, a stressed individual would be predicted to be more vulnerable to other insults such as those from EDC exposure (Burger, 2018; Fairbrother et al., 2004; Fairhurst et al., 2017; Fernie et al., 2005a; Grasman, 2002; Grasman et al., 1998; Franceschini et al., 2008; Perez et al., 2017a,b,c). Studies on the effect of crude oil on the hypothalamic–pituitary–adrenal (HPA) axis (Lattin and Romero, 2014; Lattin et al., 2014), suggest that PAHs can directly impact the adrenal gland, reducing the ability of house sparrows (*Passer domesticus*) to mount a stress response and also reduce glucocorticoid receptor density.

Data are emerging that demonstrate effects of EDCs on multiple growth and differentiation factors, which in turn affect the ontogeny of that organ system as well as impact function in the mature individual (Thackaberry et al., 2005; Walker and Catron, 2000; Head et al., 2008). For example, effect of EDCs on the ryanodine receptor has been shown to impact calcium signaling, which in turn alters neural function, neurodevelopment, and neurodegenerative processes (Pessah et al., 2010). EDCs have the potential to affect immune function both short- and long-term in individuals and can be especially potent if there are other environmental stressors (Schug et al., 2011; Ottinger et al., 2005a; Quinn et al., 2007a, Lavoie et al., 2010). At a more cellular level, dioxins, PAHs, and other EDCs have been shown to affect oxidative damage processes, with potential to impact mitochondrial function (Pereira et al., 2013). As such, the impacts of EDCs on endocrine function should not only consider "cross-talk" effects of the thyroid, stress, immune, reproductive, and growth axes with other physiological systems, but should also consider the additive impacts of environmental stressors other than EDCs.

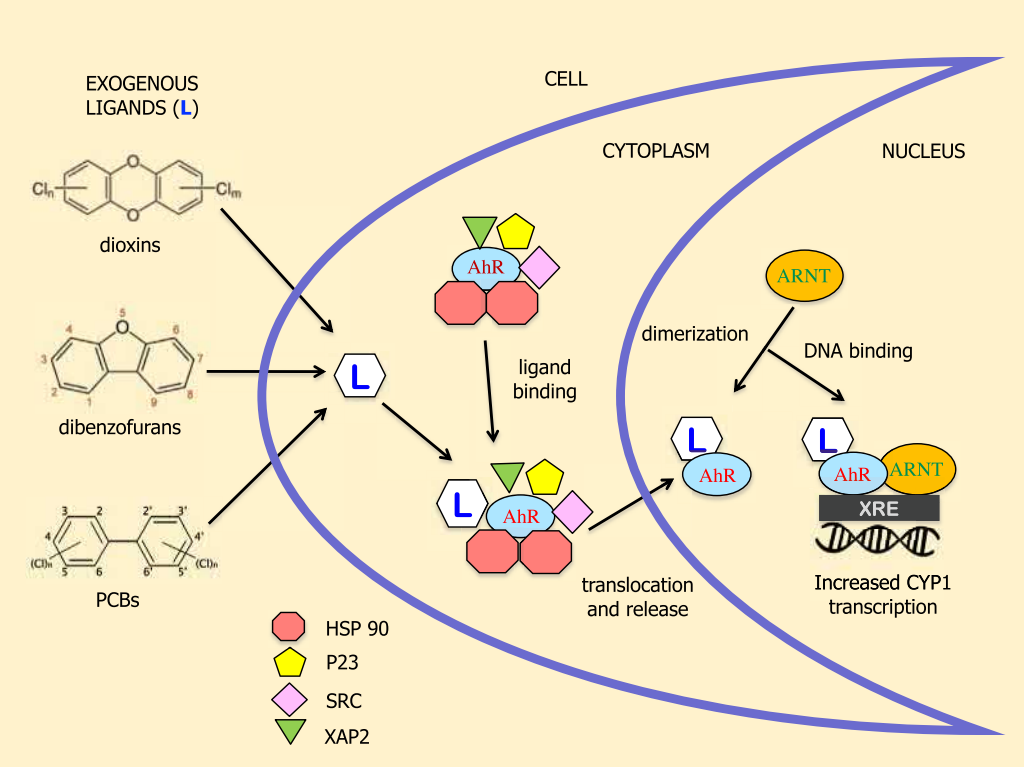

FIGURE 48.3 Aryl hydrocarbon Receptor (AhR) signaling pathway is comprised of interaction of endocrine disrupting chemicals with affinity to AhR, translocation of the complex to the nucleus, dimerization, and binding of the aryl hydrocarbon nuclear translocator complex to the xenobiotic response element on the DNA ultimately leading to increased transcription of CYP mRNA for translation to CYP enzymes.

48.4.4 Discerning endocrine disrupting chemical impacts in field birds

Effects of toxicants that affect wild populations of birds have often been associated with spills and critical exposures that gained attention due to the death of a number of individuals, such as the Deepwater Horizon or *Exxon Valdez* oil spills. Conversely, it is often difficult to detect nonlethal effects in wild populations due to the lack of curated data that includes individuals and associated metadata for the presence of environmental chemicals in the environs. Brown pelicans (*Pelecanus occidentalis*) studied along the Louisiana coastline (Gulf of Mexico) prior to and during DWH oil spill suffered from habitat destruction, including loss of preferred nesting sites in shrubby vegetation resulting in reproductive losses in 2010 following the DWH spill (Walter et al., 2013). When considered on its own, this is likely to be construed as a reproductive loss due to stressors on nesting pairs; however, in study along the coast of the Gulf of Mexico that was unrelated to oil spill damage, researchers found that nestling feather corticosterone levels were lower in chicks raised in the preferred elevated nest sites (Lamb et al., 2016), indicating that there may be further physiological and epigenetic effects to offspring from the oil itself, and the consequences of habitat destruction caused by the spill. As such, it is sometimes difficult to separate impacts of environmental chemicals from other stressors. Further, tracking data for birds, especially through migration is gradually becoming more available, as are more sensitive methods for detecting endocrine disruption. This will provide more complete metadata that will help inform the sum total of challenges faced by an individual as well as the population. Moreover, large data sets on wild birds are already available from the USGS Bird Banding lab and from annual surveys for species and individuals and other databases in eBird (https://ebird.org/home; The Cornell Lab of Ornithology). In addition, there are a number of monitoring studies and programs with short- and long-term data on the status of avian populations. Consolidating these monitoring data can provide valuable information on populations and health metrics for natural resources managers (Ottinger et al., 2019) and in combination with metadata on environmental chemicals, can provide potential risk estimates from effects of exposure over an individual's lifetime.

48.4.5 Establishing reliable and sensitive measures of adverse impacts

It is a challenge to develop reliable and sensitive measurement endpoints that can serve as indices of exposure in

birds, especially those that are field-friendly. It is particularly useful to select endpoints that are bioindicators; this requires understanding the association of an adverse impact on the individual and risk to populations as a whole. Exposure to steroid hormones or EDCs disrupt embryonic development including organ development, sexual differentiation, reproduction and immune function, reproductive behavior, and metabolic processes (Best et al., 2010; Berg et al., 1999; Darnerud, 2003; Ottinger et al., 2005a,b; Fernie et al., 2005a; Franceschini et al., 2008; Fox and Grasman, 1999). Biomedical and epidemiological data reveal clear linkages between EDC exposure, particularly early events and later disease and possibly epigenetic effects. In addition, field studies correlated EDC exposure to immunosuppression in a number of taxa, demonstrating that the effects of these compounds have conserved mechanisms and impact a range of species, including invertebrates. Laboratory studies have been successful in establishing clear effects of various classes of EDCs on a number of physiological systems (Berg et al., 1998; Halldin et al., 2005). Because many of the initially identified EDCs of concern, such as methoxychlor, dioxin, and some PCBs, have estrogenic activity. However, at any one time, wildlife species are actually exposed to many different types of EDCs (e.g., androgenic, thyroid active) as well as other toxicants; these mixtures often contain chemicals with potentially different mechanisms of action (e.g., metals) (Levengood et al., 2007; Hotchkiss et al., 2008). As a result of this complexity, it has been difficult to develop comprehensive risk assessment models. Furthermore, as mentioned above, some EDCs such as DDE are androgen receptor blockers, whereas other compounds such as trenbolone are androgenic (Mura et al., 2009; Panzica et al., 2007; Quinn et al., 2007a, 2008). As in mammals, EDCs are physiologically active on the reproductive endocrine system as well as on a variety of pathways, including not only steroid sensitive pathways but also pathways involving thyroid, metabolic, stress, and immune systems (Crump et al., 2016; Head et al., 2008; Fairbrother et al., 2004; Fernie et al., 2005a; Fox and Grasman, 1999; McNabb and Fox, 2003; Kavlock and Ankley, 1996; Knudsen et al., 2009; Qasimi et al., 2018; Quinn et al., 2007a,b). Complexities of differential EDC sensitivity among species and even within a species to different classes of EDCs, as well as differential exposure add another layer of complexity that must be considered for all wildlife, not just birds.

48.5 Methods for assessing risk

48.5.1 Predicting impact: toxic equivalency factor and toxic equivalent quotient

There is a large body of literature on the role of the AhR in response to exposure to toxicants. The signaling pathway showing activation of the AhR by dioxin or dioxin-like compounds has been well characterized; initial interaction of an EDC with the AhR triggers a cascade leading to translocation into the nucleus. After dimerization, the aryl hydrocarbon nuclear translocator complex binds to the xenobiotic response element on the DNA with transcription of mRNA for translation into CYP proteins (Figure 48.3). This AhR response to dioxin-like compounds has become an accepted toxicological measure for environmental chemicals to estimate the toxic equivalency factor (TEF) for a compound. An arithmetic calculation of added TEFs provides an estimate of toxicity potential for a mixture or compound that is termed the toxic equivalent (TEQ). The standard for comparison is dioxin (2,3,7,8-tetrachlorodibenzo-p-dioxin; Figure 48.4). Structure and functional data derived from the literature and other information relative to the functional similarities compared to dioxin are used to ascertain the relative toxicity against dioxin (van den Berg et al., 2013). For example, the structure and functional comparison for polychlorinated biphenyl 126 (PCB 126) compared to dioxin is shown in Figure 48.4. This TEQ for PCB 126 only accounts for dioxin-related activity and does not consider separate nondioxin or endocrine disrupting activity. That said, in birds as well as other vertebrates experience, a range of adverse physiological outcomes have been documented with exposure to dioxin (Hervé et al., 2010; Hsu et al., 2007; Kuil et al., 1998; Watanabe et al., 2009). Further, some dioxin-like EDCs do activate the AhR in a species-specific manner across as a relative measure among avian species (Head et al., 2008). These studies have demonstrated a wide variation in the vulnerability of avian species to toxicants, with molecular differences at the level of the AhR ligand-binding domain structure, and that these changes function across avian species (Farmahin et al., 2012; Karchner et al., 2006; Manning et al., 2012; Zhang et al., 2013). It is clear that as in mammals, EDCs can exert wide-ranging effects of

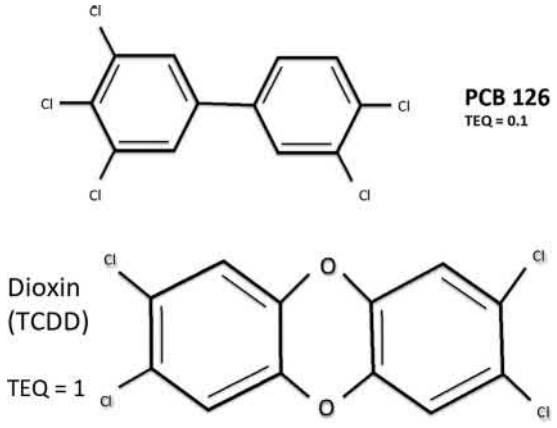

FIGURE 48.4 Structures of polychlorinated biphenyl 126 (PCB 126) with a toxic equivalency quotient (TEQ) of 0.1 compared to dioxin with a TEQ of 1.

these compounds and mixtures on endocrine processes in birds, with the potential for lifetime effects that will impact fitness of the individual and ultimately have a potential population fitness level impact.

48.6 Frameworks for visualizing risk and effects from endocrine disrupting chemical exposure

48.6.1 Visualizing predicting risk through influence diagrams and adverse outcomes pathways

A number of approaches have been developed to conceptualize the myriad of effects associated with sublethal toxicity with the overall intent to span molecular and cellular effects to the whole organism and eventual population level impacts. A comprehensive approach has been developed and termed AOPs. This approach has been conceptualized and applied for specific compounds in birds as well as applied to aquatic species (Lalone et al., 2013; Villeneuve et al., 2014; Ankley et al., 2010; Currie et al., 2005; Doering et al., 2018). Subsequent studies will utilize this and other approaches will underpin assessing the risks associated to establish probable outcomes with exposure to EDCs and establish data-based models for the potential for population level effects. In addition, it will be critical to integrate data collected from these and future studies to further refine the mechanisms that are responsible for both short- and long-term impacts to individuals and ultimately potentially for adverse outcomes to wildlife and human populations (Ottinger et al., 2013; Villeneuve et al., 2014; Zawatski and Lee, 2013). Influence diagrams and AOPs (Hotchkiss et al., 2008) are both important tools for conceptualizing effects of EDCs including fundamental actions and molecular targets and linking impacts to organism and population levels. As reviewed below, both approaches are extremely useful to gaining an understanding of the mechanisms and actions of environmental chemicals as well as insights useful for assessing potential risk. Additionally, both influence diagrams and AOPs can be customized for species and taxa.

48.6.1.1 Influence diagrams

Developing an *influence diagram* that captures exposure risks and potential impacts for field birds is challenging due to many uncertainties, such as consistency and doses of exposures, presence of complex mixtures of compounds, climate change, weather events, anthropogenic factors including habitat loss and resource availability. It is helpful to visualize primary stressors as well as their downstream effects in order to understand interactions and drivers impacting field birds. Influence diagrams visualize impacts from the Gulf of Mexico Macondo Oil Spill to birds in the Gulf and coastal environs (Figure 48.5A and B). These diagrams bring to light both potential toxicity as well as the lesser understood nonlethal physiological impacts on wild birds and adverse effects translating to population level risk. In birds, one of the most commonly observed impacts of oil exposure is feather fouling. Extreme levels of feather fouling may lead to loss of buoyancy and thermoregulatory ability, then death (Perry et al., 1978; Lambert et al., 1982; O'Hara and Morandin, 2010). Lesser oil coverage will likely cause birds to begin preening feathers to remove oil. Not only will these birds likely spend less time foraging during this period and find thermoregulation more energetically expensive (Jenssen, 1994; Walton et al., 1997; Burger and Tshipoura, 1998; Mathewson et al., 2018), they will also inadvertently expose themselves and incubating eggs to the toxic effects of oil. Through the mechanical process of preening oil may be swallowed, fumes may be inhaled, skin can become irritated and oil may be transferred to a nest. This oil will reach organ systems and activate liver detoxification pathways causing anemia, cardiac and gastrointestinal tract damage, loss of liver and kidney function, immune and adrenal dysfunction, and oxidative damage (Bursian et al., 2017; Dean et al., 2017; Harr et al., 2017a,b,c; Horak et al., 2017; Maggini et al., 2017a; Pritsos et al., 2017; Bianchini and Morrissey, 2018). Not only will the mechanical damage to feathers reduce flight efficiency (Maggini et al., 2017b,c; Perez et al., 2017a,b), organ damage and anemia will further reduce an individual's chance of survival. The EDC effects of PAHs on adult birds are not well understood, but they can result in loss of breeding success, nest abandonment, reduced parental care, and adrenal dysfunction (Peakall et al., 1981; Fry et al., 1986; Eppley and Rubega, 1990; Fowler et al., 1995; Walton et al., 1997; Lattin and Romero, 2014; Lattin et al., 2014).

Information from both laboratory and field research are considered in building the influence diagram to include outcomes and potential risks, including those for which additional testing is warranted. All aspects are critical in order to conduct an informed risk analysis. A further example of an influence diagram shown in Figure 48.7 presents a more detailed focus on physiological responses to selected environmental stressors. In this influence diagram, each of the selected environmental stressors are linked to one or more physiological responses, which in turn interact. Effects of these stressors translate into responses that can be monitored via specific metrics or measures. Furthermore, this influence diagram incorporates unique physiological characteristics and responses of birds; migration and exposure to different geographic regions are additional potential sources of stress.

There are a number of examples of well-documented environmental contamination events that impact birds.

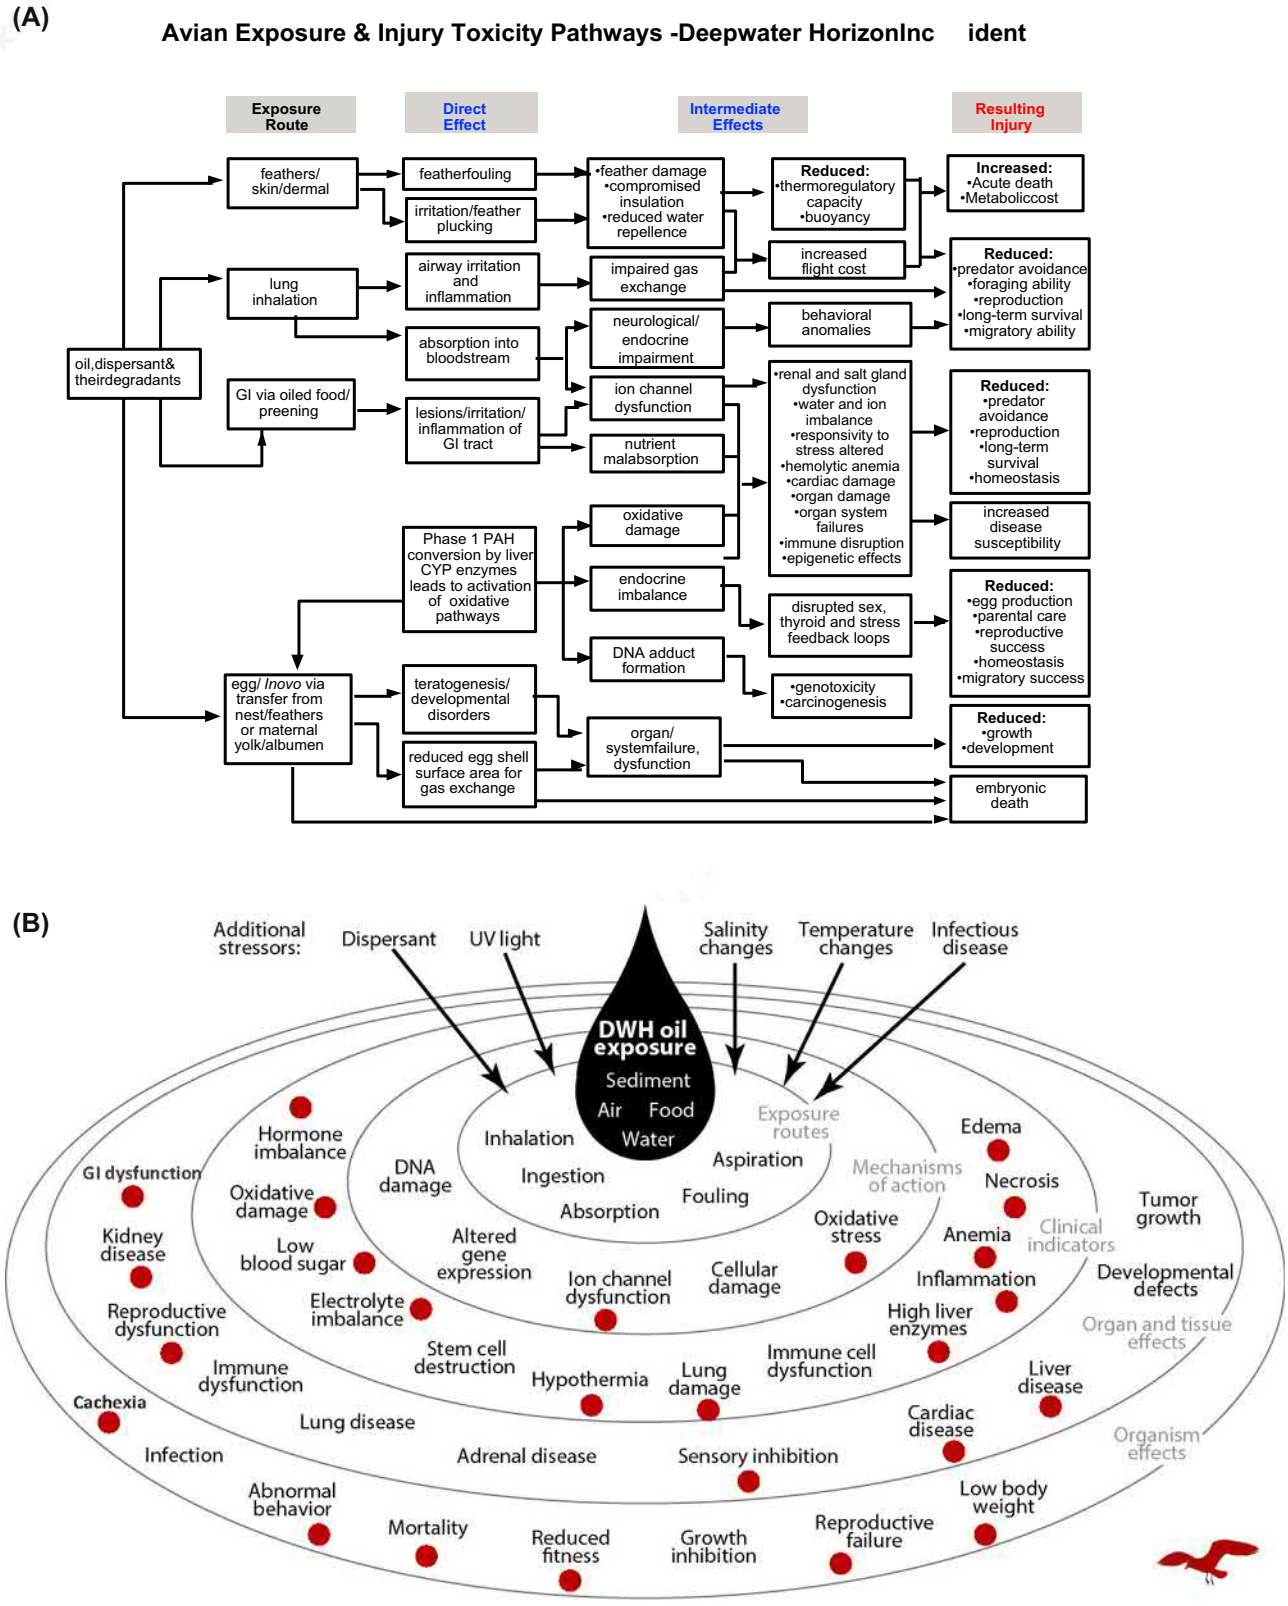

FIGURE 48.5 (A) and (B): Influence diagrams showing alternate depictions of potential routes of exposure, direct and intermediate effects, responses, and fate for birds exposed to toxicants associated with the Deepwater Horizon Oil Spill. (A). This diagram depicts how exposure routes, mechanisms of action, clinical indicators, organ and tissue effects, and organism effects (shown in light gray) in birds can be broadly linked. Oil toxicity will manifest differently in each exposed individual, leading to different combinations of the outcomes listed in this diagram. The diagram includes information from DWH NRDA studies, as well as from the literature. *(A) Adapted from illustration by Milton et al. (2003); Hooper, M.J (US Geological Survey) and Ottinger et al. (2019); In Gulf of Mexico Avian Monitoring Network Strategic Avian Monitoring Plan. eds.: Wilson, RR, Fournier AMV, Gleason JS, Lyons JE, Woodrey M. Mississippi State University, Research Bulletin 1228, 2019), depicts the multiple downstream physiological and behavioral impacts of oil on exposed birds. (B). Diagram adapted from the Deepwater Horizon Final Programmatic Damage Assessment Plan Chapter 4: Injury to Natural Resources (https://www.gulfspillrestoration.noaa.gov/sites/default/files/wp-content/uploads/Chapter-4_Injury_to_Natural_Resources_508.pdf). FIGURE 48.7 Stages in Embryonic Development. Diagram shows timing of developmental events during embryogenesis with indications of endogenous endocrine change and potential periods of vulnerability.

These include industrial chemical contamination in the Great Lakes and effects on eagles and other vertebrate species, dioxins released into the Tittabawassee River, PCB congeners released into the Housatonic and Hudson Rivers, and impacts of the *Exxon Valdez* and Gulf of Mexico Deepwater Horizon oil spills on birds and other taxa (Custer et al., 2010a,d, 2012a,b; Custer and Read, 2006; Franceschini et al., 2008; Levengood et al., 2007; Esler et al., 2018). It is important to synthesize data on these incidents of localized or widespread chemical contamination; influence diagrams can provide an effective way to diagrammatically visualize the impacts and risks to wild birds and ultimately assess the potential for population level effects.

48.6.1.2 Adverse outcomes pathways

Similarly, the AOP allows visualization of the actions of EDCs at the molecular and mechanistic level, and relates these actions to subsequent effects on physiological systems, and to the organism, and potentially population level effects. An example of an AOP is shown in Figure 48.6 (Rattner et al., 2014) visualizes the entire cascade of impacts from rodenticide exposure going from molecular and cellular responses on the left and the impacts of these responses to organ function and eventually the adverse outcomes to both the individual organism and the population. These examples of AOPs demonstrate not only the mechanisms of action by compounds on physiological targets but also the flow down effects to impair the fitness of the bird, ultimately leading to individual and potential population decline.

48.6.2 The one health concept

The *one health concept* brings together the powerful interrelationship between human and wildlife health with ecosystem health. The initial concept of One Health focused on disease transfer from wildlife to human populations (Destoumieus-Garzon et al., 2018). More recently, it is recognized that resilience to environmental stressors, including disease, align with the health of the ecosystem (Lerner and Berg, 2017; Rabinowitz et al., 2018). As such, the definition of One Health has broadened to consider environmental factors and ecohealth as essential components of the health of wildlife with resources and tools to promote implementation of multidisciplinary and multisector collaborations (Vesterinen et al., 2019). This broadened definition of the One Health concept requires this multidimensional approach incorporating factors such as health, stressors, disease incidence, societal pressures, and environmental factors. This includes selecting key

health measures, metrics to assess the impacts of stressors, such as habitat loss, anthropogenic stress, environmental toxicants, disease, climate change, among others. More specific measures of health for people, wildlife, and birds could include overall physical health, immune, metabolic, and endocrine function as well as nutrition/food availability. possible contributing factors, such as environmental toxicants, taxa specific resource availability, and species-specific characteristics, including lifespan and habitat requirements. Finally, the challenge of integrating societal needs with maintaining healthy vulture populations is key for implementing a successful one health framework as a roadmap for optimizing the health of human and wildlife populations and ensuring ecosystem health.

48.7 Why are birds unique?

Birds have specific attributes that distinguish them from other vertebrate classes (Table 48.3). These characteristics underpin differences in vulnerability to EDCs and contribute to the unique responses observed in birds compared to other vertebrate classes. Most obviously birds have feathers. These are not only adapted for flight and thermoregulation but also they provide a means by which sexual selection can occur. In birds cues for mate choice generally come in three forms: colorful male plumage to attract females, courtship displays, and in the case of songbirds, song production. EDC exposure from sewage effluent were associated with more complex song and reduced immune response in male starlings feeding in filter beds (Markman et al., 2008) and American kestrels experimentally exposed to dietary PCBs showed plumage changes in males and their offspring (Borolotti et al., 2003). Impacts on male selection cues could have repercussions for population and species health. On top of the energetic costs of daily flight and consequent plumage maintenance, large numbers of bird species face the additional energetic demands of seasonal migration which requires energy utilization that is focused on migration, seasonal changes in metabolism, and adequate feather replacement. These migration-related metabolic changes are dynamic and critical to survival, and are also vulnerable to effects from exposure to environmental chemicals and endocrine modulators (Broggi et al., 2003; Hallanger et al., 2011; Hurlbert and Haskell, 2003; Majewski et al., 2005; Perez et al., 2017a,b,c; Vyas et al., 1995; Wilson and Reinert, 1999). As such, both seasonality and exposure to environmental contaminants alter thyroid hormone system responses (McNabb, 2005; Nost et al., 2012; Ross et al., 2011; Webb and McNabb, 2008; Wilson and Reinert, 1999).

The metabolic cost of migration must be balanced with seasonal changes in reproductive physiology. Female birds have one functional ovary (the left), while males have two functional internal testes. Both sets of gonads undergo seasonal changes in size and functionality, presumably to maintain reduced body weight for flight. However, the

TABLE 48.3 Unique characteristics of avian species that influence response to endocrine disrupting chemicals.

- Growth and Metabolism
  - High-body temperature (105°F) with high-metabolic rate
  - Rapid growth rate
  - Seasonal metabolic changes associated with migration
  - Seasonal shift in mobilization of lipid reserves
  - Differential developmental patterns in altricial versus precocial birds
  - Thyroid system critical for premigratory fattening
- Reproductive system
  - Female has one functional ovary
  - Altered gonadal differentiation results in ovotestes
  - Eggs have hard shells
- Hormones and behavior
  - Males adversely impacted by xenoestrogens and androgenic compounds
  - Females less sensitive to xenoestrogens
  - Biparental care is common, particular in species with altricial young
- Sexual differentiation
  - Males are the homogametic sex (ZZ); females (ZW)
  - Hypothalamic–pituitary–gonadal axis relies on relative exposure to estradiol and testosterone
    - Males experience relatively higher exposure to testosterone
    - Females experience relatively higher exposure to estradiol
  - Song system differentiation occurs in passerines with potential role of steroids
  - dimorphic plumage involved in mate selection
- Lifespan
  - Long-lived birds produce few offspring annually over many years
  - Social learning is common in long-lived species.

energetic cost to the female bird also includes production of high-nutrient value eggs. Associated with the single ovary is the shell gland, which not only produces the hard shell unique to birds, but "plumps" the egg to ensure sufficient nutrients are available for the entire developmental period. Eggshell thinning was in fact the first reported effects of EDCs in birds; however, many environmental toxicants transferred from the maternal system to the egg yolk and albumen have direct impacts on embryonic development.

Avian species rely on genetic-based sexual differentiation with well-characterized developmental events occurring during ontogeny. The genetic basis for sex determination is reversed from that of mammals in that the male is the homozygotic sex (ZZ) and the female is the heterozygotic (ZW), providing a "different" substrate on which the effects of EDCs on sexual differentiation can act (Adkins-Regan et al., 1995; Ottinger and vom Saal, 2002; Ottinger et al., 2009a,b). Chicks hatch in one of two primary developmental states: precocial chicks are mobile and aside from thermoregulation, they are relatively independent and altricial chicks which require intensive parental care with feeding and care until they fledge from the nest. The differential pattern in development of precocial and altricial chicks impacts the maturation of thyroid and metabolic endocrine systems with precocial birds relatively functionally mature at hatch and altricial birds still undergoing maturation (Schwabl, 1996a, 1996b; McNabb, 2007; McNabb and Fox, 2003; Wada et al., 2009; Webb and McNabb, 2008; Wilson and Reinert, 1999). Many of these unique characteristics, including breeding characteristics, neural mechanisms, and lifetime impacts will be discussed below in the context of ascertaining the specific physiological and behavioral impacts associated with EDC exposure.

48.7.1 Altricial versus precocial birds: ontogeny and vulnerable life stages

Of the two developmental strategies that occur in birds, the most heavily studied in toxicology has been the precocial birds, as the direct influences of maternal contaminant deposition on development can be more readily quantified. Altricial chicks require extensive posthatch parental care, whereas precocial chicks are well developed at hatch, and therefore lend themselves to in ovo toxicity tests. However, altricial species have particular life history stages that are more vulnerable to EDCs. The neural circuitry of the song system, unique to song birds that are also altricial, is steroid-dependent with elements that are sexually differentiated primarily posthatch, and remains plastic throughout the life cycle, showing seasonal regression and hormone-induced seasonal neurogenesis (Adkins-Regan and Watson, 1990; Adkins-Regan et al., 1990; Adkins-Regan and Ascenzi, 1990; Wade and Arnold, 2004; Fusani and Gahr, 2006; Ball and Balthazart, 2010). This neuroplasticity contributes to an apparent lifelong vulnerability yet potential resilience to EDC exposure (Iwaniuk et al., 2006; Markman et al., 2008; Rochester et al., 2010; Rochester and Millam, 2009). Adverse effects of EDCs have also been observed in finches and the dark-eyed junco (Hoogesteijn et al., 2008; Satre et al., 2009). Species with altricial young often have biparental parental care, which is modulated by hormones that modulate specific neural systems (Angelier et al., 2016; Hartman et al., 2019; Smiley, 2019; Smiley et al., 2020).

Precocial birds, such as Japanese quail (*Coturnix japonica),* have often been the subject for toxicological studies and regulatory testing. They are well developed at hatch, with sexual differentiation of the reproductive endocrine and functional competency of other physiological systems already relatively complete (Adkins-Regan, 2009; Balthazart et al., 2009; Ottinger et al., 2005b; Ottinger and Dean, 2011). These studies have shown that the male Japanese quail is exquisitely sensitive to exogenous steroids, with both estradiol and androgen treatments resulting in impaired male reproductive behavior. As such, estradiol (E_2) is very useful as a positive control and as a means of comparison for the relative activity of EDCs with varying impacts on endocrine, neural, and behavioral components of reproduction (Berg et al., 2001; Halldin et al., 1999; Berg et al., 1998; Adkins-Regan and Watson, 1990; Panzica et al., 2007). Japanese quail have a 17-day incubation period and during development, each level of the reproductive [hypothalamic−pituitary−gonadal (HPG)] axis develops and begins to function as early as embryonic day 5 (gonadal differentiation), embryonic days 12−14 (hypothalamus and pituitary gland), and later in embryonic development (accessory structures). Gonadal function is initiated as early as embryonic day 5, with differential patterns of circulating steroid hormones in males and females (Figure 48.7).

Estradiol is a critical element in sexual differentiation in quail. During embryonic development, females have relatively high concentrations of estradiol/androgen whereas males have a relative low estradiol/androgen ratio. Moreover, there are sex-related differences in the patterns of plasma steroid levels during embryonic development. In female embryos, plasma E_2 rose until hatch and decreased, posthatch (Ottinger et al., 2008; Ottinger et al., 2005a). In males, plasma androgen peaked at embryonic days 14−17 (ED14-E17), during the 17-day incubation period, and declined posthatch. In addition, yolk steroid hormone content reflects embryonic steroid hormone levels. These steroid hormones are present and available to the embryo during sexual differentiation of multiple organ and endocrine systems throughout incubation. Once the embryonic gonads and adrenal glands begin to produce steroid hormones, circulating concentrations rise to make the gender-related pattern in changes more evident, especially during

the last half of embryonic development. Both sexes experience increased steroid hormones after embryonic days 10−12 in males and embryonic days 10−16 in females. Sexual differentiation of endocrine and behavioral components of reproduction occurs during this time, organizing the HPG axis and sex-specific behaviors (Adkins-Regan and Watson, 1990; Ottinger et al., 2005a). There is a large literature that links steroid hormones, brain regions that modulate reproductive behavior, onset of reproduction during maturation, and adult reproductive function. The primary hypothalamic hormone that regulates the HPG axis is gonadotropin-releasing hormone-I (GnRH-I), which is produced by the cell bodies located in the preoptic septal region of the hypothalamus. Hypothalamic GnRH-I levels rise between embryonic days 10−15; followed by a sharp drop that appears associated with activation of the function of the HPG axis and feedback regulation of GnRH-I (Li et al., 1991). Both the endocrine and behavioral components of reproduction in Japanese quail are sexually differentiated during embryonic development.

In concert with the changing steroid hormones during embryonic development, the adrenal axis and the thyroid axis develop and achieve function. Circulating concentrations of adrenal and thyroid hormones rise during embryogenesis to peak at about the time of hatching in precocial birds, with a slight delay in this pattern for altricial birds. Additionally, the steroid hormones circulating during embryonic development also impact the immune system, with circulating testosterone in males inducing regression in the bursal tissue in males (Grasman, 2010; Lavoie et al., 2007; Lavoie and Grasman, 2007). Clear effects of EDCs have been observed for the immune system, especially for the response of the bursa, which is exquisitely sensitive to steroid hormones during embryonic development. Additionally, it has been well documented that the thyroid axis is also a primary target for many EDCs, including PCBs, flame retardants, and other compounds. Effects of EDCs exerted during embryonic development may also impair the thyroid axis, which is critical for hatching as well as in overall metabolic function (McNabb and Fox, 2003).

48.7.2 Maternal deposition of compounds

Maternal deposition of steroids and EDCs into the egg is a primary mode of exposure to the avian embryo. There is increasing recognition of the important role of maternally deposited steroid hormones, as well as corticosterone and thyroid hormones (Adkins-Regan et al., 1995; Almasi et al., 2012a,b; Hayward and Wingfield, 2004). Mounting data point to both direct and epigenetic effects of maternally deposited hormones, which vary according to the condition of the female, health, reproductive status, and stressors. These steroids can affect viability as well as developmental characteristics of the chicks (Lipar et al., 1999; Schwabl, 1993, 1996a,b). Deposition of EDCs is layered on top of these endogenously produced hormones from the hen. Moreover, most maternally transferred compounds and EDCs are lipid soluble, thereby deposited primarily into the egg yolk; whereas, water-soluble compounds such as atrazine may be more evenly distributed throughout the egg compartments. There is significant deposition of EDCs into the eggs of field birds (Custer et al., 2010a,b,c,d). Similarly, laboratory studies have demonstrated that EDCs, including exogenous estradiol, methoxychlor, and soy phytoestrogens (see Figure 48.8 for phytoestrogens) all readily transfer from the hen into the egg and partition in the egg compartment according to lipid solubility (Lin et al., 2004; Ottinger et al., 2005b).

48.7.3 Posthatch growth and maturation

Posthatch growth and maturation are periods that are vulnerable to interference from EDCs. Steroid hormones continue to decline from the late embryonic and posthatch levels associated with sexual differentiation to remain at low-quiescent concentrations until the onset of sexual maturation. During sexual maturation, reproductive endocrine and behavioral responses are initiated earlier in males so that they mature by six−eight weeks of age (Ottinger and Brinkley, 1978, 1979). Females begin to mature slightly later than males with onset of egg production by 8−10 weeks of age. This dimorphism is reflected in hypothalamic GnRH-I levels, which increase in males earlier than females (Ottinger et al., 2004). Organizational effects of steroids in quail are also reflected morphologically in the sexually dimorphic preoptic region of the quail, which is larger in males and testosterone sensitive in the adult; high levels of aromatase metabolize testosterone to estradiol, which is essential for sexual behavior). Because this area in known to be important in modulating courtship and mating behavior, a number of studies have focused on the neural systems contained in this area in Japanese quail; this area is potentially vulnerable to the effects of EDCs (Panzica et al., 2007). In addition, the preoptic-septal region (POA-SL) contains many of the GnRH cell bodies; these cells project to the median eminence of the hypothalamus, making the POA-SL critical in the regulation of both endocrine and behavioral components of reproduction. All these characteristics of the HPG axis and sexually dimorphic neuroendocrine systems are vulnerable to EDC exposure, especially during organization of the reproductive axis during embryonic sexual differentiation.

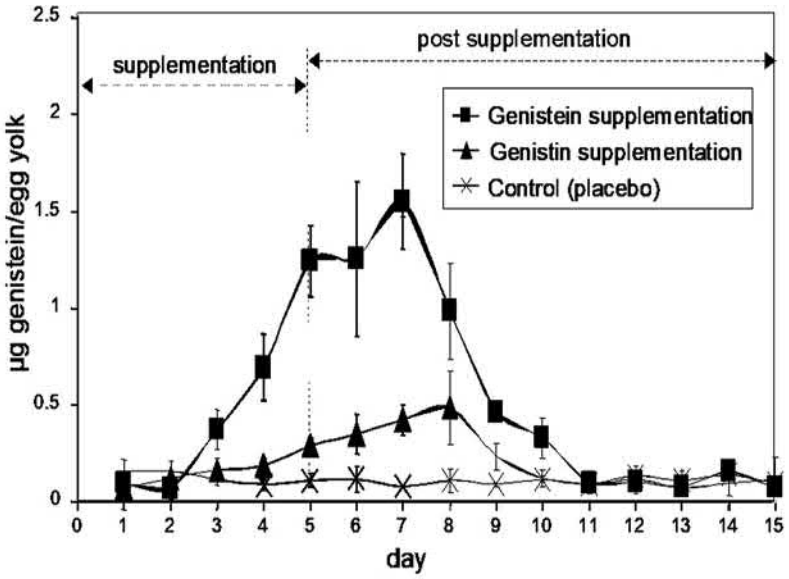

FIGURE 48.8 Maternal deposition of the phytoestrogen, genistein by the quail hen into eggs.

Concentrations of Genistein in Japanese Quail egg yolks supplemented with genistein (aglycone), genistin (glucoside) or placebo capsules. Data points represent average of 4 replicates for treatment groups and 2 replicates for the control group. Modified from Lin et al, 2004.

48.8 Investigating endocrine disrupting chemical effects in an avian model: the Japanese quail two-generation test

Laboratory tests provide important information about EDC actions and impacts in birds and have used several experimental approaches. Most studies on the actions of steroid hormones have used egg injection, with treatment with known concentrations in order to understand the role of steroids in ontogeny and sexual differentiation. Many of the studies on EDC effects have used a similar approach, and these studies have been conducted in domestic chick embryos, mallard duck, and Japanese quail. The US EPA oversees the safety of chemicals in use by industry, agricultural practices, recreational application, and individual residences. The JQTT provides a multigenerational test to assess the impacts of EDCs on all life stages, both separately and as a continuum. Current testing for registration of chemicals may require select Ecological Effects Studies, including: Avian Acute Oral Toxicity, Avian Subacute Dietary Toxicity, Avian Reproduction, the JQTT, and Simulated or Actual Field Testing (http://www.epa.gov/oppefed1/ecorisk_ders/toera_analysis_eco.htm) to ascertain safety for birds. These tests are conducted on a variety of species according to the test and are conducted in tandem with tests in other vertebrate and invertebrate species.

As discussed in the introduction to this chapter, EDCs may be difficult to detect nonlethal effects that have more subtle and long-term impacts on organisms. As a result, a series of testing protocols have been developed to address potential effects vertebrates and invertebrates over the life cycle. These two generation testing protocols consider a range of measurement end points to assess effects and potential risks to selected organisms. In birds, there is consideration of a multigeneration test using Japanese quail, which contains each primary phase in the life cycle with isolated exposure at that phase as well as cumulative exposure over the multiple life stages. Initial exposure in the current testing protocol occurs in proven breeders followed by continuous exposure to first generation (F1) offspring to evaluation of their second generation (F2) offspring as the final step in the testing protocol. As will be described below, there are a number of measures considered to assess health, toxicity effects, and endocrine disruption. The general list of measurement endpoints include: measures of health and overt toxicity (food consumption, body weights, secondary sex characteristics, activity, chick health, growth and maturation, lethargy, morbidity, or other clinical signs of toxicity, mortality); reproductive measures (sexual differentiation, sexual maturation, egg production, egg quality, fertility, embryo death, hatchability, chick survival and condition, sex ratio, reproductive behavior and reproductive hormones, testes

histology and sperm counts, cloacal gland size, and foam); endocrine and physiological endpoints (weight and histology of liver, testes, thyroid, adrenals, gonads, and brain, fecal steroid hormones, serum hormones and vitellogenin, glandular thyroid hormone). The reasoning for use of these end points in assessing EDCs is briefly discussed below to provide a more complete overview of the responses of the endocrine and physiological systems to EDCs.

48.8.1 Pertinent endpoints for assessing potential endocrine disruption

The selection of endpoints depends on the dosing regimen (i.e., amount of compound administered and the timing of administration), projected dose response, the window of exposure (i.e., life-stage), projected mechanisms of action, potential endocrine activity or induction of vitellogenin or other biochemical responses, and mode of exposure are all critical variables in evaluating potential EDCs. As more information becomes available on EDC actions, it will be possible to use the structure proposed by the AOPs framework to help elucidate both the targeted physiological systems vulnerable to a chemical/chemical class and the potential for significant impacts to avian species. This approach is not currently integrated into the testing paradigm, but may prove useful for providing structure to interpreting the observations and findings. For example, the developing embryo is much more sensitive to the effects of EDCs than the adult, and developmental defects (i.e., permanent central and peripheral disruption) often persist into maturation and adult life stages. Conversely, adult exposure does not generally have as much impact or effects appear to be more transient, especially in precocial species. Advances in our understanding of molecular mechanisms have revealed that EDCs often exert epigenetic effects. This has changed our understanding of both the activational and organizational effects of EDCs, allowing for the possibility that exposure can cause lasting effects in multiple generations (Skinner et al., 2011; Hochberg et al., 2011). Therefore, it is extremely important to understand the physiology of the model (i.e., Japanese quail) and the species-specific endocrine mechanisms behind the selection of endpoints.

Laboratory studies conducted under controlled conditions filter out some of the confounding factors encountered in field studies, thereby allowing insights into the mechanisms of action of EDCs, and distinguishing sensitive life stages. As such, EDCs may interfere with endogenous processes critical for sexual differentiation, maturation, breeding, and parental behavior. It is against this backdrop that exogenous EDCs act, with variations in specific mechanism(s) of action and targets for a particular compound. Although an emphasis of EDC studies has been on the reproductive axis, it is clear that the thyroid, immune, and stress axes are also targets of endocrine disruption. Toxicological effects are also observed with higher dose exposures to EDCs and some measures of activation of the liver detoxification processes in the form ethoxyresorufin-O-dealkylase (EROD) activity measurements are excellent indicators of exposure. Elegant studies have also shown that subtle differences in the amino acid sequence of the AhR ligand-binding domain contribute to observed variations in the sensitivity of wild birds species to EDCs (Head et al., 2008; Head and Kennedy, 2007a,b).

48.8.2 Survival

Survival is a basic endpoint or determinant of injury for acute and chronic toxicity testing of compounds. Determining the median lethal dose that will kill 50% of the population being tested (LD50) is an important value for traditional toxicology studies. In dietary studies, survival must be monitored in order to assess health effects. In the context of endocrine disruption studies, it is unlikely that the doses will approach lethal concentrations because circulating concentrations of endogenous hormones are in the pico- or femtograms. Nonetheless, sublethal treatments are important in ascertaining potential risk from endocrine disruption. For example, 50 μg/kg/day of bisphenol A has been determined to be a safe exposure by classic toxicology testing (Myers et al., 2009). However, doses 100 to 1000 times lower than that have been shown to induce feminization of the gonads in Japanese quail, with no changes in survivability among groups (Oshima et al., 2012). As such, monitoring survival following exposure to toxic chemicals provides information about potential risk and species vulnerabilities.

48.8.3 Food consumption and body weight

Food consumption is a basic measure of the general health; changes in food intake can indicate acute or chronic toxic effects of a compound. Additionally, if the route of chemical exposure is through the feed, it is important to monitor the consumption carefully to determine the exact exposure. It is also important to measure the stability of treatment compounds. Reduced food consumption has been associated with EDC exposure in Japanese quail (Yamashita et al., 2011). Similarly, body weight is closely linked with food intake and overall health and can be indicative of toxicological effects. For example, perchlorate, a thyroid hormone system disruptor, significantly reduced the growth (measured in body mass) of zebra finches dosed for the first two weeks of life (Rainwater et al., 2008). These birds also exhibited altered begging and fledging behaviors indicating that other endpoints may be linked to altered body weight, depending on the mechanism of disruption.

48.8.4 Accessory sex characteristics; sexual maturation

A number of secondary sex characteristics are gender-specific and provide excellent hormone-dependent response indices. In many species, including the Japanese quail, male and female plumage differs; with these sexual dimorphisms generally emerging during sexual maturation and in seasonal and migratory species, during the breeding season. Ultimately, the male has a rust hued chest, which is even in color; females have a buff colored chest with small dark areas in a dappled pattern. In general, feather color, especially that in more brightly colored species such as blue birds, and depends on dietary carotenoids as well as relate to overall health. In addition, males often have sexually dimorphic characteristics that are testosterone-dependent. The male Japanese quail cloacal gland produces a glycoproteinaceous secretion, termed cloacal gland foam that is critical for sperm transfer to the female (Ottinger and Brinkley, 1979). Measurements of the cloacal gland area have provided a reliable correlated measure for the sexual maturation and reproductive status of an individual male and the foam produced can be estimated on a scale of one to five or a similar ordinal subjective measurement scale. Since Japanese quail are ground dwellers and males establish territories during breeding season, cloacal gland foam provides a marker delineating their territory; the foam has been called the "topping on the dropping" (Schleidt and Shalter, 1973). Monitoring the effects of EDCs on sexual maturation provides insight into the mechanisms of action. In males, monitoring for presence of cloacal gland foam in males provides an initial indicator of testicular activity and production of androgens. Further, depending on an EDC's action(s), there may be differential effects in males and females with males maturing slightly earlier than females. By five–six weeks of age, testicular activity initiates and begins to produce increasing concentrations of testosterone leading to increasing expression of reproductive endocrine function, courtship and mating behavior whereas females initiate egg production by 9–10 weeks of age.

48.8.5 Behavioral indicators

Although the Japanese quail female exhibits a range of sex-specific behaviors, these behaviors are not readily quantifiable. Males and females both exhibit aggressive behavior, which can be quantified (Ramenofsky, 1985). Male courtship and mating behavior provide excellent bioindicators of reproductive competency. Sexual behaviors are steroid hormone-dependent, meaning that there must be sufficient circulating concentrations of androgens to enable the expression of male sexual behavior. Moreover, male sexual behavior is an exquisitely sensitive endpoint for embryonic exposure to estrogenic and highly active androgen active compounds. A three-minute test is conducted in which a receptive female (control diet female that is from the same population; nonexperimental) is introduced into the male's home cage. Latency to mount, mount attempts, and cloacal contacts by the male are recorded. An individual may be tested on three successive days if it is important to determine the effects of experience on behavioral responses. Interpretation of the outcomes of behavioral testing relates to the potential mechanisms of action of compounds under testing. More specifically, the female quail requires exposure to estradiol during embryonic development and is masculinized by exposure to androgens between embryonic days 12–18. Conversely, males are demasculinized as evidenced by impaired male sexual behavior as adults, if they have been exposed to either estrogens or androgens during this critical period. As such, the male Japanese quail is exquisitely sensitive to exposure to EDCs during sexual differentiation.

As such, behavior is a sensitive measure of endocrine disruption; however, behavioral measures that are easily implemented in field work or even in the laboratory are challenging. It is known from laboratory studies that EDCs does impair male sexual behavior in male quail and that diminished behavioral responses often parallel effects on other physiological responses (Mura et al., 2009; Ottinger et al., 2013; Panzica et al., 2007). Additionally, seabirds exposed to oil prior to or during breeding season have been observed to avoid breeding, abandon nests, and exhibit reduced parental care (Fry et al., 1986; Eppley and Rubega, 1990; Walter et al., 2013); however, the degree to which these are endocrine impacts or as a result of other physiological impacts remains unclear. As such, more work is needed to link endocrine and neuroendocrine impacts to assess behavioral impairment related to EDC exposure as well as developing clear behavioral metrics that are utilizable in field and laboratory studies. Behavioral measures also provide useful indicators of effects, including sensory deficits, stress responses, and impaired reproductive function. Finally, behavioral measures may prove to be very revealing in song birds in which the neural circuitry is steroid-dependent and in distinguishing EDC effects on altricial versus precocial birds.

48.8.6 Egg production, shell quality, fertility, and embryo viability

As early as the 1960s, exposure to DDT and DDE was linked to eggshell thinning and population decline in many wild bird species (Rattner, 2009). Egg production and onset of laying are important measures of reproductive function in birds, and are easily monitored by checking cages daily

and marking eggs. EDC exposure has related to reduced egg production as well as delayed onset of egg production by acting on the gonads, gametes, or sperm-host glands, potentially resulting in decreased fertilization success. Similarly, the fertilized egg may not develop properly due to interference from an EDC and the embryo may not survive beyond the first few hours or days of development. During this time, the uptake of yolk (white and yellow yolk) is minimal and as such reflects primarily a toxic effect of a compound or specific effects impairing the function of homeobox genes and disruption of cellular lineages contributing to the formation of organ systems, such as in the case of heart effects (Carro et al., 2013b). Eggshell thickness, strength, and gross abnormalities can affect embryo viability.

Later embryonic effects and lethality are more likely to relate to disruption of essential physiological systems, such as impacting the thyroid endocrine axis and other systems essential for the development and synchronization of endocrine and other physiological systems. A combination of early and late embryo mortality is a stronger indicator of toxicity that either alone. Moreover, there are distinct strain differences in Japanese quail, and there is an extensive literature that deals with a variety of physiological responses in Japanese quail that have been selected for multiple generations (Blohowiak et al., 1984; Bursian et al., 1983; Marks, 1996; Marks and Siegel, 1980). The Japanese quail chick begins to pip at embryonic day 15 in preparation for hatching at embryonic day 17. Once pipped, the chick is able to vocalize and often there is synchronizing in hatching of chicks in proximity. Pipping is followed by the chick pecking a hole, similar to an escape hatch, and requires a great deal of energy. The hatching success of chicks has been shown to be highly sensitive to chemical perturbation, and thus hatchability is an important endpoint in EDC studies.

48.8.7 Neuroendocrine systems regulating reproduction, metabolism, and stress

Embryonic exposures to steroids or compounds that are estrogen or androgen active result in impaired behavior in male behavior in adult quail (Ottinger et al., 2005a, 2008, 2009b; Panzica et al., 2007). Further, it has been shown that specific neural systems, including neurotransmitters (norepinephrine, dopamine, serotonergic) and neuropeptides (vasotocinergic) are modified in response to embryonic exposure to steroid hormones and to EDCs. Assessing the effects of embryonic exposure to EDCs on neurotransmitters and neuropeptides can provide information about direct effects of these compounds on regulatory systems that modulate reproductive, thyroid, and adrenal endocrine axes. GnRH-I neurons are located in the preoptic/lateral septal region of the hypothalamus. Although redundant, this system may be vulnerable to endocrine disruption (Ottinger et al., 2009b). Impact to neurotransmitter systems such as acetylcholine esterase has been used as a measure of toxicant exposure (Rattner et al., 1986).

48.8.8 Songbirds

Songbirds and other altricial birds also show impacts of EDC exposure on avian brain morphology (Iwaniuk et al., 2006; Millam et al., 2001). Further, there is a large literature about the impacts on steroid hormones on the sexual differentiation and function of the nuclei that direct and modulate song control in songbirds (Wade et al., 2004; Grisham et al., 2008; Arnold and Itoh, 2011; Wade and Arnold, 2004; Gilbert et al., 2007). Because of the neuroplasticity in songbirds, EDC effects may be more transient in songbirds; however, there are insufficient data to ascertain if this is the case. Nonetheless, there are clearly documentations of EDC effects on brain regions that modulate singing and other behaviors that are steroid dependent in both precocial and altricial birds.

48.8.9 Metabolic and thyroid systems

In addition, metabolic systems have been investigated in detail in birds, especially for domestic poultry. The thyroid system in birds has proven vulnerable to specific types of endocrine disruption in which this endocrine system is a target. Specifically, PCBs, flame retardants, and other classes of EDCs have been implicated in having thyroid system actions that impact birds, both in the laboratory and in field birds (Scanes and McNabb, 2003; McNabb and Fox, 2003; McNabb, 2005; Chen et al., 2008; Webb and McNabb, 2008; Fernie et al., 2005b). It is not clear if histological methods provide a sensitive method for revealing these EDC effects; however, impaired production and release of thyroid hormones would be observed in abnormal thyroid gland follicles size and distribution and in differences in circulating thyroxine (T4) and the more bioactive form, triiodothyronine (T3). Finally, the HPA is another endocrine system potentially responsive to EDC challenges. Measuring corticosterone in feathers may be an interesting technique to determine if long-term stress has occurred using a noninvasive technique. Seasonality and migration also complicate responses by birds to EDCs. Birds often exhibit seasonal patterns in reproduction and species that migrate often show complete regression of the reproductive axis with cessation of function followed by restimulation of the reproductive system, or seasonal recrudescence for the next breeding cycle. Initial stimulation of reproductive function in birds relies on environmental triggers, termed zeitgebers and in the case of temperate zone species; this environmental cue is often photoperiod. Birds are generally long day breeders due to their relatively short incubation and relatively quick maturation times for their offspring. As such, most photoperiodic birds become

reproductive with day length longer than 12 h. There is a very large literature on this subject that deals with the neural mechanisms, response via the eyes and pineal gland, and the hypothalamic response to regulate reproductive function; review of this literature is beyond the scope of this chapter, but it is important to recognize seasonal variations in energy demands due to reproduction, migration, and environmental challenges especially as EDCs impact critical endocrine systems involved in these seasonal and adaptive responses.

48.8.10 Histopathology

Many organ systems are highly sensitive to hormonal perturbations, particularly if exposed during development. This includes reproductive organ (i.e., testes/ovaries/oviduct) weight, gross disruption of organ morphology, and microscopic disruption (i.e., disrupted follicular function or spermatogenesis). Thyroid glands, liver, bursa, and other organs should be examined, depending on the projected target(s) for the EDC. Because sexual differentiation of the avian female involves regression of one of the two primordial ovaries with its accompanying oviduct, the presence/regression of the right ovary and oviduct provides initial information about appropriate sexual differentiation of the female reproductive axis. There are sperm-host glands in the oviduct of the avian female, in which sperm may reside for some weeks; however, there are no data available for a potential impact of EDCs on these glands. The ovary in the ovulating female should multiple follicles in varied stages of recruitment and maturation. Histological analyses will provide information as to the status of ovarian function and linking ovarian morphology to these components of ovarian function provides insight into potential EDC targets and actions. Early exposure to EDCs in males can impact gonadal development in a genetic male; however, there is less information about this type of long-term impacts. In some studies, EDC exposure resulted into transient presence of ovotestes, which are found in the hatchling but generally does not persist into the adult. Liver histology can provide information on any abnormalities associated with toxic effects. In addition, the activation of detoxification enzymes are excellent markers for initiation of these enzyme systems. Measurement of the EROD activity on liver subsamples can provide supporting evidence for histopathology findings.

There is a link between embryonic exposure to PCBs and cardiac malformations (Carro et al., 2013a,b) and kidney histology can provide information about toxicological impacts of EDCs due to the critical role of the kidneys in detoxification and elimination of water-soluble toxicants. Pathophysiological measurements of the bursa provide a powerful tool to assess endocrine disruption affecting the immune system. The bursa of Fabricius is exquisitely sensitive to steroid hormones, especially during development with testosterone having an immunosuppressive effect (Ottinger et al., 2005b). As shown in Table 48.4, embryonic exposure to trenbolone acetate resulted in persistent effects on bursal morphology with fewer, smaller follicles (Quinn et al., 2007a). Conversely, estradiol

TABLE 48.4 Summary of significant ($P < .05$) effects of trenbolone acetate and p,p- dichlorodiphenyldichloroethylene on immune, reproductive, and behavioral measures in Japanese quail.

Endpoint group	Endpoint	Trenbolone acetate (androgen)	p,p-dichlorodiphenyldichloroethylene (antiandrogen)
Immune measures	Bursa-body weight index	Decreased	Increased
	Bursal follicle number	Decreased in hatchlings and adults	Decreased in chicks
	Bursal follicle size	Increased at 0.05 µm g/g, decreased at 50 µg/g	NA
	Spleen-body weight index	NA	NA
	Humoral response to chukar red blood cells	NA	NA
	Cell-mediated response to phytohemagglutinin	NA	NA
	Hatchling plasma immunoglobulin G	Increased at only 0.05 and 0.5 µg/g	NA
	Hatchling total leukocyte counts	NA	Increased in chicks
	Hatchling differential leukocyte counts	Increased heterophil: Lymphocyte ratio	NA

treatment resulted in larger bursal size (Table 48.5); there was evidence of histopathology in treated individuals (Quinn et al., 2009). Many of these studies have also found a consistent relationship between bursal morphology and immune response. As such, bursal histopathology appears to be a reliable measure of impact to the immune system, especially assessing impacts during embryonic treatment and the persistence of these effects into adulthood.

TABLE 48.5 Summary of responses to estradiol or trenbolone with day of egg injection from the studies reviewed above.

	Hatchling effects summary[a]			
Endpoint	Estradiol ED4	Estradiol ED11	Trenbolone ED4	Trenbolone ED11
Embryo mortality	↑	–	↑	↑
Hatchability	↓	–	↓	↓

GnRH-I	–	–	–	–

[a](↑) or (↓) means effect/trend was nonsignificant, (↑↓) means a nonmonotonic dose response was observed.

48.9 Conclusions

Estradiol and estrogen active compounds are potent endocrine disruptors early in embryonic development, particularly in precocial chicks and throughout the lifespan of altricial birds, including songbirds. Effects in females may be due to direct effects on the ovary as well as on other physiological systems. Moreover, males are exquisitely sensitive to impacts from xenoestrogens, with impaired endocrine and behavioral components of reproduction, altered immune responses, and modifications in other physiological systems. Androgen active and EDCs that impact thyroid system function alter reproductive, metabolic, and immune responses. Further, EDC impacts on stress responses place individuals at risk from multiple environmental challenges. It is clear that early exposure has greater overall impacts on precocial species, which have relatively developed and functional physiological systems at hatch. Altricial birds follow a longer-term developmental pattern with seasonal recrudescence of the song system in tandem with reproductive function; thereby differing in the timing and relative vulnerability to EDC exposure throughout their lifespan. Nonetheless, there are distinct and documented effects of EDCs in birds that must be considered for effective conservation of field populations of birds and to protect these populations from adverse effects from these environmental compounds, often with severe and persistent injury. Further, there are some well-documented cases of environmental contamination in which adverse impacts on birds have experienced significant injury to the population over a long span of time, especially with persistent environmental chemicals such as DDT and PCBs. These long-term cases provide a rich set of data that are valuable in constructing both influence diagrams and AOPs. The One Health concept provides an integrative framework to structure a because these datasets contain valuable long-term monitoring and research programs, which consider physiological and reproductive impacts of exposure to chemicals found in those areas. These cases of environmental contamination and documented outcomes provide information that can be used to develop both influence diagrams and AOPs, which will help identify metrics for assessment and give managers tools to assess the status of avian populations and evaluate the success of restoration projects.

Canvasback duck (*Aythya valisineria*)	204					Calculated from Kocan, 1972
Eurasian teal (*Anas crecca*)	91.5					Elarabany, 2018
Maccoa duck (*Oxyura maccoa*)	121	12.2	6.2			Fourie and Hattingh, 1983
Mallard (*Anas platyrhynchos*)	162	12.5	6.8	6.0	2.7	Shave and Howard, 1971; Driver, 1981
Maned duck (*Chenonetta jubata*)	163					Calculated from Mulley, 1980
Northern shoveler (*Anas clypeata*)	88.1					Elarabany, 2018
Red-billed teal (*Anas erythrorhyncha*)	127					Fourie and Hattingh, 1983
Ring-neck duck (*Aythya collaris*)	196					Calculated from Kocan, 1972
Red-billed teal (*Anas erythrorhyncha*)	127	12.5	7.5			Fourie and Hattingh, 1983
Wood duck (*Chenonetta jubata*)	164					Mulley, 1980
Yellow-billed duck (*Anas undulata*)	128	12.5	7.4			Fourie and Hattingh, 1983
Canada goose (*Branta canadensis*)	161					Calculated from Gee et al., 1981
Egyptian goose (*Alopochen aegyptiacus*)	138	13.1	7.5			Fourie and Hattingh, 1983
Embden goose (*Anser anser*)	146					Calculated from Gee et al., 1981
Nene goose (*Branta sandvicensis*)	177					Calculated from Gee et al., 1981
Snow goose (*Anser caerulescens*)	204					Calculated from Williams and Trainer, 1971
Spur-winged goose (*Plectropterus gambensis*)	153	12.9	7.8			Fourie and Hattingh, 1983
Tule white-fronted goose (*Anser albifrons*)	148					Calculated from Williams and Trainer, 1971
Mute Swan (*Cygnus olor*)	170					Dolka et al., 2014
Black-necked swan (*Cygnus melanocoryphus*)	208					Norambuena and Bozinovic, 2009
Order *Caprimulgiformes*						
Alpine swift (*Apus melba*)	126	13.8	7.0	2.4		Palomeque et al., 1980
Anna's hummingbird (*Calypte anna*)	91					Calculated from Carey and Morton, 1976
Pallid swift (*Apus pallidus*)	104	13.4	6.8	2.5		Palomeque et al., 1980
Swift (*Apus apus*)	109	13.6	6.9	2.2		Palomeque et al., 1980
Tawny frogmouth (*Podargus strigoides*)	181					Calculated from McCracken, 2003
Order *Charadriiformes*						
Family *Alcidae*						
Antarctic tern (*Sterna vittata*)	127	12.0	6.3			Myrcha and Kostelecka-Myrcha, 1980
Arctic tern (*Sterna paradisaea*)	152	12.7	6.6			Kostelecka-Myrcha, 1987
Little auk (*Plautus alle*)	167	12.8	6.8			Kostelecka-Myrcha, 1987

Tables 50.1 −50.2.

TABLE 50.1 Circulating concentration of glucose in avian species.

Taxa[a] genus, species	Plasma/Serum glucose		References
	mg/dL	mmoles L^{-1}	
Order Accipitriformes			
Family Accipitridae			
African Fish Eagle (*Haliaeetus vocifer*)	223	12.4	Hollamby et al. (2004)
Bald Eagle (*Haliaeetus leucocephalus*)	315.5	17.6	Hoffman et al. (1981)
Black Kite (*Milvus migrans*)	350	19.4	Ferrer et al. (1987)
Bonelli's Eagle (*Hieraaetus fasciatus*)	353	19.6	Ferrer et al. (1987)
Booted Eagle (*Hieraaetus pennatus*)	292	16.2	Ferrer et al. (1987)
Bearded Vulture (*Gypaetus barbatus*)	239	13.3	Hernández and Margalida (2010)
Cape Griffon (*Gyps coprotheres*)	236	13.1	Van Heerden et al. (1987)
Cinereous vulture (*Aegypius monachus*)	308	17.1	Seok et al. (2017)
Crested serpent eagle (*Spilornis cheela*)	326	18.1	Chan et al. (2012)
Common Buzzard (*Buteo buteo*)	362	20.1	Ferrer et al. (1987), Garcia- Rodriguez et al. (1987)
Egyptian Vulture (*Neophron percnopterus*)	319	16.5	Polo et al. (1992), Dobado-Berrios et al. (1998)
Eurasian Griffon (*Gyps fulvus*)	275	15.3	Mean: Ferrer et al. (1987), Polo et al. (1992)
Galapagos Hawk (*Buteo galapagoensis*)	273	15.1	Deem et al. (2012)
Golden Eagle (*Aquila chrysaetos*)	368	18.6	Mean: O'Donnell et al. (1978), Polo et al. (1992)
Hen Harrier (*Circus cyaneus*)	369	20.5	O'Donnell et al. (1978)
Marsh Harrier (*Circus aeruginosus*)	196	10.9	Lavin et al. (1992a)
Northern Goshawk (*Accipiter gentilis*)	496	27.6	Stout et al. (2010)
Red-tailed Hawk (*Buteo jamaicencis*)	346	19.2	O'Donnell et al. (1978)
Snail Kite (*Rostrhamus sociabilis*)	336	18.7	Gee et al. (1981)
Spanish Imperial Eagle (*Aquila adalberti*)	317	17.6	Mean: Ferrer et al. (1987), Polo et al. (1992), García-Montijano et al. (2002)
Swamp Harrier (*Circus approximans*)	349	19.4	Calculated from Youl (2009)

TABLE 50.1 Circulating concentration of glucose in avian species.—cont'd

Taxa[a] genus, species	Plasma/Serum glucose		References
	mg/dL	mmoles L^{-1}	
Common Kestrel (*Falco tinnunculus*)	393	21.8	Ferrer et al. (1987)
Gyr falcons (*Falco rusticolus*)	321	17.8	Raghav et al. (2015)
Peregrine Falcon (*Falco perigrinus*)	316	17.6	Gee et al. (1981)
Prairie Falcon (*Falco mexicanus*)	414	23.0	O'Donnell et al. (1978)
Order *Galliformes*			
Attwater's Prairie Chicken (*Tympanuchus cupido*)	180	10.0	West et al. (2002)
Black-fronted Piping-guan (*Penelope jacutinga*)	298	16.5	Motta et al. (2013)
Bobwhite Quail (*Colinus virginianus*)	336	20.1	Mean: Gee et al. (1981), Hill and Murray (1987), Johnson et al. (2007)
Chicken or Domestic Fowl (*Gallus gallus*)	235	13.1	Mean: Dupont et al., 2008
Chukar (*Alectoris chukar*)	296	16.6	Mean: Ozek and Bahtiyarca (2004), Naza et al. (2011)
Grouse (*Lagopus lagopus*)	270	15.0	Korhonen (1987)
Helmeted Guineafowl (*Numida meleagris*)	309	17.1	Balasch et al. (1973), Weideman et al. (2012)
Horned Guan (*Oreophasis derbianus*)	280	15.5	Cornejo et al. (2014)
Japanese Quail (*Coturnix japonica*)	292	16.2	Calculated from data in Itoh et al. (1998) and Scholtz et al. (2009)
Peacock (*Pavo cristatus*)	316	17.5	Balasch et al. (1973)
Red Jungle Fowl (*Gallus gallus*)	239	13.3	Mean: Balasch et al. (1973), Zulkifli et al. (1999), Soleimani and Zulki i, 2010
Red-legged Partridge (*Alectoris rufa*)	356	19.8	Lloyd and Gibson (2006)
Ring-necked Pheasant (*Phasianus colchicus*)	290	16.1	Mean: Balasch et al. (1973), Lloyd and Gibson (2006), Naza et al. (2012)
Rock Partridge (*Alectoris graeca*)	293	16.3	Mean: Balasch et al. (1973), Ozbey and Esen (2007)
Sage Grouse (*Centrocercus urophasianus*)	328	18.2	Dunbar et al. (2005), Dyer et al. (2009)
Turkey (*Meleagris gallopavo*)	355	19.7	Lisano and Kennamer (1977)
Western Capercaillie (*Tetrao urogallus*)	396	22.0	Lavin et al. (1992b)
Order *Gaviformes*			
Great Northern Diver (*Gavia immer*)	189	10.5	Haefele et al. (2005)
Order *Gruiformes*			
***Family* Gruidae**			
Florida Sandhill Crane (*Grus canadensis pratensis*)	229	12.7	Gee et al. (1981)
Greater Sandhill Crane (*Grus canadensis tabida*)	264	14.7	Gee et al. (1981)
Mississippi Sandhill Crane (*Grus canadensis pulla*)	216	12.0	Gee et al. (1981)
Red-crowned Crane (*Grus japonensis*)	267	14.8	Carpenter (2003)
Siberian Crane (*Grus leucogeranus*)	266	14.7	Carpenter (2003)
Wattled Crane (*Bugeranus carunculatus*)	266	14.7	Carpenter (2003)
