Chapter 1

The importance of avian physiology

John C. Wingfield
Department of Neurobiology, Physiology and Behavior, University of California, Davis, CA, United States

The 20th century saw many revolutionary advances in the biological sciences. In 100 years, biology progressed from cataloging and describing species to sequencing the human genome. Along the way, astounding advances were made in cell and molecular biology, biomechanics, physiology, theoretical ecology, genetics, behavioral neurobiology, etc. These and other areas of the biological sciences continue to develop with Aves an important model group for links between environment and gene expression (e.g., Konishi et al., 1989). Environmental change including degradation, population, public health, food and energy production, education, and especially the public's understanding of science and technology are some of the most critical issues facing science and society. All of these pertain to biology. Technology and basic research in biological sciences have the potential to address the above issues, but they cannot be understood along traditional disciplinary lines. One enormous hurdle awaits 21st century biological research: how to integrate our knowledge of biology at all levels so we can pave the way for a deeper and broader understanding of how life on this planet works? This will also entail how to feed a still burgeoning population and educate future generations of undergraduates while conserving as much of the natural world as possible? If this were not enough, we must also deal with potentially catastrophic environmental problems resulting from climate change.

A major recurring problem with the spectacular success biology has experienced is that individual investigators have become so specialized and focused that in many cases they have, understandably, lost track of other disciplines. There is a growing consensus that biologists within disciplines have difficulty communicating with colleagues in other branches of biology. Clearly, the problems we face in the next decades will be solved only by taking broad integrative approaches involving expansive, multidisciplinary collaborations. In other words, molecular biology or theoretical ecology in isolation will not resolve problems that involve populations, their component individuals, as well as the complex interplay of physiology, behavior, cells, and molecules by which individuals function and interact. Management and control of these issues in relation to natural resources will also be difficult unless there are incentives to foster interdisciplinary research, integrate education, and maximize our potential to address problems by bringing to bear all of our knowledge in an effective way. Citing a report from the National Academy of Sciences, Jasanoff et al. (1997) assert that in the next decades, young scientists will be impeded in their advancement unless they are trained from an early age to diversify their expertise and career objectives.

As an example of the need to integrate ecology, behavior, and evolutionary biology with mechanisms at physiological, genetic, cell, and molecular levels, we can consider the functions of a differentiated cell in which complex interactions of many proteins occur. These functions can be modified by hormones that coordinate gene activity among various cells and tissues of the organism leading to the ultimate responses to internal and external environmental signals. A critical question is then how do hormones orchestrate transitions in morphology, physiology, and behavior of individual organisms in relation to a changing, and sometimes capricious environment? We can imagine observing an ecosystem and focusing on certain populations of individuals within it that have problems dealing with change in the environment triggered by, for example, human disturbance. It quickly becomes apparent that some populations, and individuals within them, deal with the environmental challenges better than others. It is reasonable to then ask what aspects of their physiology, behavior, and morphology are the causes of this failure, or success, and what the cell, molecular, and genetic bases of these differences might be. The investigation of interindividual variation will be another foundation for understanding how populations will evolve in response to environmental change. It is relatively simple to construct hypothetical scenarios whereby we traverse the spectrum of

Sturkie's Avian Physiology. https://doi.org/10.1016/B978-0-12-819770-7.00004-9

biological science from ecosystem to molecule in either direction, but it is not so intuitively obvious how we do this in practical terms. If such an interdisciplinary and integrative approach can be achieved, it will be possible to determine how we will deal with global changes already underway and ultimately prepare future generations to cope with ongoing changes.

Avian physiology has a long history of providing models for integration of disciplines, and it will continue in this role in the future (Konishi et al., 1989). In general, there are exceptionally broad data bases for birds on ecology and evolution across the globe. Match this with rapidly developing tools at genomic, transcriptomic, and epigenetic levels, then avian physiology is uniquely poised midway along the spectrum from genes to environmental to explore the molecular bases of adaptation and the integration of ecological and evolutionary aspects at the interfaces of morphology, physiology, and behavior. In addition, many wild avian species are abundant and easy to study making them ideal subjects for field observations and experiments in their natural environment, as well as in laboratory experimentation. Specific examples how avian physiology has played a major role in the development and integration of biological processes at many functional levels are discussed next.

1.1 Specific examples of the importance of avian physiology

Avian physiology has its roots in over 100 years of research on domesticated species, particularly the domestic fowl (*Gallus gallus*) as presented in the original version of Sturkie's Avian Physiology (Sturkie, 1954). Over the decades since there have been huge advances in avian physiology focused primarily on the poultry industry and food production. Then in the early 21st century, the chicken genome was sequenced and annotated (e.g., Burt, 2005; Burt and Pourquie, 2003). This opened up a new generation of biological studies at many of the interfaces outlined above, and was followed by sequencing the genome of a songbird, the zebra finch, *Taeniopygia guttata* (Warren et al., 2010). As technologies developed to sequence genomes more quickly and cheaply, the genomes of many other species have been sequenced as part of ambitious and exciting projects to eventually sequence the genomes of all the extant species of birds and some extinct ones as well (e.g., Zhang et al., 2014). If successful, such an unprecedented data base will allow analyses at so many levels of biological function. However, it should be borne in mind that the computational technologies to analyze such enormous amounts of data and integrate them with other diverse and unique data bases on morphology, physiology, behavior, and environment are huge challenges. Avian physiology will be a central focus for such integration. The examples given below are by no means all inclusive and new concepts and research directions are inevitable.

1.1.1 Physiology and poultry production

Physiological functions of domestic fowl from reproduction and growth to responses to diseases and stress such as weather factors (especially heat) also triggered thorough investigations of environmental biology and hormonal control of these processes (see Sturkie's Avian Physiology revised editions from 1954 to 2020). The domestic fowl and some other domesticated species (e.g., quail. duck, turkey) provide phenomenally broad data bases of physiology that rival those of mammals and fish. These in turn provide endless opportunities for other studies on wild species and gene-environment interactions—the foundations of understanding adaptation to a changing world.

1.1.2 Physiological ecology and birds, marine, freshwater, and terrestrial

Birds have played a central role in the development of physiological ecology, especially building on the vast array of data, techniques and tools made available from agricultural research (Phillips et al., 1985; Konishi et al., 1989). Avian physiological ecology is a thriving branch of biology that has provided a framework for other emerging topics such as environmental endocrinology, the regulation of seasonal changes in physiology, and individual differences and fitness. (e.g., Hau et al., 2010; Taff and Vitousek, 2016). Avian migration is a prime example of the integration of physiological systems that has benefitted enormously from avian physiology in general (Newton, 2010; Dingle, 2014; Ramenofsky and Wingfield, 2007). This has fueled investigations of one of the most integrative biological processes—the evolution, ecology, morphology, physiology, and behavior of movements across the environment in general.

Fundamental and applied research on domestic fowl has enriched development of avian physiology in relation to the comparative biology of environmental stress (Romero and Wingfield, 2016). All organisms must be able to cope with perturbations of the environment that are largely unpredictable, but require individuals to express facultative physiological and behavioral responses to cope. The "stress response" is common to most, if not all, organisms from bacteria and plants to invertebrate as well as vertebrate animals. Although the mechanisms involved vary fundamentally from plants to animals, they are well conserved within the vertebrates making avian systems excellent models. One aspect of climate change is the increase in frequency, duration, and intensity of extreme weather

events such as unseasonal storms, hurricanes, and typhoons. Understanding how some populations cope with these unpredictable events and others do not will have profound implications for understanding adaptation and consequences for conservation and agriculture.

New emerging avian models such as the zebra finch, great tit (*Parus major*, Santure et al., 2011), white-throated sparrow (*Zonotrichia albicollis*, Tuttle, 2003), and dark-eyed junco (*Junco hyemalis*, Ketterson and Atwell, 2016) and others, provide field and laboratory contexts for understanding physiological ecology as well as advancing basic research in neurobiology such as the physiology underlying behavioral patterns and avian song control systems (see Konishi et al., 1989; Pfaff and Joëls, 2017). These approaches using experiments both in the laboratory and the field have allowed the beginning of investigations of coping with climate change, shifts in habitat range, urbanization etc. (e.g., Partecke et al., 2006; Fokidis et al., 2009; Martin et al., 2010; Bonier, 2012; Caro et al., 2013; Visser and Gienapp, 2019). Birds have become important examples of models for conservation physiology (Wikelski and Cooke, 2006; Madlinger et al., 2016). For example, avian physiology is providing critical insights into one of the most important aspects of conservation—the impact of invasive species resulting from human activity as well as range expansions and contractions that have important and often devastating impacts on the survival of indigenous species from plants to mammals.

Another spin-off from avian physiology is the use of birds as sentinels of endocrine disruption—physiology, morphology, and behavior (National Research Council, 1999; Dawson, 2000; Norris and Carr, 2006; Carere et al., 2010). Although the responses of plants, invertebrates, as well as vertebrates, in general, are all important foci to document toxicology and endocrine disruption, the use of birds as models, and their well-known physiology both in the laboratory and field once again provide a useful model for understanding how organisms respond to disasters such as leakage of toxic chemicals, oil spills, etc. An example of a remaining critical issue of endocrine disruption is how organisms will cope with the now ubiquitous and global distribution of chemical mixtures in varying concentrations and how we may be able to ameliorate some of the effects of endocrine disruption by broad ranging "clean up" programs to levels of chemicals that organisms can at least tolerate?

1.2 Conclusions

Reading Sturkie's original avian physiology text (Sturkie, 1954), it is astonishing to learn how avian physiology has developed, expanded, and progressed in almost 70 years. The contributions of avian physiology to agriculture, biomedicine, veterinary science, and practice, as well as fundamental biology are vast. In the 21st century, with technologies until recently unimagined, these contributions will continue. What could not have been envisaged all those decades ago is how avian physiology has helped pioneer, initiate and develop new environmental aspects of biological sciences such as morphology and behavior at the interfaces with gene-environment interactions and coping with global change from urbanization, endocrine disrupting pollutants, and invasive species to the burgeoning effects of climate change. There is no question that avian physiology is very important and will continue to be at the cutting edge of so many branches of biological sciences. It will continue to influence not only basic research but also policy in managing planet Earth for future generations.

Chapter 2

Avian genomics

Hans H. Cheng[1], Wesley C. Warren[2] and Huaijun Zhou[3]
[1]USDA, ARS, Avian Disease and Oncology Laboratory, East Lansing, MI, United States; [2]Department of Animal Sciences, Bond Life Sciences Center, University of Missouri, Columbia, MO, United States; [3]Department of Animal Science, University of California, Davis, CA, United States

2.1 Introduction

All fields of biology have been greatly influenced by the generation of complete genome assemblies. This impact is most apparent with the findings and resulting applications from the Human Genome Project (HGP), which has transformed biomedical science (Green et al., 2015). Hoping for a similar transformation in agriculture, a genome assembly was first made for chicken in 2004 (International Chicken Genome Sequencing Consortium, 2004). More recently, as the feasibility and economics of generating a genome assembly increased, the number of species across all avian orders has increased dramatically (e.g., 48 were produced and analyzed in the landmark Zhang et al. (2014) paper), which strongly suggests that the field of genomics will only grow in its ability to shape the future direction for all fields of avian biology.

The original justification for having a genome assembly was to get a complete "parts list" of elements that contribute to an organism's phenotype with the primary goal being the identification and location of all genes. However, it soon become readily apparent that genomes were much more than just sequences that code for proteins; protein-coding regions account for ~1% of the human genome. Thus, current efforts have been focused on finding other relevant functional elements, such as noncoding elements that regulate when, where, and how much specific genes and/or particular isoforms are expressed. As these annotation efforts become more complete, the power and utility of genomes to inform other biological fields, like physiology, will become more apparent and enhanced.

Besides providing an incredible resource, genome assemblies and the field of genomics have fundamentally changed how experimental biology is conducted. It is now common to begin with discovery-based genomics science to build agnostic large datasets to analyze, which contrasts with traditional, reductionist hypothesis-based experiments. For example, many studies now start with transcriptome profiling (RNA sequencing) with the goal of generating hypotheses on what relevant genes and pathways to investigate further. Without genomics and its accompanying tools and resources, this approach would not have been possible. It is likely that this trend will only increase as more genomes are sequenced and functionally understood, along with the continuing development of more empowering and economical genomic-based technologies, and the desire to have and integrate multidimensional types of data to help understand complex biological problems. Having stated this, traditional experiments and the detailed information that they provide at many levels are still critical needs and inputs to truly empower avian genomes. In short, genomics adds another powerful approach to understanding biology.

Our target audience of this chapter is avian physiologists who might not be aware of the field of genomics. Specifically, we briefly summarize the current status of avian genome assemblies with the focus on chicken, as this is the most developed avian species to date, and common approaches that focus on DNA-based genomics. Key references are provided in each subsection to aid further reading.

2.2 Genome

2.2.1 Size

Eukaryotic genomes vary immensely, over 60,000-fold, from as small as 2.3 Mb for *Encephalitozoon intestinalis*, an intestinal parasite of humans and animals, to as large as 150 Gb found in the plant *Paris japonica* (Elliott and Gregory, 2015). This range in genome size, which does not correlate with organismal complexity (commonly referred to as the C-value paradox), has been recognized for a long time (Swift, 1950). However, genome size does seem to correlate positively with cell size and negatively with cell division rate (Elliott and Gregory, 2015). When considering

Sturkie's Avian Physiology. https://doi.org/10.1016/B978-0-12-819770-7.00047-5

only vertebrates, the size range (0.35−133 Gb) is less but still large (333-fold) (www.genomesize.com). In contrast to most other taxa, the interspecific variation for bird genome size is quite narrow − 0.9 Gb for the black-chinned hummingbird to 2.1 Gb for the ostrich; see Damas et al. (2019) for a more comprehensive review. The likely explanation for the relatively small genome size and stability of avian genomes is the low occurrence of transposable elements (TEs) and the loss of large segments that could counteract any TE expansion, which is the main driving force for the increase (Kapusta et al., 2017). Of interest to physiologists is the observation that genome size variation within bird species is associated with metabolism with smaller genomes having higher metabolic rates (Gregory, 2002).

2.2.2 Karyotype

Avian species are unique in having fairly high number of chromosomes. The majority of the species have 74 to 86 total chromosomes, which is equivalent to 37 to 43 pairs, though the reported range is 40 to 126 chromosomes (Griffin et al., 2007). The chicken karyotype is fairly typical (Fig. 2.1). It possesses 39 pairs of chromosomes, 38 pairs of autosomes and the Z and W sex chromosomes; unlike mammals, males are the homogametic sex (ZZ). An unusual feature of avian chromosomes is the variation in size distribution. Although arbitrarily defined as (1) macrochromosomes—autosomes one to five plus the Z chromosome are comparable in size to mammalian chromosomes, (2) intermediate microchromosomes—autosomes 6 to 10 and the W chromosome are similar in size to smaller human chromosomes, and (3) microchromosomes—all the remaining autosomes (11 to 38). The microchromosomes can be identified only through fluorescent in situ hybridization using specific probes (e.g., Romanov et al., 2005; Delany et al., 2009; Zhang et al., 2011). Due to their small size and the need for at least one recombination event during meiosis, microchromosomes are more gene dense, GC-rich in sequence content, and have higher recombination rates compared to macrochromosomes (International Chicken Genome Sequencing Consortium, 2004).

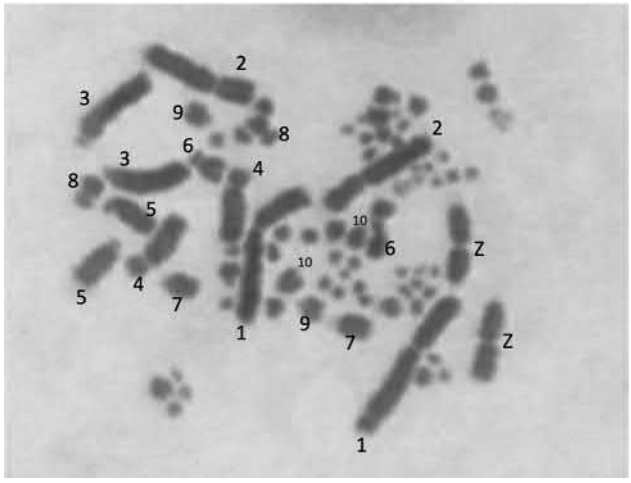

FIGURE 2.1 Mitotic metaphase chromosomes of a male (ZZ) chicken illustrating macro- and microchromosomes and the sex chromosomes. The cell shown was stained with the fluorochrome DAPI, which stains DNA and the image then inverted to black/white. Chromosome pairs one to nine and the Z are indicated by numbers. *Figure contributed by M.E. Delany, University of California, Davis, CA.*

2.3 Genome assemblies

2.3.1 Chicken legacy genomes

Since the first assembled chicken genome in 2004 (International Chicken Genome Sequencing Consortium, 2004) that used Sanger sequencing efforts, improvements in quality have closely followed the technological advancements in sequencing and mapping (Schmid et al., 2015). Furthermore, multiple upgrades (Gallus_gallus-2.1, 4.0, 5.0, GRCg6a) have greatly benefited from the better assembly of segmental duplications (SDs) (Eichler et al., 2004), closure of scaffold gaps, specialized approaches to resolve the complex sequence structure of the avian sex chromosomes (Bellott et al., 2018), and traditional bacterial artificial chromosome (BAC) clonal sequencing efforts that have improved sequence representation of chicken chromosome 16 (GGA16), which contains the major histocompatibility complex (MHC) (Miller and Taylor, 2016). Many of the genes, critical in governing immune responses, across species are clustered, multigenic families containing individual members that vary across haplotypes with intricate differences in sequence.

As with other vertebrate genomes, in chicken, a recurring hurdle to accurate computational experimentation is falsely collapsed or redundant SDs, repetitive elements and fragmented sex chromosome assemblies, mostly due to the organization of highly identical sequences that confuse de novo assembly attempts at constructing simple bifurcating graphs of each haplotype. Bellott et al. (2010) provide an exemplary case of the difficulties encountered where identification of a tandem array of four testis-expressed genes that constitutes ∼15% of the Z chromosome, one-fifth of all chicken SDs and in total about a third of the protein-coding genes on Z. Study of the W sex chromosome illustrates even more extreme heterochromatin stretches and a tandemly arranged gene with 40 copies (Bellott et al., 2017). It is well known that such duplications are frequently missed ("over-collapsed") in draft quality assemblies that they are common sites of copy number variation (CNV), and that such variation frequently have major phenotypic consequences (Conrad et al., 2010). Another example is that of the MHC-*B* complex in chicken on GGA16 (one of the smallest microchromosomes), a

region of great immunological importance with many gene duplications and CNVs. Directed sequencing of selected chicken BACs was critical to elucidate the partial organization of this region (Shiina et al., 2007), but in the future extreme sequence lengths (>500 Kb), such as the outcome of Oxford Nanopore sequencing technology, will be needed for gap-free genome sequence characterization.

Over the years, genetic linkage maps comprised of ordered and oriented molecular markers have helped to guide the genome assembly chromosome build. However, even though the consensus chicken genetic linkage map contains 50 linkage groups (Groenen et al., 2000), several microchromosomes were missing sequence marker alignments to a linkage group and still today chicken genome references have not captured the full autosome composition. This is of primary importance to the avian genome analysis process, especially given the high gene density per microchromosome. Recently improved sequencing and de novo assembly approaches or alternatively the use of advancing cytogenetic techniques will be crucial in efforts to assemble and assign these missing microchromosomes. In the current reference, GRCg6a, many of these unassigned sequences are likely found within the unplaced bin of chicken assembly reference files. However, in GRCg6a, there are only 14 Mb of unplaced contigs and scaffolds indicating there is also an inability to sequence or assemble some of these microchromosomes.

Ideally, the goal is to have complete sequence representation of all 40 chicken chromosomes, this includes Z and W sex chromosomes, but, of course, today this is not technically feasible for any vertebrate genomes, even human, although a recent telomere to telomere assembly of human X is encouraging (Miga et al., 2020). This study also highlights the incredible amount of manual curation that is needed to achieve this feat. Basically, automated methods to stitch together complex sequence structures still requires significant human intervention. Although the reasons for the breaks in vertebrate assembly contiguity "gaps" aren't always apparent, the usual culprits are repeats and base composition distortions, such as high GC homopolymers. In the chicken, we have observed assembly gap edges including elevated GC content approaching 75% in some regions and low-complexity sequences (International Chicken Genome Sequencing Consortium, 2004). Collectively this loss of sequence knowledge demonstrates more work is essential to not limit impending experiments. Of late, through longer read lengths, improved de novo assembly algorithmic methods and evolving mapping technology the ability to close ~80% of existing spanned gaps within assembled scaffolds, scaffolds defined as an ordered collection of contigs, are feasible (Bickhart et al., 2017; Koren et al., 2018).

2.3.2 Future chicken genome assembly

A need to represent the genome variation that exists within species has recently led to pangenome reference efforts (Computational Pan-Genomics Consortium, 2018). In chicken, a pangenome reference build must include mainstream and rare breeds, as well as commercially selected lines, both layers and broilers. De novo assembly methods, continue to evolve rapidly, where best practice is now, when possible, long-read sequencing of an F1 offspring and use of short reads from the parents to near fully phase haploid genomes of their offspring (Koren et al., 2018). In fact, the success of this approach has been recently documented for 16 vertebrate genomes, including bird species (Rhie et al., 2021). Assemblies created with this method offer more accurate assessments of complex structural variation (Kronenberg et al., 2018) and for some chromosomes gap-free starting points, such as human X that was spanned telomere-to-telomere (Miga et al., 2020).

In chicken, the primary objectives are to reduce sequence gaps and correct misassemblies that exist in the GRCg6a reference. Currently single haplotype genome references for an F_1 cross of a commercial layer (paternal) and broiler (maternal) line are under construction using this technique. Preliminary measures of sequence contiguity completeness show N50 contig "ungapped" lengths of 16 and 14 Mb in paternal and maternal genomes, respectively. After iterative scaffold builds with a long fragment physical map (BioNano) and chromosomal proximity ligation data, the near theoretical chromosome N50 scaffolds lengths of 60 and 89 Mb for paternal and maternal genomes is achieved, respectively. Further curation of these single haplotype assemblies promises to advance chicken genetic research by resolving much of the sequence structure presently fragmented and misappropriated in the GRCg6a reference.

2.3.3 Genes

The original chicken genome assembly estimated there were 20,000−23,000 protein-coding genes (International Chicken Genome Sequencing Consortium, 2004). However, more recent estimates from the comparison of 48 avian genomes indicates the number for bird genomes is lower at 15,000−16,000 (Zhang et al., 2014). Based on this number, this would reflect a ~30% reduction compared to the number found in mammals. At least 1241 of the loss in genes can be explained by large segmental deletions during the evolution of birds. However, ~70% of the lost genes show paralogs suggesting functional compensation. In addition, some of the gene loss may not be true but rather the inability to detect genes in high GC-rich regions (Bornelov et al., 2017).

Avian genes are ~50% smaller than their mammalian counterparts, mainly due to the shortening of introns and reduced distances between genes, which helps to account for the reduced size of avian genomes. Interestingly, with respect to avian-specific highly conserved elements, most are significantly associated with transcription factors associated with metabolism. Having a complete list of genes in many avian species has also enabled hypotheses on the evolution of flight, diets, vision, and reproductive traits (Zhang et al., 2014).

2.3.4 Transposons and endogenous viral elements

Avian genomes have a relatively low amount of TEs. In chicken, the most abundant TE is chicken repeat 1 (CR1), a long interspersed nucleotide element that with 200,000+ copies, comprises over 80% of all interspersed repeats in the chicken genome (International Chicken Genome Sequencing Consortium, 2004). A complete CR1 element is 4.5 kb in length, however, more than 99% of CR1 elements are truncated from their 5′ end, which is necessary for retrotransposition. Short interspersed nuclear element transposons are extremely rare, which contrasts to all other vertebrate genomes.

With respect to endogenous viral elements, analysis of 48 avian genomes has shown that there are five families of endogenous viruses—Retroviridae, Hepadnaviridae, Circoviridae, Parvoviridae, and Bornaviridae (Cui et al., 2014). However, over 99+% of these are endogenous retroviruses (ERVs), and the copy number of these elements range from 132 to 1032. There is great interest in ERVs as they are likely to contribute to evolution of gene expression and, thus, contributing to complex traits including ones for physiology. In humans, there are ~110,000 ERVs that contain over 300,000+ transcription factor binding sites (Buzdin et al., 2017). As many chicken ERVs are found in promoters and introns, they are likely to play a similar role.

2.3.5 Genome browsers

The chicken genome can be queried multiple ways using the major established genome browsers: Ensembl (https://useast.ensembl.org/index.html), NCBI (https://www.ncbi.nlm.nih.gov), and UCSC (https://genome.ucsc.edu/). Each genome browser offers a gateway to varied data types and search abilities for your sequence of interest. For example, using the UCSC genome browser any chicken chromosome can feature Ensembl or NCBI gene annotation, aligned mRNAs, conserved sequence chains against other vertebrates, simple repeats, CRISPR targets, and much more (Fig. 2.2). One can display a gene of interest, for example, the T cell receptor *CD3E*, and evaluate all putative targets for editing its gene structure as well as surrounding genes and their associated functional features. Future iterations of these browsers and new ones, such as FAANGMine.org for exploring sequence structures associated with gene regulation, will be of great value for researchers seeking information to design functional experiments in poultry. Another portal created by the Genome Reference Consortium (GRC; https://www.ncbi.nlm.nih.gov/grc) exists to report errors in the underlying chicken genome reference by the community. The GRC will ensure this resource continues to attain higher levels of reference quality and reporting accessibility with its readily useable web interface. All these public access points bode well for the continued use of this resource and advancing the knowledge of avian genome biology.

2.4 Connecting genome sequence to phenotype

2.4.1 Connecting genotype to phenotype

As discussed previously, a major driving force for generating genome assemblies was to accelerate the power of biology, and especially in the ability to identify the elements that define the makeup of an organism. Put another way, for few exceptions, while every cell in a chicken has the same DNA sequence, these cells vary greatly in many biological attributes primarily due to differences in gene expression. Couple this existing variation with genetic variation, then one begins to understand how the genome contributes to the wide diversity of traits observed within and between bird species. A mechanistic understanding of these processes can be harnessed to solve many important questions such as improvement of health, growth, reproduction, etc.

In the following sections, we briefly discuss the major approaches used to identify features in avian genomes that define trait variation observed in organisms.

2.4.2 Genome wide association study

It's been known for a long time that many traits have a genetic basis. A prime example is the tremendous progress made by poultry breeders to improve agronomic traits. However, prior to the genome sequence, identifying the underlying causative gene or genes was a very difficult task. Two contributing reasons for the lack of precision were (1) most traits are complex and controlled by many genes, each of which have can only have a small effect, and (2) there was a lack of known genetic markers that could survey the majority of the chicken genome.

The second deficiency was largely removed with the advent of the chicken genome assembly. More specifically, by sequencing additional chickens, millions of single nucleotide polymorphisms (SNPs) were identified that

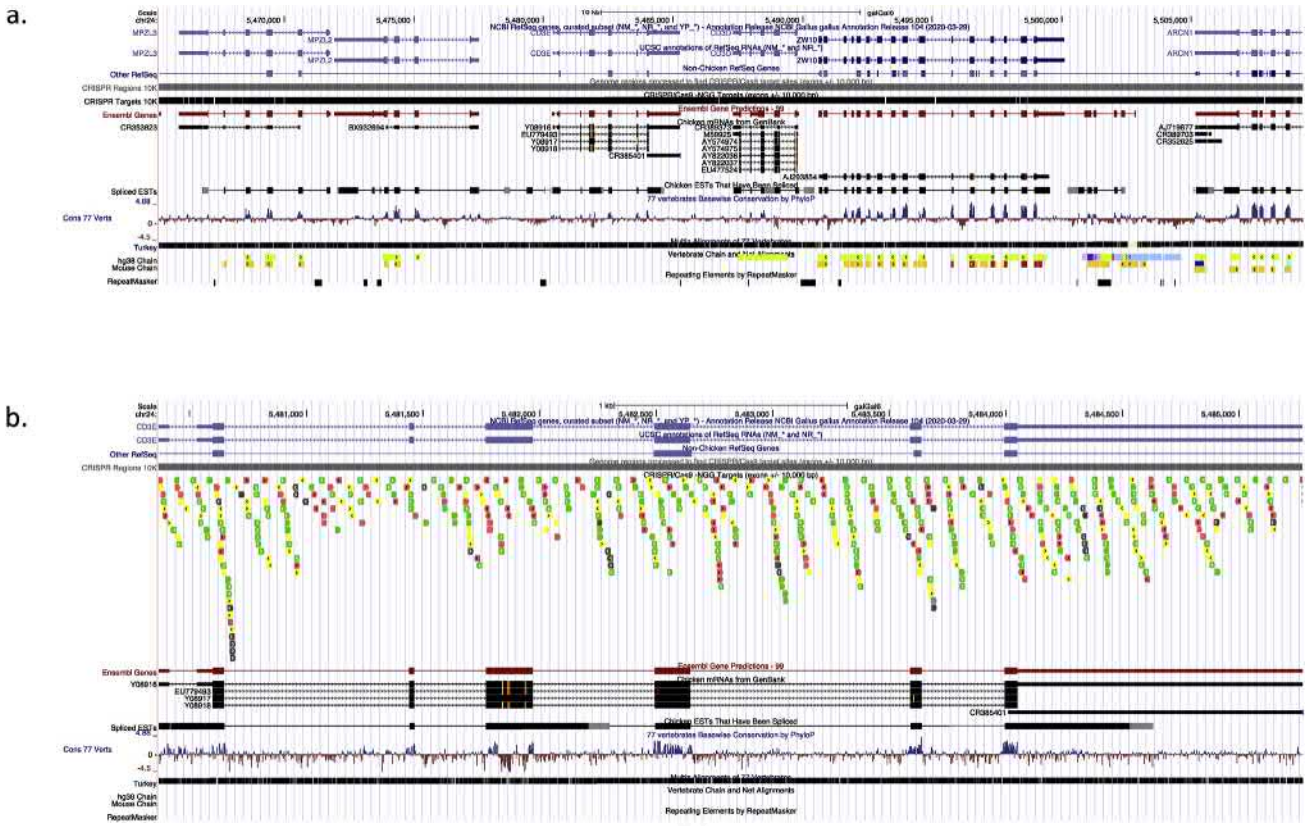

FIGURE 2.2 A UCSC Genome browser representation of GRCg6a chromosome 24. (A) regional overview at 44 kb window size that highlights the T cell receptor gene CD3E with other annotation tracks, (B) a higher resolution overview (4.9 kb) of the CD3E gene where the track is shown for CRISPR gene editing targets in this gene are represented by *multicolor boxes*.

could serve as genetic markers (International Chicken Polymorphism Map Consortium, 2004). Combined with affordable arrays that could determine the genotype tens to hundreds of thousands genetic variants, it was now feasible to survey the entire chicken genome. Studies that survey large numbers of birds with SNP chips are known as genome wide association studies or GWAS, for short; for more comprehensive reviews, see Uitterlinden (2016), Dehghan (2018), Tam et al. (2019). As a result, currently Animal QTLdb (animalgenome.org) lists 11,818 trait associations from 318 publications for chicken alone.

A typical GWAS experiment to dissect a complex trait requires thousands, if not tens of thousands of individuals, to have both genotype data from SNP chips and phenotypic data. Then statistical analysis is used to determine whether each SNP contributes to the trait of being studied. GWAS power is greatly enhanced by having more individuals surveyed and accurately measured phenotypes.

Like any genomic screen, the primary objective of GWAS is to identify candidate genes to interrogate further. Stated differently, while GWAS has revolutionized the genetic analysis of complex traits, any associated SNP is unlikely to be causative and only linked to the underlying causative genetic variant. Thus, further experimentation is needed to validate and better refine the association in order to identify the relevant gene or regulatory element.

Besides identifying trait associations, large-scale genotyping efforts can have other applications. One that might be more relevant to surveying avian diversity is the ability to define population structure. One of the first examples in birds was the study to examine whether heavily selected chicken populations were losing alleles (Muir et al., 2008).

2.4.3 Resequencing

Another major technological advancement that greatly impacted genomics was the development of next generation sequencing (NGS); for reviews on the NGS technologies, impact, and history see Koboldt et al. (2013), Goodwin et al. (2016), Heather and Chain (2016), Levy and Myers (2016), Slatko et al. (2018). Largely driven by the needs of the HGP, NGS is defined by highly parallel methods that produce extremely large amount of data. Existing platforms can easily provide reads that, when combined, cover the entire chicken genome many fold times at economical costs. With the widespread distribution of sequencing

machines, like SNP chips, NGS has enabled almost all laboratories to conduct large-scale sequencing efforts. This power continues to increase with the continuing declines in costs and, in particular, the increasing capability of "long read" platforms. And compared to SNP arrays, NGS allows for the interrogation of the entire genome and provides single base resolution. On the other hand, this increased power and sequence information comes at a cost mainly with the increased need for computational biology skills.

The great challenge in resequencing is in interpreting the results. This is because there are a large number of polymorphisms between any two individuals, of which only a small fraction will be associated with the trait of interest. For this reason, most resequencing efforts have been most successful in identifying genes of large effect, e.g., dermal hyperpigmentation (Dorshorst et al., 2011), polydactyly (Dunn et al., 2011), comb phenotypes (Wright et al., 2009; Dorshorst et al., 2015), sex-linked barring (Schwochow Thalmann et al., 2017), and talpid 2 (Chang et al., 2014). Typically, these efforts relied on mapping the mutations to a locus or having comparative knowledge from similar mutations in other organisms, which was then further characterized by whole genome resequencing. Analysis of the data revealed likely causative alleles.

2.4.4 Annotation

Functional characterization of genetic variants is often required to move from statistical association to causal variants and genes, especially in the noncoding genome. Recent studies have revealed that regulatory mutations in the noncoding regions are one of major drivers of phenotypic variations in complex traits (e.g., She and Jarosz, 2018). Therefore, functional annotation of regulatory elements in the chicken genome is essential in understanding biological mechanisms of physiological traits. In order to functionally annotate regulatory elements of genes, one must know the locations and functions of various sequence features such as promoters, enhancers, insulators, and silencers. In the past few years, the International Functional Annotation of Animal Genomes Consortium (FAANG.org) has developed core assays and bioinformatic pipelines that can be used to annotate these regulatory elements in the genomes of farm animals including chicken (Andersson et al., 2015; Giuffra et al., 2019).

Assays for characterizing chromatin accessibility and posttranslational histone modification can be used to identify and annotate regulatory elements. These posttranslational histone modifications can affect chromatin accessibility and gene expression. Chromatin immunoprecipitation sequencing (ChIP-seq) has been widely used to characterize histone modifications such as methylation and acetylation. For example, assays for histone H3 lysine 4 trimethylation (H3K4me3), H3 lysine 27 trimethylation (H3K27me3), H3 lysine 27 acetylation (H3K27ac), and H3 lysine 4 monomethylation (H3K4Me1) have been utilized to characterize chromatin state (ENCODE Project Consortium, 2012). An abundance of H3K4me3 correlates with promoters of active genes (Bernstein et al., 2002; Santos-Rosa et al., 2002; Xiao et al., 2012), while increased levels of H3K27me3 are associated with promoters of inactive genes (Heintzman et al., 2007). H3K27ac is a mark of active regulatory elements, and may distinguish active enhancers and promoters from their inactive counterparts (ENCODE Project Consortium, 2012). H3K4me1 is a mark of regulatory elements associated with enhancers and other distal elements, but also enriched downstream of transcription starts (ENCODE Project Consortium, 2012). High levels of H3K27ac and H3K4me1 are associated with enhancer regions and also correlate with areas of chromatin accessible sites (Greer and Shi, 2012). Insulators also play an essential role in regulating gene expression. The insulator-binding protein CCCTC-binding factor (CTCF) is the main insulator protein (Ong and Corces, 2014) for animal species. Chromatin accessibility provides a direct interpretation of epigenetic state, since chromatin organization and transcription factor binding together dictate the impact of regulatory elements on gene expression, determining cell-specific expression patterns and cell fate (Rivera and Ren, 2013). Assay for transposase-accessible chromatin (ATAC-seq) can be used to profile chromatin accessibility. Using the histone marks and CTCF binding sites in concert with ATAC-seq and RNA-seq can provide an unprecedented view of regulatory elements in the chicken genome. Active and inactive regulatory elements including promoters, enhancers, and insulators can be identified and annotated based on combinations of the assays above (Table 2.1).

Based on these assays of eight tissues in chickens, our results suggest that chicken genome has about half of the number of active regulatory elements including enhancers and promoters compared to mammals such as cattle and pig, especially on the number of enhancers, which may be due to same size of the chicken genome, one third that of a typical mammal (Kern et al., 2021).

2.4.5 CRISPR

Clustered, regularly interspaced, short palindromic repeats (CRISPR) is another revolutionary tool for genomic research that has very quickly become an indispensable tool for use in many organisms. Originally discovered in bacteria as a defense mechanism against invading viruses, CRISPR loci express small RNAs that complement viral genome sequences and when combined with associated CRISPR-associated nucleases (Cas) result in the enzymatic cleavage of both strands of the targeted viral DNA. Thus, only two components are required for DNA cleavage:

TABLE 2.1 Identification of promoter, enhancer, and insulator elements based on activation marks on ATAC-seq and ChIP-seq.

	Activation marks					
Regulatory element	ATAC-seq	H3K4me3	H3K27me3	H3K27ac	H3K4me1	CTCF
Active promoter	+	+	−	+	−	+/−
Inactive promoter	+	−	+	−	+	+/−
Active enhancer	+	+/−	+/−	+	+	+/−
Inactive enhancer	+	+/−	+/−	−	+	+/−
Insulator	+	−	−	−	−	+

+, indicates peaks on the marks; −, indicates no peaks on the marks; +/−, indicated poised peaks on marks depends on tissues, developmental or physiological status.

(1) an RNA molecule, called guide RNA (gRNA), which includes 17−20 bases that are complementary to the target DNA and (2) a Cas nuclease.

Recognizing the simplicity of the system, innovative scientists (Jinek et al., 2012; Cong et al., 2013) harnessed this system for widespread use in many other organisms including avians that allows for a programmable endonuclease, a feat that was previously difficult, if not impossible to achieve (Adli, 2018). After inducing double-stranded breaks in the genome, the resulting DNA damage must be repaired either by nonhomologous end-joining (NHEJ) or homology-directed recombination (HDR), resulting in a modified sequence. NHEJ can be used to cause small, random indel mutations, while HDR can generate precise replacement of targeted DNA or insertion of novel transgene cassettes up to many Kb in length. Given the power and simplicity of the system and different Cas proteins, there are many other new uses that are being employed including the ability to regulate gene expression, modify epigenetics, etc (Pickar-Oliver and Gersbach, 2019). In short, CRISPR allows for all groups to conduct gene editing and more in their cells or organism of interest.

With respect to avian systems, there are likely to be at least two key uses in the immediate future. The first is validation of the function of predicted genomic sites by knocking out the hypothesized DNA sequence and observing the phenotype. While this method is most amenable to cell lines (e.g., Chavali and Gergely, 2015), there are several reports on the deletion of various genes associated with chick development (e.g., Veron et al., 2015; Williams et al., 2018). The ultimate goal is to observe bioengineered birds (reviewed by Chojnacka-Puchta and Sawicka, 2020), which has recently been achieved using CRISPR to demonstrate that chickens lacking the receptor for avian leukosis virus subgroup J are resistant to viral infection (Koslová et al., 2020).

Another major approach that has not been reported yet for chickens is to use CRISPR in genomic screens. As stated by Neff (2020), genomic screens are comprised of three components: (1) the perturbation, (2) the model, and (3) the assay. With barcoded gRNAs and pooled cells, perturbations are clean and thorough as one can knockout the gene in every cell. The key is to have relevant cell types and ability to measure relevant phenotypic changes associated with loss of function.

2.5 Conclusions

Since the generation of the chicken genome assembly in 2004, the pace of genomics continues unabated. Due to the continued decline in sequencing costs and technologies, the ability to produce genome assemblies in other avian species or members within a species has grown immensely (Jarvis et al., 2014). These improvements have and will continue to greatly enhance of the power of genomics. Having stated this, the challenge is how to get parallel increases in other fields such as physiology. Although obtaining and accurately measuring many phenotypes is a difficult and time-consuming process, this new information will surely spur massive gains in our fundamental knowledge of genome structure, genetic variation, gene regulation, genome evolution, and many other areas of study.

Chapter 3

Transcriptomic analysis of physiological systems

Tom E. Porter

Department of Animal and Avian Sciences, University of Maryland, College Park, MD, United States

Abbreviations

ACTH Adrenocorticotropic hormone gene
ADRB2 Beta 2 adrenergic receptor gene
ALD Anterior latissimus dorsi
BDNF brain-derived neurotrophic factor gene
cDNA Complementary DNA
CGA Glycoprotein hormones, alpha subunit gene
DIO2 Thyroid hormone deiodinase 2 gene
DNA Deoxyribonucleic acid
ESTs Expressed sequence tags
FSH Follicle-stimulating hormone gene
FSHB FSH beta subunit gene
FSHR FSH receptor gene
GLUT1 Glucose transporter 1 gene
GRM8 Type 8 glutamate receptor gene
LH Luteinizing hormone
LHB LH beta subunit gne
LPS Lipopolysaccharide
MAPK Mitogen-activated protein kinase
miRNA Micro-RNA
MR mineralocorticoid receptor gene
mRNA Messenger RNA
NFκB Nuclear factor kappa B gene
NPYR5 Neuropeptide Y receptor type 5 gene
PLD Posterior latissimus dorsi
POMC Proopiomelanocortin gene
PPARγ Peroxisome proliferator-activated receptor gamma gene
RNA Ribonucleic acid
RNAseq Massively parallel sequencing of RNA
TTR Transthyretin gene
VIP vasoactive intestinal peptide gene

3.1 Introduction

How does the brain integrate environmental cues to control behavior, vocalization, and reproduction? How do the endocrine tissues respond to internal and external signals to coordinate physiological responses? What governs immune cell responses to pathogens? What are the mechanisms underlying muscle differentiation and development? How do hepatic, gastrointestinal, and adipose tissues respond to mediate nutrient uptake and metabolism? How does the cardiovascular system adjust to systemic and environmental needs? These questions have been asked by physiologists for decades. Multiple approaches have been taken to advance our knowledge in these areas. With the sequencing of the genomes for multiple avian species and the development of genome-wide tools for analysis of mRNA levels, physiologists have begun to address these still open questions on a genomic scale. Transcriptomics, also known as transcriptional profiling and functional genomics, involves large-scale and in many cases genome-wide analysis of mRNA levels in samples using DNA microarrays and massively parallel sequencing of RNA (RNAseq). The discussion below will highlight some of the efforts by avian physiologists to apply transcriptomics to the open questions noted above.

3.2 Early efforts

The first major effort in transcriptional profiling in avian species occurred with the chicken. A dramatic increase in the number of expressed sequence tags (ESTs) for chicken submitted to GenBank occurred between 1999 and 2002, prior to the release of the chicken genome sequence in 2004. During that four-year period, the number of ESTs for the chicken increased from a few hundred to more than 400,000. Assembly of these ESTs allowed for the production of more than a dozen DNA microarray platforms. Details on the production of these microarrays have been reviewed in detail (Cogburn et al., 2007; Gheyas and Burt, 2013). In 2001, three papers were published that marked the beginning of transcriptomics in birds (Liu et al., 2001; Morgan et al., 2001; Neiman et al., 2001). These first avian

Sturkie's Avian Physiology. https://doi.org/10.1016/B978-0-12-819770-7.00006-2

cDNA microarrays contained cDNAs representing approximately 2000 genes expressed in lymphoid tissues that were printed on nylon membranes. Several other tissue-specific cDNA microarrays were developed in the following few years (Bailey et al., 2003; Carre et al., 2006; Cogburn et al., 2003, 2004; Ellestad et al., 2006), and two groups produced cDNA microarrays representing more than half the expressed genes in the chicken (Burnside et al., 2005; Cogburn et al., 2004). These systems-wide cDNA microarrays were followed by oligonucleotide arrays representing the majority of expressed genes in the chicken (Affymetrix, ARK-Genomics/Operon, Agilent). Within five years of the foundation of functional genomics in the chicken and shortly after the release of the chicken genome sequence, tools were established for near genome-wide analysis of mRNA levels in chicken samples. Subsequent to these early efforts in the chicken, similar projects established resources for genomics studies in the zebra finch (Li et al., 2007) and Northern bobwhite quail (Rawat et al., 2010). These genomics tools were rapidly put to use in studies of physiological systems, which will be discussed below.

Early studies on transcriptomics in birds frequently resulted in long lists of genes that were either up-regulated or down-regulated in one set of samples relative to another. While these lists represented candidate genes for potential involvement in physiological responses, they did not add substantially to our understanding of the gene interactions mediating those responses. Many studies used hierarchical clustering, heat maps, or self-organizing maps to group genes based on their expression patterns in responses to treatments or during time-course studies. Examples of heat map and SOMS clustering are presented in Figs. 3.1 and 3.2, respectively. The rationale used was that genes that respond with similar patterns are likely regulated by shared mechanisms or even common transcription factors. More recent transcriptomic studies have placed differentially expressed genes into known or predicted gene networks and pathways based on reports in the literature (see example in Fig. 3.3). One commonly used pathway analysis software is Ingenuity Pathway Analysis. Taking multiple approaches to analyze transcriptomic results can lead to a broader understanding of the cellular pathways, gene networks, and transcriptional regulation of gene expression involved in physiological processes.

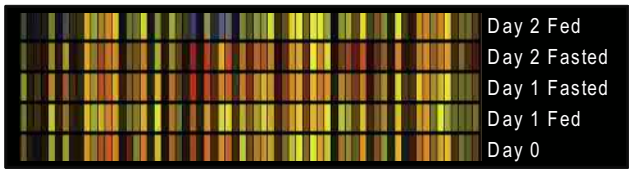

FIGURE 3.1 Heat map illustrating effects of fasting or feeding of newly hatched chickens on mRNA levels in the hypothalamus. Hypothalamic mRNA samples were analyzed using cDNA microarrays, and the results were clustered. Shown is a cluster of genes for which mRNA levels were increased (red) in response to fasting. Among these were *DIO2* and neuropeptide Y receptor type 5 (*NPYR5*). The data presented have been published previously (Higgins et al., 2010), but not in this format.

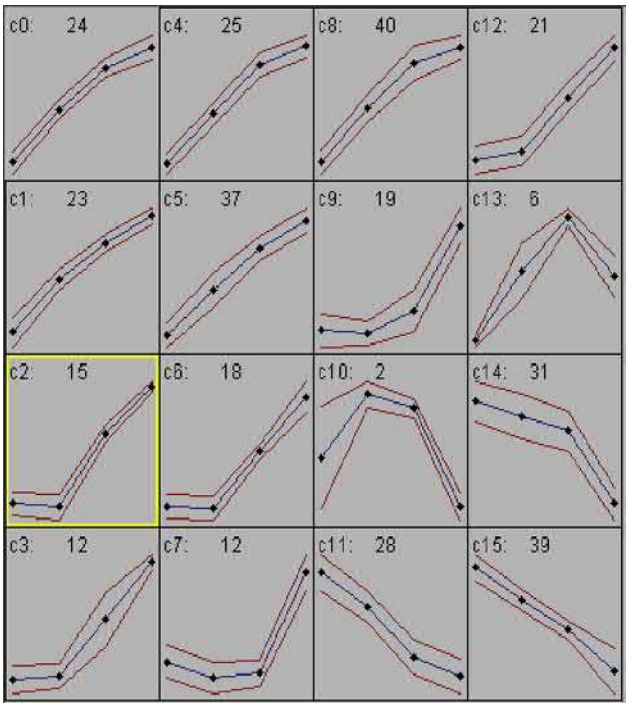

FIGURE 3.2 Self-organizing maps (SOMS) clustering of mRNA levels in the anterior pituitary gland during embryonic development. Pituitary gland mRNA samples from embryonic days 12, 14, 16, and 18 were analyzed using cDNA microarrays, and the results were clustered into SOMS based on mRNA level profiles during development. Cluster 2 (C2) outlined in yellow contains 15 genes whose expression increased on embryonic day 16. Growth hormone (*GH*) was among the genes in this cluster. These results have been published previously in a different format (Ellestad et al., 2006).

3.3 Nervous system

Vocalization in songbirds is part of the courtship ritual and an important neuroscience model for speech in humans and for sexual dimorphism in the central nervous system. However, the genes involved in establishing differences in vocalization between male and female songbirds were not known. Using microarray technology, differences in hypothalamic gene expression in response to territorial intrusion were found between the spring and autumn in free-living song sparrows (Mukai et al., 2009). Among the genes that were differentially expressed between the seasons were genes involved in thyroid hormone regulation and action, including genes encoding for the alpha subunit of thyroid-stimulating hormone (*CGA*) and transthyretin (*TTR*), supporting a role for thyroid hormones in modulating hypothalamic control of territorial aggression during seasonal reproduction. Gene express ion in the high-vocal

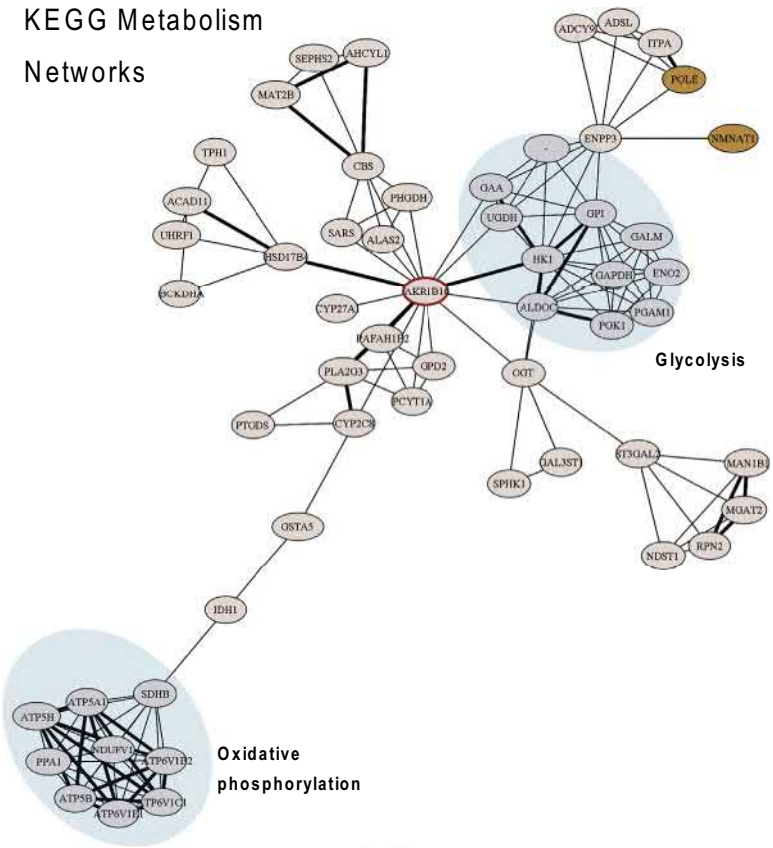

FIGURE 3.3 Network of genes that were differentially expressed in the hypothalamus of chickens genetically selected for high or low-body fat. Hypothalamic RNA samples from the two genetic lines were analyzed using cDNA microarrays, and the results were further analyzed using Ingenuity Pathway Analysis software. Genes involved in glycolysis and oxidative phosphorylation were among those that were differentially expressed in the hypothalamus of the fat and lean chickens. Additional details on these finding can be found in a previous publication (Byerly et al., 2010).

center (HVC) of zebra finches and canaries was similarly characterized (Li et al., 2007). Relative to a whole-brain reference RNA sample, expression of 190 genes was greater in the high vocal center of both zebra finch and canaries, suggesting that these genes might function in controlling vocalization. Genes expressed specifically within the song control nucleus (HVC) were also identified in the Bengalese finch using microarrays (Kato and Okanoya, 2010). In a more comprehensive study, microarray analysis of the basal ganglia identified thousands of genes differentially expressed in area X of singing zebra finches (Hilliard et al., 2012). Microarray analysis was also used to identify genes located on the Z chromosome that are expressed within the song control nucleus of the male zebra finch that are involved in cell survival (Tomaszycki et al., 2009), supporting their role in formation of the sexually dimorphic nucleus involved in masculinization of song. A similar microarray analysis of gene expression in the telencephalon of zebra finch and whitethroat indicated that most of the genes differentially expressed in males were linked to the Z chromosome (Naurin et al., 2011). However, only half of these were differentially expressed in males of both passerine species. Transcriptional profiling of the auditory lobe of zebra finches identified genes whose expression changed with the introduction of a novel song and reverted upon habituation of the birds to the introduced song (Dong et al., 2009; London et al., 2009). Interestingly, RNAseq revealed micro-RNAs (miRNA) in the auditory forebrain responsive to song that target genes whose expression changes with song (Gunaratne et al., 2011), indicating that expression of miRNAs likely contributes to song in birds.

The central nervous system plays an essential role in regulating metabolism, growth, and body composition. However, the full complement of genes expressed within the central nervous system that function in regulating these processes is not known. Transcriptomics has been used to identify genes and gene networks involved in these processes. Transcriptional profiling of the telencephalon of the white-crowned sparrow during the migratory and nonmigratory seasons revealed differences in expression of genes involved in glucose transport, including glucose transporter 1 (*GLUT1*) (Jones et al., 2008). These findings support an increased need by the nervous system for glucose during

the migratory season. In a study in which metabolism of newly hatched chickens was perturbed by fasting, microarray analysis revealed that fasting altered expression in the hypothalamus of genes involved in the regulation of metabolic rate, including thyroid hormone deiodinase 2 (*DIO2*) and proopiomelanocortin (*POMC*; Fig. 3.1), suggesting hypothalamic modulation of metabolic rate in order to compensate for decreased feed intake (Higgins et al., 2010). Genes not previously associated with hypothalamic regulation of feed intake and metabolism were also identified, including the beta 2 adrenergic receptor (*ADRB2*) and the type 8 glutamate receptor (*GRM8*). Functional relationships between *ADRB2*, *GRM8*, and *POMC* were confirmed in cultures of hypothalamic neurons, and effects were dependent on whether the neurons were derived from chicks that were previously fed or fasted. In two other reports, hypothalamic gene expression was profiled in genetic lines of chickens divergently selected for high or low-body fat (Byerly et al., 2010) or high or low-body weight (Ka et al., 2011). Differences in expression of genes associated with glucose sensing, transport, and metabolism were detected in the hypothalamus of birds selected for low or high-body fat, suggesting that differences in hypothalamic regulation of body fat in birds might involve the capacity of the hypothalamus to sense and metabolize glucose (Fig. 3.3). In contrast, selection for body weight did not affect hypothalamic expression of genes known to regulate feed intake and metabolism, even though the high body weight birds are hyperphagic. These studies demonstrated how involvement of novel gene pathways within the central nervous system in physiological processes can be identified using transcriptomics.

The central nervous system plays an integral role in stress responses. In an effort to define divergent mechanisms regulating long-term responses to stress occurring during embryonic and early posthatch development, corticosterone was administered to Japanese quail during pre- or postnatal development, and the effects on gene expression within the hippocampus and hypothalamus was assessed at adulthood using RNAseq (Marasco et al., 2016). Results indicated that effects depended on the developmental age of corticosterone treatment and on the region of the brain. Corticosterone-treated birds exhibited increased levels of mRNA for brain-derived neurotrophic factor and mineralocorticoid receptor (*MR*) in the hippocampus and corticotrophin-releasing hormone and serotonin receptors in the hypothalamus. Interestingly, mRNA levels in the hippocampus for the thyroid hormone transporter *TTR* were increased in response to prenatal but not postnatal corticosterone treatment. Conversely, levels of mRNA for the serotonergic system were up-regulated in the hypothalamus following postnatal but not prenatal corticosterone treatment. These findings indicate that early life stress can have prolonged effects within the central nervous system and that the effects are brain region and developmental stage dependent.

Maternal care of offspring is coordinated by the central nervous system, with particular involvement of the hypothalamus. Neuroendocrine regulation of brooding behavior in birds has been studied extensively. However, details on the molecular regulation of brooding behavior remain elusive. Transcriptional profiling of the hypothalamus of laying and brooding Muskovy ducks was performed using RNAseq analysis (Ye et al., 2019). Genes in the dopaminergic and serotonergic pathways, along with the principle regulator of prolactin secretion vasoactive intestinal peptide (*VIP*), were up-regulated in brooding birds. In contrast, genes in the glutamatergic pathway were down-regulated in brooding birds. Interestingly, *DIO2* and *TTR* mRNA levels were decreased in the hypothalamus of brooding ducks, implicating a potential role for thyroid hormones in the transition from laying to brooding states. Not all avian species brood their young. Some species are brood parasites, laying their eggs in the nests of another species to be brooded by the host. In a comparison of brood parasitic and nonparasitic blackbirds, transcriptional profiling of the preoptic area of the brain was conducted using RNAseq (Lynch et al., 2019). Two brood parasitic Icterids, brown-headed (Molothrus ater) and bronzed cowbirds (Molothrus aeneus), were compared with juvenile and adult red-winged blackbirds (*Agelaius phoeniceus*), a nonparasitic Icterid. Gene expression profiles for the parasitic birds more closely resembled those of the juvenile nonparasitic birds than the adult nonparasitic birds. These findings raise the intriguing possibility that the evolution of brood parasitism in birds might have involved a failure of the preoptic area to transition from the juvenile state to the reproductively mature state, a neotenic phenomenon.

3.4 Endocrine system

Transcriptomics has been used to characterize gene expression within endocrine tissues and the responses to hormonal treatments in birds. In one of the first microarray analyses in birds reported, transcriptional profiles were defined within the pineal gland of chicks during a light-dark circadian cycle (Bailey et al., 2003). Expression of hundreds of genes in the pineal gland oscillated during the light-dark cycle, including genes involved in melatonin synthesis. Importantly, this transcriptomics analysis revealed many genes associated with immune responses, stress responses, and hormone binding, suggesting other roles for these genes within the pineal gland or for the pineal gland within these other physiological systems. A similar analysis was subsequently performed in the chick retina (Bailey et al., 2004). Although some overlap in oscillating gene expression was found between the retina and the pineal gland, distinct differences were also noted,

suggesting that differences might exist in circadian regulation at the molecular level within the two tissues. Effects of thyroid hormone and growth hormone on hepatic gene expression have been characterized in the chicken using microarrays (Wang et al., 2007b). Dozens of thyroid hormone- and growth hormone-regulated genes were identified. Interestingly, cross talk between the two systems was noted, as thyroid hormone status affected mRNA levels for growth hormone receptor and insulin-like growth factor binding protein 1. Microarrays were used to characterize the response of the avian adrenal gland to adrenocorticotropic hormone (ACTH). Injection of ACTH increased mRNA levels for several steroidogenic genes but also genes with other functions, such as transcription, cell division, and electron transfer (Bureau et al., 2009). The effects of insulin immunoneutralization through administration of antiserum to insulin were evaluated in the chicken (Simon et al., 2012). Microarray analysis of mRNA samples from liver and muscle revealed that expression levels for more than 1000 genes were affected by decreased insulin levels or the elevated glucose levels associated with insulin immunoneutralization. The results demonstrated the wide range of effects of insulin on two of its target tissues. Microarrays were used to characterize changes in gene expression in the pituitary gland during chicken embryonic development (Ellestad et al., 2006). Numerous genes were identified with expression profiles that suggested involvement in differentiation of pituitary thyrotrophs, somatotrophs, and lactotrophs (Fig. 3.2). Effects of glucocorticoids on pituitary gene expression were also identified using cDNA microarrays. Treatment with corticosterone of chicken embryonic pituitary cells affected mRNA levels for hundreds of genes, and these were placed into networks of affected genes (Jenkins et al., 2013). The results were also used to identify putative glucocorticoid receptor targets in the chicken, demonstrating the power of pathway and network analysis of transcriptional profiles.

3.5 Reproductive system

Development and function of the reproductive system involves gonadal differentiation and hormonal effects on reproductive tissues, including testes, ovary, and oviduct. However, the full extent of the genetic mechanisms underlying these processes is not known. A number of studies have been reported in which investigators used transcriptomics to shed light on the underlying mechanisms controlling development and function of the reproductive system in birds. A comparison of gene expression in the shell glands of juvenile and laying chicken hens using cDNA microarrays identified hundreds of genes that are differentially expressed in the mature shell gland (Dunn et al., 2009). Similar transcriptional profiling of the uterus of the chicken using cDNA microarrays revealed genes expressed specifically in the magnum or the isthmus (Jonchère et al., 2010). Among these were genes encoding for antimicrobial proteins and ion transporters, respectively, supporting their role in antibacterial properties of the egg albumen and for eggshell formation. An analysis of the effects of a synthetic estrogen on gene expression in the oviduct demonstrated that estrogen affects expression of genes associated with epithelial differentiation and tissue remodeling (Song et al., 2011), consistent with the dramatic effects of estrogens on oviduct size and glandular development. Microarrays were used to identify genes expressed specifically within the germinal disk of the developing oocyte (Elis et al., 2008). These genes are likely to play a role in oocyte maturation or early embryonic development. Other genes found to be expressed in the granulosa cells are more likely involved in follicular maturation. Within the developing gonad of the chicken, miRNAs that were specific to the testes or ovary were identified using microarrays (Bannister et al., 2009), suggesting a role for miRNA expression in gonadal differentiation. One reproductive organ that is often overlooked is the pigeon crop that produces "crop milk" for the nutritional supply of offspring. A comparison of gene expression in nonlactating and lactating pigeon crop using oligonucleotide arrays identified genes that are differentially expressed in the lactating crop (Gillespie et al., 2011). Genes associated with extracellular matrix receptors, adherens tight junctions, and Wnt signaling were found. This finding supported hyperplasia and cellular release into the crop lumen in the formation of pigeon crop milk.

Several studies using transcriptional profiling of the hypothalamo-pituitary-ovarian axis have been reported. Transcriptional profiling of prehierarchical, preovulatory, and postovulatory ovarian follicles in the chicken using RNAseq identified genes involved in adherens junctions, apoptosis, and steroid biosynthesis (Zhu et al., 2015). RNAseq analysis was conducted on small white, large white, and small yellow ovarian follicles of laying and broody Zhedong white geese (Yu et al., 2016). Differentially expressed genes identified included many involved in hormone responses, follicular development, autophagy, and oxidation. Interestingly, those related to autophagy were up-regulated in ovarian follicles from broody hens, indicating that autophagy might play a significant role in follicular atresia associated with broodiness. RNAseq analysis of individual small yellow follicles with different levels of mRNA for the follicle-stimulating hormone (*FSH*) receptor (*FSHR*) was used to identify a novel mechanism for follicular recruitment (Wang et al., 2017). The Wnt signaling pathway was significantly up-regulated in the follicles with the highest levels of *FSHR* expression. Wnt4 was shown to stimulate proliferation of follicular granulosa cells and increase granulosa cell *FSHR* mRNA and decrease anti-Müllerian hormone mRNA levels, while FSH

was found to increase Wnt4 mRNA. These findings, based initially on transcriptional profiling, suggest that Wnt4 plays an important role in follicle selection in the chicken ovary. Transcriptomic analysis using RNAseq was performed on the hypothalamus and anterior pituitary gland of domestic turkey hens producing high or low numbers of eggs in a reproductive season. Pathway analysis of the differentially expressed genes revealed differences in thyroid hormone and estradiol signaling between the two groups of hens (Brady et al., 2020). Treatment of pituitary cells in culture confirmed that T_3 suppressed mRNA levels for the beta subunits of luteinizing hormone (*LHB*) and FSH (*FSHB*), with the effect being greater for cells from the high egg-producing hens. In contrast, treatment with E_2 increased mRNA levels for *LHB* and *FSHB*, with the effect being more pronounced for cells from the low egg-producing hens than the high egg-producing hens. These findings indicate that differences in thyroid hormone and estradiol signaling might account, in part, for differences in egg production rates. Moreover, they highlight how transcriptional profiling can uncover novel mechanisms governing physiological processes.

3.6 Immune system

Differences exist in immunological responses to pathogens among individuals in a species. However, the genes expressed within cells of the immune system that account for responses to pathogens and differences in responses among individuals are not entirely known. Microarray analysis was used to study gene expression in one lymphoid organ, the spleen, of susceptible and resistant lines of chickens in response to *Campylobacter jejuni* infection (Li et al., 2012b). Not surprisingly, expression of genes for lymphocyte activation and humoral responses, including immunoglobulin heavy and light chains, was increased following infection in the resistant line. Surprisingly, expression of genes related to erythropoiesis and apoptosis was affected in the susceptible line. These differences in genetic responses within the spleen to *Campylobacter jejuni* infection could contribute to susceptibility or resistance of individual birds to infection. In a similar study, transcriptional responses of the spleen to *Escherichia coli* infection were profiled (Sandford et al., 2011). Immunological pathways including cytokine signaling and Toll-like receptors were affected by *E. coli* challenge, and the magnitude of transcriptional changes was correlated with the severity of infection. Surprisingly, immunization prior to *E. coli* challenge had no significant effects on transcriptional profiles in response to *E. coli*. Similarly, transcriptional profiling of macrophage responses to *Salmonella*-derived endotoxins revealed effects on expression of genes for multiple cytokines and Toll-like receptors (Ciraci et al., 2010). In an earlier study of macrophage responses to lipopolysaccharide (LPS) or *E. coli*, downstream targets of the Toll-like receptor pathway were affected (Bliss et al., 2005). Transcriptional profiling of cecal gene expression in *Salmonella*-challenged neonatal chicks followed by pathway analysis revealed that expression of genes associated with the nuclear factor kappa B (*NFκB*) complex and apoptosis were affected by *Salmonella* administration (Higgins et al., 2011). In each of these studies, other genes not previously associated with immune responses were identified that might play a role in immunological responses to pathogens. In an analysis of miRNA expression within the spleen and the bursa of Fabricius of embryonic chicks, divergent expression of numerous miRNAs was noted, suggesting that these miRNAs might play diverse roles in the functions of the various tissues of the immune system (Hicks et al., 2009).

3.7 Muscle, liver, adipose, and gastrointestinal tissues

Multiple tissues are involved in nutrient absorption, metabolism, and partitioning into tissues for animal growth or energy storage. Among these are the intestine, liver, skeletal muscle, and adipose. However, all of the genes expressed in these tissues to regulate growth and nutrient partitioning are not known. In a comparison of skeletal muscle from slow-growing layer and fast-growing broiler chickens, transcriptional profiling using microarrays revealed differences in expression of genes encoding for muscle fiber proteins and regulators of satellite cell proliferation and differentiation (Zheng et al., 2009). Genes associated with slow muscle fibers were expressed at a greater level in breast muscle of layer than broiler chickens, while mRNA levels for genes associated with satellite cell growth were greater in muscle of broiler than layer chickens. In a similar analysis of gene expression in muscle types, microarray analysis was used to identify differentially expressed genes between the anterior latissimus dorsi (ALD) and posterior latissimus dorsi (PLD) muscles of turkeys (Nierobisz et al., 2011). Expression of genes encoding for extracellular matrix proteins was greater in the slow twitch, red ALD muscle than in the fast twitch, white PLD. In contrast, expression of genes involved in glycolysis was greater in the PLD than ALD. In a comparison of a random-bred turkey line with a line selected for increased body weight, microarray analysis of mRNA levels in breast muscle revealed alterations in expression of genes associated with extracellular matrix, apoptosis, Ca^{2+} signaling, and muscle function. Transcriptomics has been used to identify genes associated with meat quality of chicken breast muscle. Genes associated with lipid and carbohydrate metabolism were associated with meat quality (Sibut et al., 2011). In a similar study aimed at identifying genes involved in deposition of intramuscular fat in chickens,

transcriptional profiling of breast muscle from broiler chickens and a slow-growing Chinese breed using DNA microarrays revealed differential expression of genes involved in lipid metabolism and muscle development (Cui et al., 2012). DNA microarrays for chicken were also used to study pectoralis gene expression in juvenile and sea acclimated king penguins (Teulier et al., 2012). Genes associated with lipid metabolism were up-regulated, while genes associated with carbohydrate metabolism were down-regulated in older, sea acclimated penguins.

High environmental temperatures impair growth performance in chickens, but the molecular mechanisms involved have not been elucidated. Microarray analysis of gene expression in breast muscle of chickens exposed to chronic heat stress revealed changes in expression of genes involved in protein turnover, tumor necrosis factor signaling, and mitogen-activated protein kinase (*MAPK*) signaling (Li et al., 2011). Effects of acute and chronic heat stress on gene expression in the liver of broiler chickens were compared using RNAseq (Lan et al., 2016). The transcriptomic results indicated that acute heat stress had a greater impact on the broiler liver than chronic heat stress. Moreover, pathway analysis resulted in a novel network that combined the heat shock protein genes with immune response genes. In another study examining effects of heat stress on liver function in broiler chickens, transcriptomic and metabolomic analyses were combined (Jastrebski et al., 2017). Both analyses indicated that glycogenolysis and gluconeogenesis were elevated in the liver in response to heat stress. RNAseq was used to compare effects of acute and chronic heat stress on cardiac and skeletal muscle in two indigenous chicken ecotypes, from the lowland and highland regions of Kenya (Srikanth et al., 2019). The p53 and PPAR signaling pathways were enriched in both lowland and highland chickens, while MAPK signaling and protein processing in the endoplasmic reticulum were enriched only in the more heat-sensitive highland chickens. These results indicate that the ecotypes activated or suppressed different genes, demonstrating different underlying mechanisms in heat stress responses between the two ecotypes.

Domestic turkeys and broiler chickens have been bred for increased feed conversion and muscle growth. In studies aimed at identifying mechanisms responsible for differences in feed efficiency in broiler chickens, transcriptional profiling of breast muscle mRNA levels using microarrays indicated that an up-regulation of genes involved in anabolic processes and energy sensing and a down-regulation of genes involved in muscle fiber development and function are associated with high-feed efficiency (Bottje et al., 2012; Kong et al., 2011). Excessive deposition of body fat in commercial poultry leads to decreased conversion of feed into muscle for meat. However, the genetic mechanisms involved in accumulation of body fat in poultry are not known. Transcriptional profiling of adipose tissue from chicken lines divergently selected for low or high-body fat revealed that genes involved in lipid metabolism and endocrine function were differentially expressed between the genetic lines (Wang et al., 2007a). Genes identified included lipoprotein lipase (*LPL*), fatty acid binding protein, thyroid hormone-responsive protein (*Spot14*), and leptin receptor. In a more comprehensive study of a different pair of chicken lines genetically selected for low or high-abdominal fat, microarray analysis of adipose tissue was used to identify genes and gene networks involved in the observed differences in adiposity (Resnyk et al., 2013). Many genes involved in adipogenesis and lipogenesis were up-regulated in the fat line. Again, many genes involved in endocrine signaling were also differentially expressed between the two genetic lines, including *TTR*, *DIO1*, *DIO3*, *Spot14*, and chemerin. These findings suggest that differences in adiposity among individual birds might be related to differences in endocrine regulation of adipocyte differentiation and growth and lipid metabolism.

Lipogenesis in birds occurs primarily in the liver, and this process is regulated by the energy needs of the animal. Transcriptional profiling of newly hatched chicks that were fed or fasted revealed that the metabolic perturbation of fasting delayed the up-regulation of lipogenic genes in the liver (Richards et al., 2010). Expression of one gene that encodes for a transcription factor that regulates expression of the lipogenic genes, peroxisome proliferator-activated receptor gamma was also delayed, supporting coordinated regulation of lipogenesis. A similar analysis of transcriptional responses of the liver to fasting of older chickens has also been reported (Désert et al., 2008). In this study, fasting resulted in up-regulation of genes involved in ketogenesis, gluconeogenesis, and fatty acid beta-oxidation, while genes involved in fatty acid synthesis were down-regulated. These findings demonstrated the coordinated regulation of genes involved in nutrient partitioning by the liver in response to the metabolic perturbance of fasting.

Development of the intestine has also been studied using transcriptomics. Transcriptional profiles of the duodenum during embryonic development of the turkey were characterized using microarrays (de Oliveira et al., 2009). Results indicated that expression of peptidase and lipase genes (*LPL*) decreased toward hatch, while expression of genes encoding for peptide and glucose transporters (e.g., *PEPT1* and *SLC5AP*) increased toward hatch. Transcriptional profiles of the chicken jejunum were characterized during the first three weeks after hatch (Schokker et al., 2009). Microarray analysis indicated that genes involved in morphological and functional development were highly expressed immediately after hatch, while expression declined during later juvenile development.

3.8 Cardiovascular system

Chicken embryos are a widely used model for studies of cardiac development. As such, much is known about development of the heart in chickens. However, the complex relationships among genes necessary for cardiac development are not known. Gene expression profiling of early embryonic heart tissues was used to identify genes associated with cardiac development (Buermans et al., 2010). Results from this analysis included components of Wnt signaling. In another microarray analysis of heart development, differences in gene expression between the left and right ventricle were defined (Krejčí et al., 2012). Not surprisingly, the set of differentially expressed genes included genes associated with cardiac cell differentiation, heart development, and morphogenesis. However, many other genes not associated with these processes were also identified, providing a novel list of candidate genes for future research on the mechanisms underlying cardiac development. The cardiovascular system acclimates to life at higher altitudes and the associated hypoxia. However, the genes involved in cardiac acclimation in birds are not known. Microarray analysis of gene expression in the heart of the Tibetan chicken and chickens not adapted to life at high altitudes has been performed (Li and Zhao, 2009). Results provided a list of candidate genes that might function in chronic acclimation to high altitudes. Although not part of the cardiovascular system, microarray analysis of pectoral muscle was performed on rufous-collared sparrows sampled at 2000 and 4000 m above sea level in the Andes Mountains (Cheviron et al., 2008). Differentially expressed genes included those involved in oxidative phosphorylation and oxidative stress. Interestingly, none of the genes identified remained differentially expressed when high altitude and low-altitude birds were allowed to acclimate to life at sea level, supporting functional involvement of the candidate genes identified in acclimation of the birds to high altitudes.

3.9 Hurdles and future developments

One hurdle facing comparative physiologists in performing transcriptomics on nonmodel species is a lack of genomics resources. These include an assembled and well-annotated genome sequence. However, the number of avian genomes sequenced continues to grow, making functional genomics possible for investigators interested in nonmodel and wild species. Furthermore, the advent of RNAseq makes it possible to perform transcriptional profiling in species for which no DNA microarrays exist. With declining costs of RNAseq, this transcriptomics approach is now the preferred analysis for most studies of gene expression in physiological systems. A number of investigators have used RNAseq for characterization of mRNA and miRNA levels in the chicken (Goher et al., 2013; Hicks et al., 2010; Kang et al., 2013; Nie et al., 2012; Wang et al., 2011). Importantly, RNAseq has been used in nonmodel species to sequence and annotate the transcriptome in the dark-eyed junco (Peterson et al., 2012) and song sparrow (Srivastava et al., 2012), identify genes involved plumage coloring in ducks (Li et al., 2012a), study gene dosage compensation in the European crow (Wolf and Bryk, 2011), compare gene expression between the black carrion crow and the gray coated crow (Wolf et al., 2010), and identify genes differentially expressed between the ovaries of laying and broody geese (Xu et al., 2013). These studies using RNAseq were among the first transcriptomics studies in nonmodel avian species, and they demonstrate the utility of RNAseq for transcriptional profiling in physiological systems of any avian species. However, one major hurdle remains for comparative physiologists. Relatively few of the thousands of animal genomes now sequenced are well annotated. Prediction and annotation of genes in most genomes is based on sequence homology. With more than 10,000 avian species characterized, the possibilities for incorrect annotation of differentially expressed genes and, therefore, interpretation of transcriptional profiling results, are potentially equally as large as the number of species. Similarly, most commonly used pathway tools are based on the functions of genes determined from studies in mice and humans. Investigators and readers should use caution when interpreting transcriptomic results in avian species that have not been confirmed experimentally.

4.1 Introduction

Whereas genomics provides and analyzes the entire set of functional elements encoded in a genome, and transcriptomics studies gene expression by measuring RNA levels, proteomics analyzes protein expression, modification, structure, localization, interaction, and function. Having a completed genome sequence of an organism is a

Sturkie's Avian Physiology. https://doi.org/10.1016/B978-0-12-819770-7.00001-3

key step toward understanding how that organism is built and maintained, and thus its complex biology. This information is stored in the genome in the form of genes, which are transcribed into RNA, and RNA is translated into proteins. The entire set of RNA transcripts and proteins encoded by the genome is called transcriptome and proteome, respectively (Velculescu et al., 1997; Wilkins et al., 1996). Although genes provide instructions, proteins are the functional units of almost all biological processes and the principal structural building blocks of all living organisms. Systems-level understanding of cell physiology is thus inevitably based on understanding the multifaceted interplay of gene expression and protein functional networks. An individual's genome sequence (with the exception of some regions dedicated to the adaptive immune system) is static, its epigenome (the methylation patterns on DNA) less so, and the transcriptome and proteome are extremely dynamic. These latter two differ from cell to cell, and change dramatically according to conditions that cells are exposed to. The transcriptome is more complicated than the genome because of both frame-shifting and alternative splicing. The proteome is even more complex because most proteins are co- and posttranslationally modified (Walsh, 2006). More than 200 different types of protein modifications are documented in vertebrates, and more than one of these modifications routinely occurs on most proteins (Walsh, 2006). Measurement of the proteome is also more challenging than that of the transcriptome because the dynamic range of proteins in tissues is higher than of transcripts, and can span over 11 orders of magnitude in body fluids (Anderson and Anderson, 2002), and most importantly, from a technical perspective, there is no equivalent of the polymerase chain reaction (PCR) for proteins—we must use very expensive machinery to directly identify proteins. Although mRNA quantities measured by quantitative (q)PCR, microarrays, or sequencing are often used as surrogates for protein quantities, and indirectly, protein activity, there is no or little correlation between mRNA and levels of its corresponding protein (Gygi et al., 1999a; Cullen et al., 2004; Nagaraj et al., 2011; Marguerat et al., 2012). This means that the presence or quantities of proteins in biological samples cannot be satisfactorily estimated solely through their mRNA levels. In addition, posttranslational modifications often profoundly affect protein activities. Though arguably less sensitive, proteomics methods are more specific for determining what is happening at the protein level—they can identify and quantify protein amounts and posttranslational modifications as well as be combined with other omics data to produce a complete biological picture of the organism or physiological state in question. Proteomics thus provides a direct measure of the predominant functional units responsible for cellular behavior. Although not absolutely essential, a sequenced and structurally annotated genome greatly facilitates proteomics. The more accurate the genome assembly and annotation, the more accurate the proteomics methodologies can be; this extends to the individual—the most accurate proteomics experiments will be done using the individual's own genome sequence and, to be more accurate still, the transcriptome that corresponds to the proteome. Conversely, proteomics can be used to improve the structural annotation of genomes (Nanduri et al., 2010; Jaffe et al., 2004). Red jungle fowl (*Gallus gallus*), the major wild ancestor of the domestic chicken, was the first avian and nonmammalian amniote to have its genome sequenced (International Chicken Genome Sequencing Consortium, 2004). The chicken is the principal nonmammalian vertebrate animal model for studying development, infectious disease, immunology, oncogenesis, and behavior. It is also one of the most important agricultural species for production of meat and eggs. Until additional avian complete genomes became available, the chicken genome served as de facto model bird genome, and most of the proteomics studies have utilized this model to study various aspects of bird biology. Complete or draft genomes of several other avian species have become available, including several lines of domestic chicken (*Gallus gallus domesticus*), zebra finch (*Taeniopygia guttata*), domestic turkey (*Meleagris gallopavo*), collared flycatcher (*Ficedula albicollis*), pied flycatcher (*Ficedula hypoleuca*), large ground finch (*Geospiza magnirostris*), scarlet macaw (*Ara macao*), mallard duck (*Anas platyrhynchos*), ground tit (*Pseudopodoces humilis*), Puerto Rican parrot (*Amazona vittata*), and budgerigar (*Melopsittacus undulatus*) (Ellegren et al., 2012; Warren et al., 2010; Oleksyk et al., 2012; Dalloul et al., 2010; Rands et al., 2013; Rubin et al., 2010; Huang et al., 2013; Cai et al., 2013; http://aviangenomes.org/, 2013). The turkey, duck, and domestic chicken were sequenced because they are economically important (Dalloul et al., 2010; Rubin et al., 2010; Rao et al., 2012). These species are also used as biomedical models, which is the reason that the zebra finch, scarlet macaw, and Puerto Rican amazon were sequenced—they are important in neuroscience for studying their behavioral, cognitive, and speech abilities (Warren et al., 2010; Oleksyk et al., 2012; Seabury et al., 2013). Darwin's finches are model organisms to study of various aspects of evolution and development (Rands et al., 2013). Flycatchers are important models for speciation (Ellegren et al., 2012), and the genome of the ground tit provides new opportunities to study adaptation mechanisms to extreme conditions (Cai et al., 2013). Collectively, the availability of these additional genomes is opening up new vistas for genome-wide research and studies of various aspects of bird biology both on the RNA and protein levels. It is expected that

large-scale analysis of the avian genome, transcriptome, and proteome will increase our understanding of complex molecular processes that determine phenotype.

4.2 Protein identification and analysis

Although traditional protein biochemistry focuses on studying properties of individual proteins, proteomics encompasses nearly any type of technology that enables studying proteins on a large scale. There have been numerous tools developed for identification of proteins, including two-hybrid systems (Fields and Song, 1989), protein/peptide microarrays (Haab, 2003; Panse et al., 2004), nuclear magnetic resonance (NMR) spectrometry, and mass spectrometry (MS)-based approaches (Fenn et al., 1989). The two-hybrid systems and peptide/peptide microarrays had limited applicability which although was alleviated through analytical capabilities of MS, resulted in more MS-based approaches taking over. MS, and occasionally NMR, are now being utilized in conjunction with bioinformatics for larger pathway annotations in high-throughput protein profiling and analysis (Aslam et al., 2017). NMR is less sensitive than MS; however, it benefits from more stable spectrometer, an absence of spectrum quenching, and its ability to use in a large range of experiments (Dona et al., 2016). The versatility of MS and modifications to its ionization method has made MS the most commonly used technique in large-scale proteomic and high-throughput analysis. In addition to its versatility, MS has also the ability to handle the difficulties associated with the complex and dynamic nature of proteomes (Han et al., 2008). MS simplifies and accelerates the analysis and characterization of proteins. MS-based proteomics refers to approaches that use MS for identifying, characterizing, and/or quantifying proteins in biological samples (Fig. 4.1). Mass spectrometers are used to detect, identify, and quantify small molecules based on their mass and charge (m/z) ratios with high precision, sensitivity, and speed. Many

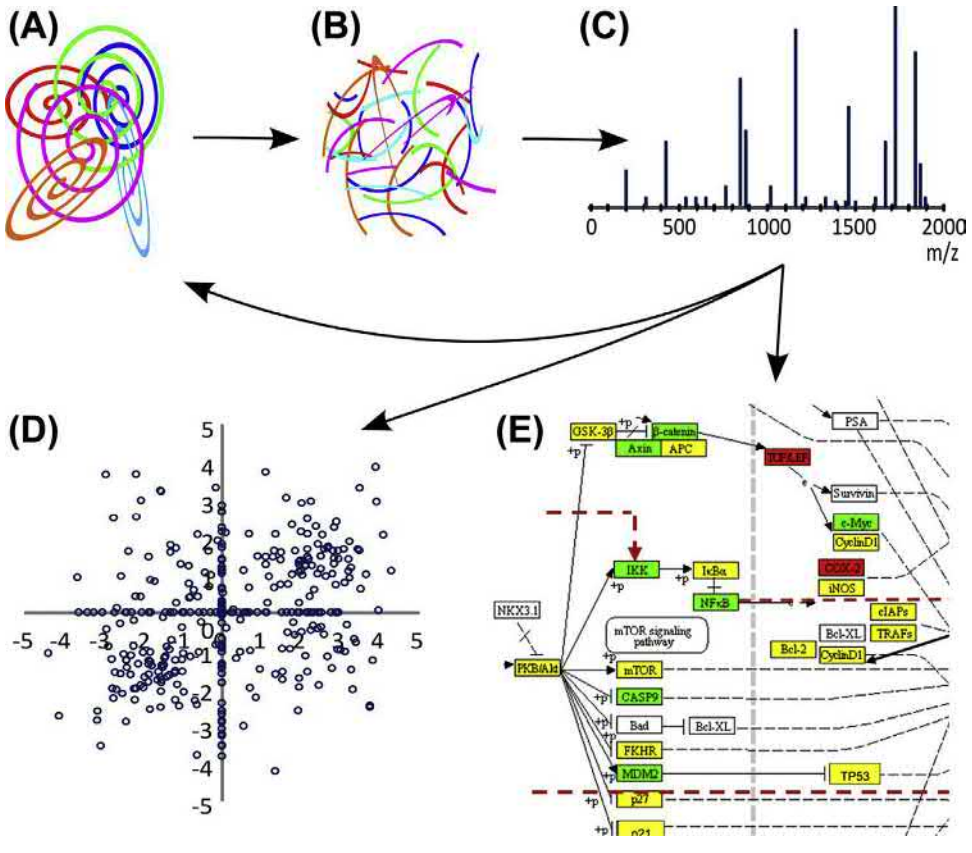

FIGURE 4.1 The workflow of mass spectrometry-based proteomics. The goal of proteomics is physical (protein identity, modifications, structure, localization) and functional (protein interactions, composition of protein complexes) characterization of the proteome. Proteomics denotes the collection of diverse technologies that enable the study of proteins on a large scale. In current proteomic research, mass spectrometry (MS) plays prime and indispensable role because several thousand proteins can be rapidly analyzed, correctly identified, and accurately quantified in a single MS-based experiment. Proteins (A) are typically too large for accurate mass determination by mass spectrometry, therefore, they are first digested into peptides (B), which are then analyzed by a mass spectrometer. The obtained peptide masses, peptide (tandem) mass spectra (C), are then searched against predicted peptide masses derived from DNA or protein sequence databases by using one or several different mass spectral search algorithms and their amino acid sequence is determined. The amino acid sequence of an identified peptide is often unique to its parental protein, and such peptides are used for unambiguous identification of proteins that were present in the analyzed sample. In addition to protein identification, MS enables accurate relative or absolute quantification of proteins. As a result, MS is commonly used to identify proteins that are qualitatively and/or quantitatively differentially expressed between studied conditions. The obtained proteomic information is integrated with existing knowledge and/or data from other large-scale studies (mRNA profiling, siRNA screens) to better understand cell or tissue biology at the system level. For example, protein expression levels are compared with mRNA levels (D), and differences in protein expression are analyzed in the context of biological pathways or interaction networks (E) in effort to identify the underlying causalities and mechanistic principles that give rise to a studied phenomenon or phenotype.

excellent reviews have been written that cover instrumentation and principles of protein identification by MS (Yates et al., 2009; Yates, 1998; Steen and Mann, 2004; Cottrell, 2011), and we will not replicate this information. Rather, we will introduce the key methods. A typical biological sample contains extremely complex proteomes. Because mass spectrometers can analyze only a limited number of different peptides at a time, the sample complexity must be reduced before MS. This has been historically done on the protein level by gel electrophoresis and more commonly done on the peptide level by various chromatography techniques.

4.2.1 Historical to current techniques

Two-dimensional (2D) polyacrylamide gel electrophoresis (PAGE) was the first technique that allowed truly complex proteomic analysis and was instrumental for the development of proteomics (O'Farrell, 1975; Rabilloud et al., 2010). 2D PAGE is the most widely used technique in gel-based proteomics; it simply deconvolutes a protein mixture in two dimensions. Proteins are first separated in the first dimension by their isoelectric point (pI), and then in the second dimension according to their electrophoretic mobility (which is a function of molecular weight and charge of a protein) in a polyacrylamide gel. Separated proteins are then stained and appear as spots in the gel. The amount of protein in a spot is determined by measuring the spot volume. This quantification is used as a screening process to select a limited number of corresponding spots that contain different amounts of protein on related gels. This technique is very useful for comparing two samples that have similar protein expression profiles in order to find proteins that differ between the samples in their expression levels or posttranslational modifications (Rabilloud et al., 2010). The major advantage of this method is that it is intrinsically quantitative. The major drawbacks are the limited capacity of protein separation; poor reproducibility of 2D gels; and low sensitivity, dynamic range, and throughput. Although efforts to overcome some of the shortcomings inherent to gel-based approaches resulted in the development of improved 2D gel methods, such as 2D fluorescence gel electrophoresis (Unlu et al., 1997), gel-free chromatographic approaches, which offer a number of advantages over gel-based methods, now completely dominate the field of proteomics. One of the most common approaches being multidimensional high-performance liquid chromatography (HPLC). Multidimensional HPLC quickly became the technique of choice for large-scale proteomic studies. Here, in contrast to gel-based approaches, the entire analyzed proteome is first digested, and the resulting peptides are then separated by multidimensional HPLC and further analyzed by MS. Digestion of a protein mixture generates a highly complex mixture of peptides, in which the connection between the peptide and the originating protein is lost. Peptides detected and identified by MS are then used to infer the presence of all original proteins in the sample, which is the principle of the "shotgun" proteomics named by an analogy to shotgun DNA sequencing. Multidimensional HPLC combines several separation steps to improve resolution of complex mixtures of peptides. One of the most popular multidimensional separation methods utilizes strong cation exchange and reversed-phase (RP) chromatography to separate peptides in two dimensions: first peptides are separated based on charge, and then on hydrophobicity (Washburn et al., 2001). This separation method is the basis of the shotgun proteomic strategy known as multidimensional protein identification technology (MudPIT) (Washburn et al., 2001). Another important chromatographic technique that is often used in gel-free approaches is affinity purification. Selective enrichment affinity materials are either used to enrich for peptides that contain certain posttranslational modifications, such as phosphorylation (Ficarro et al., 2002; Cao and Stults, 1999) or glycosylation (Geng et al., 2000; Durham and Regnier, 2006), or peptides that contain a specific selectable amino acid residue, such as cysteine (Wang and Regnier, 2001) or histidine (Wang et al., 2002). Affinity-enriched peptide mixtures are usually directly (online) or offline transferred to RP HPLC columns and further analyzed by MS. Gel-free approaches overcome many of the drawbacks that are inherent to gel-based methods (for example, proteins with extreme size, pI, or hydrophobicity are amenable for analysis); but more importantly, they allow a large number of proteins to be identified and quantified in a high-throughput manner and short time. The ability for high-throughput proteomics to detect low-abundance proteins was heavily investigated as it was a major drawback compared to gel-based approaches. Techniques on the front end of MS analysis that improve sensitivity include fractionation, affinity enrichment, and immune-depletion, depending on the sample (Shi et al., 2012). Improvements in statistical modeling of liquid chromatography tandem mass spectrometry (LC-MS/MS) in the MS-spectrum count label-free quantitative proteomic approach have also resulted in improved detection and attenuated bias toward low-abundance proteins (Lee et al., 2019). Recently, a combined approach of nanoparticles and MS, called Nanoproteomics, has shown to be an antibody-free, scalable and reproducible strategy to enable analysis of low-abundance proteins directly form samples such as serum (Tiambeng et al., 2020).

4.3 Quantitative proteomics

In addition to protein identification, mass spectrometry can quantify proteins in complex biological samples. The

proteome of a cell is highly dynamic and expressed proteins often change their locations, interactions, and modifications in response to different stimuli. The goal of quantitative proteomics is to obtain a snapshot of a proteome at a particular time. Accurate quantification of proteins is important for understanding of physiological or pathological phenomena, and for identification and modeling of functional networks. Traditionally, protein quantification has been based on the 2D PAGE approaches, but several gel-free methods allow accurate protein quantification solely by MS. Methods of quantitative proteomics are classified into two major categories: those that use stable isotopes and those that do not. The most popular stable isotope-labeling techniques either label peptides with isobaric tags for relative and absolute quantitation (iTRAQ) (Ross et al., 2004), or label proteins metabolically by incorporation of stable isotope labels with amino acids in cell culture (Ong et al., 2002) or enzymatically with isotope-coded affinity tags (Gygi et al., 1999b). Protein quantification by label-free approaches is based on the observation that the chromatographic peak area for any given peptide in an LC run (Bondarenko et al., 2002; Chelius and Bondarenko, 2002) and the number of tandem MS spectra of a given peptide (Liu et al., 2004) are proportional to peptide concentration in the analyzed sample. Thus, relative quantification by label-free approaches can be done by measuring and comparing the intensities of precursor ions, or by counting and comparing the number of tandem MS spectra derived from a particular protein in different experiments.

4.4 Structural proteomics

A protein's function is determined by its structure. The major goals of structural proteomics are to elucidate the three-dimensional (3D) protein structures and to determine the relationship between protein structure and function. Traditionally, static 3D protein structures are determined by X-ray crystallography (Sherwood et al., 2011) or NMR spectroscopy (Wuthrich, 1990). However, experimental determination of protein structure by these methods remains a difficult and laborious task in vitro but can be improved upon by utilizing current software for predictive models (Sherwood et al., 2011; Hyung and Ruotolo, 2012; Nealon et al., 2017). Alternatively, protein structures can be predicted computationally by homology modeling or ab initio (Flock et al., 2012). However, and despite decades of intensive research, these approaches do not always produce reliable models (Flock et al., 2012). Hydrogen-deuterium exchange (Wales and Engen, 2006), covalent labeling (Chance, 2001), or chemical cross-linking (Young et al., 2000; Petrotchenko and Borchers, 2010) have been coupled with MS to emerge as viable methods to probe 3D protein structure. Protein foot-printing methods modify the surface of the protein that is exposed to the solvent by exchanging amide protons with heavier deuterium atoms (Wales and Engen, 2006) or by different covalent modifications (Stocks and Konermann, 2009). The labeling changes the molecular weight of a protein, and this enables MS to identify the modified sites. Protein foot-printing methods are used to investigate protein conformation in solution. Chemical cross-linking covalently couples parts of a protein(s) that are close in space under native conditions. Subsequent MS analysis identifies the location and identity of the cross-linked sites, which provides important clues about the structural topology of the protein or protein complexes (Young et al., 2000; Petrotchenko and Borchers, 2010). Determining interacting partner proteins has become of increasingly high interest and poses additional challenges and is especially time consuming in *in-vitro* models. Predictive protein interaction software enables predictive models that alleviate the difficulty of protein interaction prediction in vitro. A fusion of experimental and predictive models allows the use of sparse experimental data to produce more accurate protein interactions. Numerous bioinformatic software have been developed to aid in predictive modeling approaches to protein structure and protein interactions, and there are extensive reviews covering the differences and uses of the software (Pagadala et al., 2017; Nealon et al., 2017; Aslam et al., 2017). Spatial proteomics is a relatively new method of determining proteins in the vicinity of a bait without a high affinity between interactors as long as they are in a defined region. Current techniques include an engineered version of ascorbic acid peroxidase (APEX) fused to proteins or involved in epitope tagging of Cas9. APEX fusion results in a hydroxyl radical when hydrogen peroxide and phenoxy biotin are added, labeling protein. In conjunction with Cas9, proteins surrounding a gene found using the Cas9 guide RNA can be labeled. Another strategy is BioID which uses biotin ligase enzyme BirA for similar data (Yates, 2019; Kim and Roux, 2016; Myers et al., 2018).

4.5 Application of proteomics in avian research

Until recently, red junglefowl, the ancestor of domestic chickens, was the only avian species with a sequenced genome (2004) (International Chicken Genome Sequencing Consortium, 2004). Because proteomics greatly depends on a complete and well-annotated genome sequence, most of the proteomics studies in birds have been done on this animal model. Since then, the complete genomes of zebra finch (2010) (Warren et al., 2010), turkey (2011) (Dalloul et al., 2010), and two flycatchers (2012) (Ellegren et al., 2012) have been sequenced and assembled and many more are underway (Oleksyk et al., 2012; Rands et al., 2013;

Rubin et al., 2010; Huang et al., 2013; Cai et al., 2013; Seabury et al., 2013). The increasing number of sequenced avian genomes expands the range of unique bird phenomena that can be studied on a global protein level, but more importantly, makes it possible to study avian proteomes directly through their genomes, obviating the need for cross-species peptide matching. A number of proteomic studies have been done to study various aspects of bird biology including egg production, embryogenesis, development, metabolism, behavior, cognition, immunity, cancer, disease, and infection.

4.5.1 Proteomics of egg physiology, embryonic development, and reproduction

A number of studies have focused on initial description and functional characterization of proteomes of different avian tissues, anatomical structures, or entire organs. The avian egg is a reproductive cell and a highly elaborate biological structure that protects and nourishes the developing embryo. The major components of the egg—the crystalline shell (Mann et al., 2006, 2007; Ahmed et al., 2017), albumen (egg white) (Mann and Mann, 2011; D'Ambrosio et al., 2008; Mann, 2007; Sun et al., 2017), yolk (Farinazzo et al., 2009; Mann and Mann, 2008; Liu et al., 2018), and the vitelline membrane (Mann, 2008)—have been extensively characterized by various proteomic approaches. Recent work combining transcriptome, QTL, and proteome data determined differentially expressed and significant genes and proteins from six different bird species (chicken, duck, goose, turkey, pigeon, and quail) in egg formation. Eleven common differentially expressed proteins were found in the egg white proteomes of all six species, but numerous genes and proteins were found to be uncommon in either the egg proteome of oviducts of the species (Zhang et al., 2020a,b,c). This type of large-scale, multifaceted research reveals key differences in proteomes across species while also highlighting the conservation of certain proteomes in egg formation. A key difference in Guinea Fowl compared to chicken eggs is the hardness of shell. A quantitative proteomic study using nano-LC-MS/MS identified 149 proteins, nine unique to Guinea Fowl, in the eggshell organic matrix at key stages of bio-mineralization. 61 of the proteins were found in the zone of microstructure shift, 17 were abundant in all zones, and some were involved in the control of calcite precipitation (Le Roy et al., 2019). This study provides potential biomarkers for selection of layers producing eggs with improved shell mechanical properties and therefore enhance food safety and potential decrease in vertical transmission of bacteria. Proteins involved in eggshell brownness were investigated via iTRAQ analysis with proteomics of the shell gland epithelium of hens laying dark and light brown eggs. About 147 differentially expressed proteins with 65 upregulated in light and 82 upregulated in dark egg layers. Functional analysis indicated that light brown egg layers produced less protoporphyrin IX for brownness, potentially via down-regulated Iba57 and up-regulated SLC25A5 with down-regulated TSPO (Li et al., 2016).

The chicken embryo is one of the most useful and investigated comparative and biomedical models for studying development, physiology, and pathogenesis. Proteomics has been used to characterize the proteome of a chicken embryonic cerebrospinal fluid (CSF) (Parada et al., 2006). This study identified, among others, 14 proteins that are also present in human CSF, and 12 of them are altered in neurodegenerative diseases and/or neurological disorders. Bon and co-workers identified and quantified selected proteomes of three different heart tissues and studied them at three different developmental stages (Bon et al., 2010). By comparing the identified proteomes, it was possible to study the changes in proteome expression and to identify proteins that were specific for particular heart structures or developmental stages. Grey et al. (2010) used an alternative approach, based on MALDI tissue imaging MS, to study spatial distribution of proteins in chicken heart structures such as vessels, valves, endocardium, myocardium, and septa. To better understand embryonic chicken bone formation, Balcerzak et al. applied proteomics to identify protein machinery of matrix vesicles, which is essential for the formation of hydroxyapatite (Balcerzak et al., 2008). Functional analysis of the matrix vesicle constituents suggested what roles these proteins might have in the mineralization process. The embryonic development of skeletal muscle has also been investigated in chicken using iTRAQ analysis and protein interaction network analyses (Ouyang et al., 2017). There were 19 up-regulated and 32 down-regulated proteins in embryonic age 11 versus 16, 238 up-regulated and 227 down-regulated proteins in embryonic age 11 and day 1 of age. The differentially expressed proteins were involved in pathways of protein synthesis, muscle contraction, and oxidative phosphorylation. By combining transcriptome data, results found 189 differentially expressed proteins correlating to mRNA levels and these proteins also were involved in muscle contraction and oxidative phosphorylation. A recent study on haptic proteins in embryonic and newly hatched chicks revealed 41% of the 3409 differentially expressed proteins were involved in metabolic processes and significant differences in haptic proteins from embryonic development to hatching (Peng et al., 2018). Most importantly, key factors controlling fat deposition during chicken embryonic development were elucidated to be ACAA2, CPT1A, and ACOX1. This study also revealed an alternative model using chicken for human obesity and insulin resistance. To better understand how birds are prepared for transition from a fat-rich diet *in ovo* to saccharide- and protein-based diet after hatch, Gilbert et al. (2010) analyzed the proteome of chicken small

intestine at hatch and during the early posthatch period in two different broiler lines (Gilbert et al., 2010). This study identified differences in expression of digestion and absorption-related proteins between different genetic lines.

A proteomic approach was also used to identify hypothalamic biomarkers associated with high-egg production in chickens (Kuo et al., 2005). Comparison of the hypothalamic proteomes from two related chicken lines selected for meat and high-egg production resulted in identification of six proteins that differed in their expression between the lines, and some of these proteins are involved in regulation of gene expression, signal transduction, and lipid metabolism. The heterogeneous nuclear ribonucleoprotein H3 was suggested as novel biomarker for high-egg production. A contributing factor in egg production is follicle selection. A study comparing transcriptome and proteome of small yellow follicles and hierarchical follicles in laying hens identified nine proteins and seven genes with VLDLR gene and protein being higher in hierarchical follicles as well as being stimulated by FSH in granulosa cells (Chen et al., 2020b). This study has implications for both laying hens and broilers as broiler breeders often undergo multiple follicle selection (Hocking and Robertson, 2000). 2D PAGE MS was used to compare expression profiles of proteins in the oviduct in chicken hens of different ages during the egg-laying period (Kim et al., 2007). The analysis revealed that anterior gradient homolog 2 (AGR2) protein was among the most differentially expressed proteins. Analysis of the mRNA showed that expression of AGR-2 was limited to the magnum and isthmus of the oviduct, and that this expression was approximately 900-fold higher in the mature oviduct in comparison to the premature one. Because AGR-2 is a secreted protein that shows estrogen dependent expression, and egg laying is strongly affected by estrogen, it was suggested that AGR-2 might be important for the development of the epithelial cells in the oviduct during the egg-laying period in chickens. 2D PAGE and MudPIT have been used to discover genetic and molecular mechanisms that compromise sperm mobility in chickens (Froman et al., 2011). Analysis of the sperm proteome from chicken lines of low or high-sperm mobility allowed deduction of a proteome-based model that explained well the differences in sperm mobility between lines, and confirmed the initial hypothesis that defects in ATP metabolism and glycolysis are responsible for premature mitochondrial failure, which results in sperm immobility. MALDI and top-down MS of chicken spermatozoa and seminal plasma along with comparative analysis using spectral count and XIC revealed unique profiles of most fertile males compared to least fertile male chickens (Labas et al., 2015). Over-represented enzymes in the most fertile males were involved in energy metabolism and respiratory chain activity and least fertile males differed in proteins including acrosin, ACE, AvBD10, and AvBD9. Selection for higher fertility was shown to impact proteomic profile of seminal fluid in white leghorn males compared to the red junglefowl ancestor (Atikuzzaman et al., 2017). 2DE and immunoassays were conducted on the seminal fluid of pooled males from each breed with statistics to cover intra- and intergroup variability. The results showed conserved proteins being serum albumin and ovotransferrin, but clear enrichment of proteins related to immune response regulation for sperm survival in female reproductive tract including less proinflammatory cytokines and an abundance of immunomodulatory/anti-inflammatory peptides. Taken together, these studies demonstrate the diverse application of proteomics in elucidating key pathways and proteins involved in avian reproduction and development.

4.5.2 Proteomics of behavior and plumage

The zebra finch is the dominant animal model for studying molecular mechanisms underlying learning, memory, vocalization, and social behavior. A natural perceptual experience, such as a sound of another bird singing, triggers rapid changes in expression of specific genes in the auditory region of the zebra finch brain (Mello et al., 1992). Repeated exposure to the same song leads to stimulus-specific habituation of the original response (Petrinovich and Patterson, 1979). To understand the process of habituation better, Dong et al. (2009) used DNA microarrays and 2D PAGE MS approaches to analyze global changes of gene expression at different stages in the development of habituation. This study showed that exposure to a song induces massive changes in gene expression, and that song response habituation is not a simple loss of the original responses but rather a change of neuronal responses underpinned by a novel and different gene expression profile. Analysis of protein expression showed that habituation is accompanied by a decrease in expression of cellular and mitochondrial proteins that are involved in biosynthesis and energy metabolism. Neuropeptides are signaling peptides found in neural tissue that modulate a wide range of physiological and behavioral processes including metabolism, reproduction, learning, and memory. Xie et al. (2010) used a combination of bioinformatics, MS, and biochemistry for prediction, identification, and localization of neuropeptidome of the zebra finch. Computational analysis of the zebra finch genome predicted 70 putative prohormones and 90 peptides derived from 24 putative pheromones identified in the zebra finch brain by two different MS approaches. The power of MS was further used for localization of a subset of peptides in the major song control nuclei of the zebra finch brain. Furthermore, gene expression of a subset of pheromone genes was anatomically mapped in selected zebra finch brain sections by in situ hybridization.

Birds display an enormous range of plumage colors, and this diversity rivals or exceeds that of plants (Stoddard and Prum, 2011). Still, bird plumage occupies only about 30% of the possible colors that birds can see (Stoddard and Prum, 2011). The molecular mechanisms that determine and drive the development of this diversity are largely unknown. The breeding plumage of male pied flycatchers varies from a brown to dark black. Leskinen et al. (2012) characterized and quantified the proteome of developing pied flycatcher feathers to advance understanding of physiological processes that underlay the variation in pigmentation. In total, 294 proteins were identified in the developing feathers. About 65 proteins were linked with epidermal development and/or pigmentation in the developing feathers, and 23 proteins were associated with pigment-containing organelles—melanosomes. The comparison of the brown- and black-specific proteomes revealed several proteins and functional networks that differed in expression between the two phenotypes and that are candidates for further studies. The most pronounced differences were detected in immunological signaling, oxidative stress, energy balance, and protein synthesis networks, and these differences might be responsible for differential feather growth and color pigmentation. A recent study tried to determine the molecular mechanism behind Columbian plumage feathers in the H line of the "Yufen I" commercial egg-layer (Wang et al., 2019). Both transcriptome and proteome were utilized in the analysis with 209 genes and 382 proteins differentially expressed in two locations. The melanogenesis pathway and melanin synthesis were involved via nine proteins that were differentially expressed. Melanogenesis, cardiomyocyte adrenergic, calcium, and cGMP-PKG were all activated pathways in Columbian plumage.

4.5.3 Proteomics of performance and physiology

Food products derived from farm animals, birds, and fish represent a significant part of the human diet. Understanding the nutrient metabolism, muscle accretion, and fat deposition in food birds provides practical knowledge that can be used to improve feed conversion efficiency, food quality, and the health and welfare of animals. Animal feed represents the major cost of poultry production. A balanced poultry diet is reflected in optimal growth and production at minimal nutrient expense. Because of the composition of poultry diet, where corn and soybeans are used as major sources of energy and proteins, respectively, some amino acids become more limited than others. Corzo et al. (2005) utilized the power of MS to understand amino acid requirements in chickens. Blood plasma proteome from chickens fed an adequate or lysine-deficient diet was analyzed to identify potential biomarkers of dietary lysine deficiency. The analysis revealed that lysine deficiency might not result in a simple overall reduction of protein synthesis in chickens fed with a lysine-deficient diet, but rather in reduced anabolism of specific proteins. Corzo et al. (2006) and Zhai et al. (2012) also evaluated the effect of dietary methionine on breast muscle accretion in broiler chickens (Corzo et al., 2006; Zhai et al., 2012). This study showed that four canonical pathways related to muscle development (citrate cycle, calcium signaling, actin cytoskeleton signaling, and clathrin-mediated endocytosis signaling) were differentially regulated between chickens that were fed with low- and high-methionine diets (Zhai et al., 2012). In addition, this study suggested that a methionine-rich diet preferably induced muscle accretion by sarcoplasmic over myofibrillar hypertrophy. A recent study concluded that changes in the diet composition can have large impacts on protein origins leaving the ileum by analyzing 160 Ross PM3 broilers fed either maize/soy-based diet as reference or the addition of 20% raw soy-meal to putatively cause changes in protein flow from the ileum (Cowieson et al., 2017). The raw soy-meal addition caused an increase in endogenous protein relative abundance and decrease in protein from soy and no effect on protein from maize. This study describes the ability of proteomics to be used to determine changes in digestion and secretion in chickens for a more in depth understanding of diet effects on the digestive tract. The blood plasma is an extremely complex tissue that contains thousands of distinct proteins. It is also the most common tissue used in diagnosis of disease and nutritional status. Several authors analyzed blood plasma protein composition to gain better understanding of protein dynamics during chicken development (Huang et al., 2006) or for discovery of plasma biomarkers that reflect nutritional conditions (Corzo et al., 2004, 2006). Muscle meat food products derived from birds, and in particular chickens, are important sources of essential nutrients and energy intake in the human diet. Proteomics has an obvious potential to study a broad range of aspects related to the meat production including nutrition, muscle formation, breed differentiation, meat quality, and meat contamination (Paredi et al., 2013; Schilling et al., 2017). Chicken strains selected for meat production show dramatic growth rates and accelerated accretion of the pectoralis (breast) major and minor muscles. The proteome of the chicken pectoralis muscle has been extensively profiled (Corzo et al., 2006; Zhai et al., 2012; Doherty et al., 2004; Teltathum and Mekchay, 2009), and another study identified over 5000 unique proteins in the pectoralis muscle of studied birds (Zhai et al., 2012). A complementary study identified the proteome of the pipping muscle, which is primarily used for breaking the egg's surface during hatching (Sokale et al., 2011). A recent study identified the potential role of mitochondria in the breast meat of feed efficient broilers through analysis of

152 differentially expressed proteins using IPA (Kong et al., 2016). A complementary study involving the proteogenomic analysis of breast meat in high-feed efficiency broiler males found those birds showed enrichment of ribosome assembly as well as proteasomes and autophagy processes for quality control and nuclear transport and protein translation compared to low-feed efficiency males (Bottje et al., 2017). This study is also a basis for phenotyping feed efficiency from a proteogenomic perspective and improving selection through a more well-defined phenotype. The identified proteins, 676 in all, were analyzed using the assigned Gene Ontology categories for molecular function, biological process, or cellular component. This analysis revealed which protein functions and cellular activities are important for rapid development of pipping muscle during embryogenesis.

McCarthy et al. (2006) analyzed the proteomes of the supporting stromal and B cells isolated from the chicken bursa of Fabricius, a unique bird organ and a common experimental system for B-cell development (McCarthy et al., 2006). Proteins were isolated from the two major functional cell types of bursa by a sequential detergent extraction procedure that increased proteome coverage and helped to localize known and previously unknown proteins to different cellular compartments. Functional modeling of the identified proteins provided insights about signaling pathways involved in programmed cell death, proliferation, and differentiation. In a similar study, van den Berg et al. (2007) applied whole organ proteomics to study frozen spleen. To gain a better understanding of B-cell development in the bursa of Fabricius, Korte et al. used a quantitative 2D PAGE approach to study bursal proteomes from the embryonic and posthatch developmental stages. They showed that enzymes of the retinoic acid metabolism play a crucial role in the early development of the primary avian B-cell organ (Korte et al., 2013). Similar observations were done in mammals, where vitamin A plays a similarly important role in the development of secondary lymphoid organs (van de Pavert et al., 2009). Proteomic analysis of the Harderian gland showed that Harderian gland is a site of active mucosal immunity also due to expression of hematopoietic prostaglandin D synthase (Scott et al., 2005), which is necessary for production of prostaglandin D2, the potent activator of inflammatory responses (Serhan et al., 2008). Several proteomic studies have used chicken embryos to study embryonic development of retina (Lam et al., 2006; Mizukami et al., 2008; Finnegan et al., 2008, 2010), face (Mangum et al., 2005), CSF (Parada et al., 2005, 2006), liver (Jianzhen et al., 2007), cardiovascular system (Bon et al., 2010), and vasculature (Soulet et al., 2013). Lam et al. (2006), Mizukami et al. (2008), and Finnegan et al. (2008) used 2D PAGE to catalog the most abundant proteins in young chicken retina and to identify those that were differentially expressed between different stages of retina development (Lam et al., 2006; Mizukami et al., 2008; Finnegan et al., 2008). These studies identified known and novel proteins that play roles in early ocular growth and neural development. The retinal dysplasia and degeneration (rdd) chick was used as a model to identify proteins that are differentially expressed during the onset of degeneration of retina (Finnegan et al., 2010). Mangum et al. (2005) studied the development of the first pharyngeal arch, an embryonic structure that is crucial for the formation of the face, as a model for the craniofacial defects in humans (Mangum et al., 2005). This study showed that expression of molecular chaperones, cytoskeletal proteins, and plasma proteins associated with vascularization was altered the most between the different stages of craniofacial development. Initial characterization of the zebra finch retina and optic tectum, a major structure of the midbrain, proteomes have been done using the one-dimensionl PAGE approach coupled with MS (Sloley et al., 2007a,b). Because these studies were done before the complete zebra finch genome was available, potential zebra finch proteins had to be identified by cross-species matching using the nonredundant NCBI, Ensemble, and Swissprot protein databases.

4.5.4 Proteomics of disease, myopathy, and infection

The recent explosion of animal and pathogen genomes has not only enabled identification of genes involved in the etiology and pathology of diseases (such as mutant gene variants or virulence factors) but also has opened up the door for proteomics to probe the pathogenesis and pathogen–host interactions on a global protein level. Proteomics has greatly improved understanding of diseases; it has been very valuable in diagnostic marker discovery, and it has a great potential in drug discovery. Despite its great value, disease proteomics remains to be one of the least-developed areas in avian research. Nevertheless, proteomics has been used to study the pathogenesis, etiology, and pathology of several avian (infectious) diseases. In addition, proteomics has been used to study various human diseases on chicken experimental models (Andrews Kingon et al., 2013).

4.5.4.1 Disease proteomics

The chicken is an ideal and unique animal model to probe the etiology and progression of spontaneous human epithelial ovarian cancer, largely because the domestic chicken has a high prevalence of spontaneous ovarian carcinomas. EOC remains the most lethal gynecologic malignancy in part because early detection and therapeutic strategies have been largely unsuccessful (Kurman and Shih, 2010). Hawkridge et al. (2010) used this model to study the onset and progression of EOC by a large-scale

biomarker discovery effort involving longitudinal sample collection and protein analysis by MS. Inter- and intra-individual measurement of proteins identified ovomacroglobulin (ovostatin) as a potential EOC biomarker because its levels in plasma were undetected in a healthy individual and significantly higher during later stages in an EOC bird. Pulmonary hypertension syndrome, or ascites syndrome, is a metabolic pathogenesis in meat-type chickens that is manifested by the formation of ascites. Ascites syndrome is one of the major problems in the chicken industry, and is caused by cardiopulmonary insufficiency during high-oxygen demands spurred by a rapid tissue growth (Currie, 1999). Proteomic analysis of the cardiac mitochondrial matrix proteomes of the ascites-resistant and ascites susceptible line broilers suggested that the mitochondria of susceptible chickens may respond inappropriately to hypoxia (Cisar et al., 2005). A complementary proteomic analysis of the hepatic proteomes of healthy birds and those with ascites suggested that insufficient energy generation in the liver is responsible for development of pulmonary hypertension syndrome (Wang et al., 2012).

4.5.4.2 Proteomics of muscle myopathy

Understanding the mechanism behind serious metabolic disorders is crucial for the development of treatment and preventative strategies. In the modern broiler, major metabolic disorders affecting producers and consumers are muscle myopathies in the form of wooden breast (WB), white striping (WS), and spaghetti meat (SM). In the case of WB, Cai et al. (2018) found eight differentially expressed proteins between normal and WB meat samples with differences indicating increased oxidative stress in addition to decreased glycolytic enzymes in WB muscle. When analyzing five different genetic strains of broilers, more abundant proteins in WB were involved in carbohydrate metabolism, oxidative stress, cytoskeleton structure, and signaling with regulated pathways involved in similar functions as well as cell death and survival and cellular organization (Zhang et al., 2020a,b,c). Postmortem proteomic analysis of WB affected tissue using 2D gel electrophoresis revealed changes in protein degradation, including desmin fragments, ovotransferrin chain A, and troponin I chain I degradation (Zhang et al., 2020a,b,c). Interestingly, some glycolytic proteins in WB showed evidence of posttranslational modification, including enolase, phosphoglucomutase-1, PGAM1, and pyruvate kinase. A study using a hybrid LTQ-OrbitrapXL LC-MS/MS compared proteomic profiles of normal breast and breast meat affected by WS or WB (Kuttappan et al., 2017). Using ingenuity pathway analysis (IPA) software, the 800 differentially expressed proteins were associated to biological pathways. IPA showed eIF-2 signaling, mTOR signaling, and regulation of eIF4 and $p70^{S6K}$ signaling were up-regulated in breast with severe myopathy compared to normal. The indication of increased protein synthesis pathways could be due to rapid growth and cellular stress due to degradation and attempted tissue repair. Down-regulated pathways included glycolysis and gluconeogenesis which coincided with higher pH. For WS, SDS-Page and further analysis of chemical composition of WS meat showed higher fat and lower protein content along with higher collagen and decreased protein quality (Petracci et al., 2014). SM meat was also analyzed in a similar study using SDS-PAGE and found that while the proteome profile varied little from SM to normal, the overall protein abundance was reduced as with other myopathies (Tasoniero et al., 2020).

4.5.4.3 Proteomics of infections

Some strains of the highly pathogenic avian influenza A subtype H5N1 cause severe acute encephalopathy and neurodegeneration in poultry and migratory birds. To reveal the mechanisms that cause the observed neuropathogenesis, Zou et al. (2010) used comparative proteomics to identify the proteins that were expressed differently in the brains of healthy and H5N1-infected chickens (Zou et al., 2010). Among the differentially expressed proteins were septin 5 and collapsin response mediator protein 2 (CRMP2). Septin 5 is dysregulated in Parkinson's disease and CRMP2 in Alzheimer's disease, Down syndrome, and human T-cell lymphotropic virus type I associated myelopathy (Vincent et al., 2005; Lubec et al., 1999; Son et al., 2005). This suggests that these proteins might also have a role in neurodegenerative pathologies associated with influenza H5N1 infection. Gallid herpesvirus 2 (GaHV-2) is an avian oncogenic herpesvirus that causes a highly infectious and rapidly progressive lymphomatous disease of chickens, Marek's disease (MD). GaHV-2 infects and transforms cells in all chicken genotypes, but some chickens are genetically resistant to gross lymphoma formation (Burgess and Davison, 2002). To better understand the molecular mechanisms of differential susceptibility to MD, spleen proteomes of MD susceptible and MD-resistant chickens were analyzed using the 2D PAGE MS approach (Thanthrige-Don et al., 2010). Among the differentially expressed proteins identified in this study were antioxidants; molecular chaperones; and proteins involved in the activation and migration of T lymphocytes, formation of cytoskeleton, protein degradation, and antigen presentation; and some of these were implicated as potential factors in MD resistance. In a similar study, analysis of the changes in the chicken spleen proteome induced by the GaHV-2 infections revealed that protein expression was the most altered during early stages of infection. Comparative analysis showed that proteins that were differentially

expressed at different timepoints postinfection were involved in a variety of cellular processes that are crucial for the host response to GaHV-2 infection and pathogenesis (Thanthrige-Don et al., 2009). To better understand how GaHV-2 infection changes the host protein expression, several proteomic profiling studies have been done to determine the proteome of GaHV-2-lytically infected chicken embryo cells (CECs) (Liu et al., 2006; Chien et al., 2011, 2012; Ramaroson et al., 2008) compare the phosphoproteomes of mock- and GaHV-2-infected CECs (Chien et al., 2011; Ramaroson et al., 2008); and quantify protein expression changes caused by GaHV-2 infection (Chien et al., 2012). Collectively, these studies revealed GaHV-2 infection dramatically changes the protein expression profile of infected cells. Overlaying quantitative and phosphorylation data revealed that GaHV-2 infection altered both protein expression and phosphorylation of proteins from several cellular pathways, and among the most affected processes were RNA transport, signal transduction, initiation of translation, and protein degradation. Perhaps the most interesting discovery of these studies is that GaHV-2 causes unique phosphorylation of the translation initiation factor 4E-binding protein 1, which is important for the assembly of the protein translation initiation complex after virus infection. In a complementary study, Buza and Burgess (2007) used MudPIT to profile the proteome of the GaHV-2-transformed lymphoblastoid cell line UA01. Functional modeling of the UA01 proteome showed that cells had a typical cancer phenotype. UA01 cells were activated, differentiated, and proliferative, but antagonistic to apoptosis, energy, quiescence, and senescence. Identified cytokines, cytokine receptors, and related proteins suggested that the UA01 proteome had a T-cell regulatory (T-reg) rather than T-helper (Th)-2 phenotype. MD, a CD4+ T cell lymphoma of chickens, and many human lymphomas overexpress the Hodgkin's disease antigen CD30 (CD30hi). MD lymphomas, like its human homologs, are formed by a minority of transformed (CD30hi) and a majority of nontransformed (CD30lo) cells (Burgess and Davison, 2002; Shack et al., 2008). Although the GaHV-2 gene meq is the principal oncogene, which acts as a transcription factor and transforms via the Jun pathway (Levy et al., 2005; Mescolini et al., 2019), the exact mechanism of neoplastic transformation and transition from CD30lo to CD30hi neoplastic phenotype is unknown. As described in this review, most of the proteomics work that has been done in aves has been descriptive, based on differential expression. Kumar et al. (2012), though, compared microRNA, mRNA, and protein levels and from this data imputed functional models. As described by many others in many different systems, there was poor overall correlation between mRNA and protein expression (Gygi et al., 1999a,b; Cullen et al., 2004). However, to identify the key regulatory proteins responsible for neoplastic transformation, all gene products which were differentially expressed in the same direction at both mRNA and protein levels (i.e., concordant) were selected for further analysis, and these did have an overall positive correlation. Those gene products with the greatest mRNA and protein correlation are known to be involved in human CD30-over expressing lymphomas. When ranked into pentiles based on protein expression levels, the Gene Ontology Biological Processes of cell cycle and proliferation to programmed cell death ratios were greatest in pentile 1. The authors then identified the numbers of putative canonical MDV Meq (the virus oncogene) binding sites in each of the 88 concordantly expressed genes' promoters; and genes in pentile 1 had the most Meq binding sites. Of the five concordant genes previously implicated in lymphomagenesis in other species most were in pentile 1 suggesting direct transcriptional regulation by Meq. In contrast, one gene product, CST3 was likely regulated by a micro-RNA. Recent proteomic MD research has revealed that MD viruses inhibit type I interferon in the thymus and bursa of Fabricius infected chickens and that strains of varying virulence affected type I IFNs differently (Sun et al., 2019). *Plasmodium gallinaceum* is a protozoal avian malaria parasite and the most relevant animal model of the human parasite *Plasmodium falciparum* sexual stages zygote and ookinete. The early stages of the *P. gallinaceum* life-cycle occur in its definitive host, the mosquito, but this process is largely unknown. To better understand the initial molecular mechanisms of *P. falciparum* vector interaction, Patra et al. (2008) used high-throughput proteomics to identify 966 orthologous proteins of *P. falciparum* present in the zygote and ookinete proteomes (Patra et al., 2008). About 40% of the identified proteins had hypothetical status, and the majority of these were transmembrane or secreted proteins. This suggests that these proteins might play important roles in parasite−host interactions. Coccidiosis of fowl, an intestinal disease caused by a protozoal parasite Eimeria, causes significant losses for the poultry industry. Plasma proteome profiles of two different chicken lines infected with one of three common Eimeria species were compared by the 2D PAGE MS (Gilbert et al., 2011). About 46 proteins displayed significantly changed expression in response to Eimeria infection. The differentially expressed proteins were found to participate in innate immunity, blood clotting, and iron and mitochondrial metabolism, and these processes fit well within the host acute-phase responses that are initiated when a tissue is invaded by a microorganism. Some of the identified proteins were suggested as candidate biomarkers for early diagnosis of Eimeria infection. A recent study investigating the interaction between *Eimeria maxima* and chicken jejunal epithelial cells utilized shotgun LC-MS/MS and Western blot analysis to reveal 35 annotated (Gene Ontology) peptides, 22 of which were associated with binding activity

and 15 with catalytic activity (Huang et al., 2018). This revealed novel findings of host-parasite interaction on a cellular level. Another protozoan parasite affecting poultry is *Histomonas meleagridis* which causes histomonosis or blackhead disease in poultry including turkeys. Proteomic study involving virulent and attenuated strain of *Histomonas* showed increased metabolism, in vitro adaptation and ameboid morphology pathways implicated in virulence based on MS analysis of 49 protein spots (Monoyios et al., 2018). Interestingly, MS also identified differential expression of *Escherichia coli* DH5α proteins indicating reciprocal interaction between two strains during monoxenic cultivation. *Salmonella enterica* subspecies enterica is a gram-negative enterobacterium and an important pathogen that infects a broad range of vertebrate species including chicken and man. The subspecies is routinely divided into more than 2500 serotypes (serovars) based on antigenic epitopes (Franklin et al., 2011). Salmonella serovars differ in host range and pathogenic potential, but molecular mechanisms underlying these differences are not well understood. Several proteomic studies compared proteomes of different avian Salmonella serovars and discovered possible molecular mechanisms responsible for the observed phenotypic differences (Encheva et al., 2005; Osman et al., 2009; Sun and Hahn, 2012).

4.5.5 Proteomics of avian welfare

Consumer concern for animal health and welfare has risen along with the popularity for chicken as a healthy protein source (Powers, 2020). The poultry industry now faces regulations as well as consumer preferences for birds raised in nonstressful and enriching environments. The ability for industry to measure and report factors that demonstrate good animal welfare has been limited with the definition of avian welfare itself left largely undefined. Proteomics has been utilized to determine novel biomarkers for and measurements of welfare in the modern broiler and other food animals with the major stress indicators being cortisol, creatine kinase, and lactate (Harkati et al., 2018; Sardi et al., 2020; Marco-Ramell et al., 2016; Bozzo et al., 2018). New research into improved techniques and specific markers for stressors such as heat stress, immobility, fasting, and ammonia exposure have been developed using the avian model and proteomics.

In the case of heat stress, understanding the mechanism behind physiological responses to heat stress in the high-metabolic, temperature-intolerant broiler is key, especially as global temperatures rise due to climate change. Proteomic work has resulted in the identification of novel molecular signatures for a bird's response to heat stress through measuring GRP75, a member of the heat-shock protein family (Dhamad et al., 2019). Another heat shock protein marker for heat stress was investigated, and most interestingly, was from a noninvasive source, the feather (Greene et al., 2019). HSP70 protein was detectable in the growing feather of heat-stressed Cobb500 broilers. This study is a direct example of proteomic technique providing noninvasive phenotypes and measures of welfare in the poultry industry. A study analyzing the proteomic response to heat stress in the avian hypothalamus revealed damage to the hypothalamus and provocation of pathways involved in attenuating protein destabilization and degradation and improving cytoskeleton integrity, oxygen transport, and neural development after acute heat stress (Tu et al., 2018). A study investigating response to heat stress during transportation found glycolysis pathway, calcium signaling, and molecular chaperones in the breast muscle of heat-stressed birds to be significantly different using iTRAQ proteomic analysis (Xing et al., 2017). Heat stress analysis on other tissues such as liver, spleen, and hypothalamus revealed differentially expressed proteins related to immune response, metabolism, and cellular processes including cell death (Tang et al., 2015; Ma et al., 2019; Tu et al., 2018). The ability for proteomic analysis to not only identify key signatures of responses but also annotate key proteins to a specified biological pathway makes advances in mechanistic understanding of animal welfare possible.

Although the modern broiler is extremely heat-intolerant, its high metabolism results in the fastest growth of almost any other food animal. This rapid growth is often associated with increased incidence of lameness and impaired mobility which is a major concern for animal welfare and health. Tonic immobility has been used to investigate the potential modulation of emotional reactivity on chronic stress-related behavior and physiological dysfunction in animals and corticosterone (CORT) delivered in drinking water is an established model for chronic stress in broilers. A study utilized these models conducted 2D gel electrophoresis and Western blot analysis of proteins in the breast muscle. Analysis showed CORT treatment, mimicking chronic stress, reduced growth of muscle by suppressing protein synthesis, and long tonic immobility had similar negative effects on muscle growth potentially via glucose metabolism (Fu et al., 2014). This along with similar studies demonstrates not only the physiological implications of immobility, but also the effect of chronic stress on health and performance (Hayward and Wingfield, 2004; Minvielle et al., 2002; Wang et al., 2013). A leading cause of lameness and immobility is bacterial chondronecrosis with osteomyelitis (BCO), also called femur head necrosis (FHN). Currently, identification of BCO requires necropsy of the femur head itself within the bird. However, proteomic research seeks to not only understand the mechanism behind this disorder but also identify a biomarker for earlier and easier phenotyping of BCO. To that end, a proteomic analysis used matrix-assisted laser desorption ionization time of flight mass spectrometry

(MALDI-TOF-MS) and liquid chromatography/electrospray ionization-tandem mass spectrometry (LC-MS/MS) to determine differential peptides in the plasma of FHN affected versus healthy broilers. Fibrinogen- and fetuin-derived peptides as well as alpha-1-acid glycoprotein, albumin, and SPINK7 were reduced in FHN affected birds with gallacin-9, apolipoprotein A1, and hemoglobin being elevated in the plasma of birds with FHN (Packialakshmi et al., 2016). The results of this study suggest tissue adhesion, proteolysis, and infection could be culpable for FHN. Although the study provides the basis for circulating biomarkers for FHN, more research is needed to determine the significance of these differential peptides and their efficacy as biomarkers. Tibial dyschondroplasia (TD) is another disorder which commonly causes lameness in fast-growing broilers. A proteomic analysis of high altitude Tibetan chickens, which have low incidence of TD, compared to low-altitude broilers revealed increased vascular distribution in the tibia accompanied by up-regulated hypoxia-inducible-factor-1 alpha as well as vascular endothelial growth factor A (VEGFA) and VEGF receptors. Hypoxia exposure of low-altitude broilers resulted in increased angiogenesis and upregulation of similar factors. This study describes the potential role in inhibition of angiogenesis in the pathology of TD and sets the ground work for potential target pathways in selection of broilers for resistance to TD.

A common practice in poultry production is fasting and has raised concerns by animal welfare advocates regarding detrimental effects on animal health not being considered. About 24 hour fasting has shown to impact broiler health by delaying growth and performance. A study using 2D electrophoresis and MALDI-TOF on intestinal samples of fasted chickens revealed differences in proteins related to fatty acid binding, stress response, and ion transport (Simon et al., 2019). The results of this study also revealed decreased intestinal absorption and differential expression of structural proteins. Studies of the hypothalamus revealed fasting induced differentially expressed enzymes involved in metabolic pathways between lines selected for low and high-body weights. Oxidative phosphorylation, citric acid cycle, and carbon metabolism were the major pathways connected to differentially expressed proteins. Fasting responsive proteins and their associated pathways were significantly over-expressed in high weight selected broilers in response to fasting (Liu et al., 2019). Taken together, these studies support the welfare effects of fasting on broilers and demonstrate proteomics capacity for identifying and defining pathways involved in welfare of fasting birds.

Ammonia is a major component of haze and often associated with certain management practices in the poultry industry and is often a cause of animal welfare concerns as birds are exposed to it low to the ground for long periods of time. Proteomics analysis in the thymus of chickens exposed to NH_3 had ultrastructural changes and 66 differentially expressed proteins involved in immune function, metabolic processes, and apoptosis. This proteomics analysis demonstrated ammonia toxicity mechanism in the thymus through immunosuppression, metabolic disruption, and apoptotic effect (Chen et al., 2020a). iTRAQ proteomic analysis revealed in a separate study that 30 differentially expressed proteins in the liver of ammonia exposed birds were related to nutrient metabolism, immune and stress response, as well as detoxification/biotransformation and transcriptional and translational regulation (Zhang et al., 2015). This resulted in differences in overall bird health and taken together, these studies suggest potential target pathways for measuring welfare in management related to ammonia exposure.

4.6 Conclusions

One of the primary goals of biology is to understand how organisms function on a molecular level. Because proteins are the "makers of life," understanding their functions is central to understanding biology. Proteomics is an extremely versatile and comprehensive platform to study proteins on a large scale. It offers a broad range of tools that can be used to determine the identity, structure, quantity, and quality of expressed proteins in biological systems as well as physiological responses to disease and environmental stressors. Proteomic data have also shown to be integral in the combined analysis of other omics technologies as the indicator of functional units in a given organism. Thus, while scientific questions in avian research remain essentially the same, proteomics has the potential to transform the form of biological inquiry.

5.1 Introduction to metabolomics

Physiology is an emergent property produced from continual and dynamic interactions between an organism and its environment. The study of physiology relies on readouts, such as hormone levels or physical pressures, to monitor the inner workings of cells and tissues that maintain homeostasis. For centuries, these indicators of physiological function were made one analyte-at-a-time. Over the past few decades, however, revolutionary advances in technology, bioinformatics, and instrumentation enabled the development and use of "-omics" approaches, in which an organism's entire collection of genes, proteins, or other molecular phenotypes can be queried simultaneously, and with high sensitivity and throughput. Metabolomics refers to the comprehensive analysis of an organism's metabolome, the collection of small molecules, and intermediary metabolites that cells use and produce to function. Because the metabolome essentially records the results of upstream processes, it can be thought of as an ultimate phenotype that comprehensively capture's a snapshot of an organism's physiological state (Figure 5.1, Cui et al., 2018).

The first metabolomics study can be traced back to Linus Pauling in the late 1960s in which he used gas chromatography (GC) with flame ionization detection to monitor changes in the gut microbiota (Robinson et al., 1973). While metabolites were successfully detected, lengthy analysis times, lack of analytical resolution, and the inability to confirm metabolite identities or elucidate structures limited the overall utility of this technique. Still, this emerging technology was instrumental in helping Pauling and coworkers determine the inborn error in metabolism that leads to human disease (Robinson et al., 1973). Over the past two decades, advances in mass spectrometric instrumentation, improvements in sensitivity and reductions in cost have enabled widespread adoption of metabolomics, allowing researchers to monitor thousands of metabolites concurrently (Emwas et al., 2019). Accordingly the use of metabolomics has gained traction in a variety of disciplines, with applications to both human and animal physiology (Figure 5.2).

5.2 Methods of metabolomics

5.2.1 Instrumentation

The metabolome consists of small molecules (typically < 1500 Da) that span a range of polarities and structural types (Christians et al., 2016; Schrimpe-Rutledge et al., 2016). This chemical complexity creates a unique analytical challenge as compared to other -omics types, which tend to measure molecules of similar composition and structure. Metabolites can be divided into two major classes: polar (water-soluble) and nonpolar (lipid-like). Lipidomics is often used to describe the subclass of metabolomics methods that measure lipid-based metabolites (Figure 5.3). At their core, all metabolomics techniques rely on separation and measurement science to analyze highly complex mixtures. The most common metabolomics approaches are based on nuclear magnetic resonance (NMR) spectroscopy or mass spectrometry (MS), each of which has its advantages as well as intrinsic bias for detecting specific classes of metabolites (Grzybek et al., 2019). A typical metabolomics workflow for MS platforms is outlined in Figure 5.4.

5.2.1.1 Nuclear magnetic resonance spectroscopy

NMR spectroscopy poses significant advantages for some applications. NMR spectroscopy and imaging can quantify

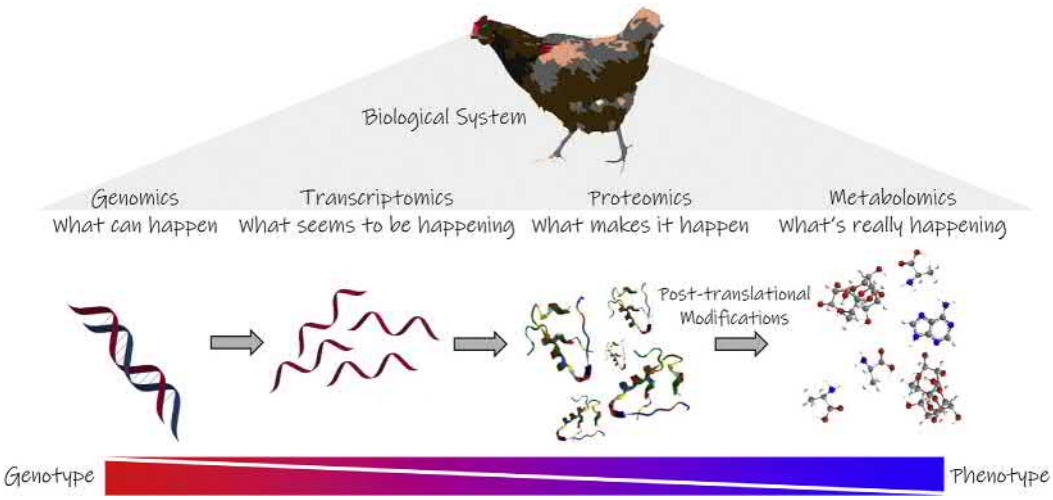

FIGURE 5.1 Concise overview of the "-omics" cascade. The cascade proceeds from tools that determine the blueprint of an organism to those that measure physiology directly. In reality, biological processes do not move in this manner as each component of the cascade may influence another.

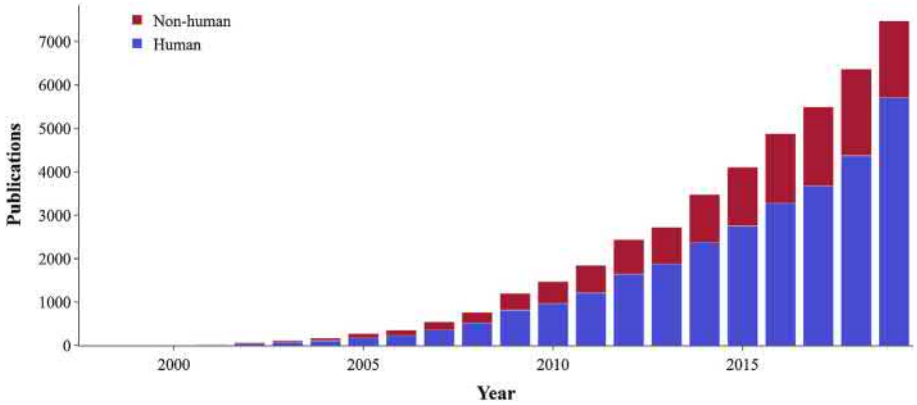

FIGURE 5.2 Number of publications per year available on PubMed.gov during 1998–2019 using search criteria "metabolomics" or "metabonomics." Results are filtered to include "Species: Nonhuman" and colored to delineate human versus nonhuman studies.

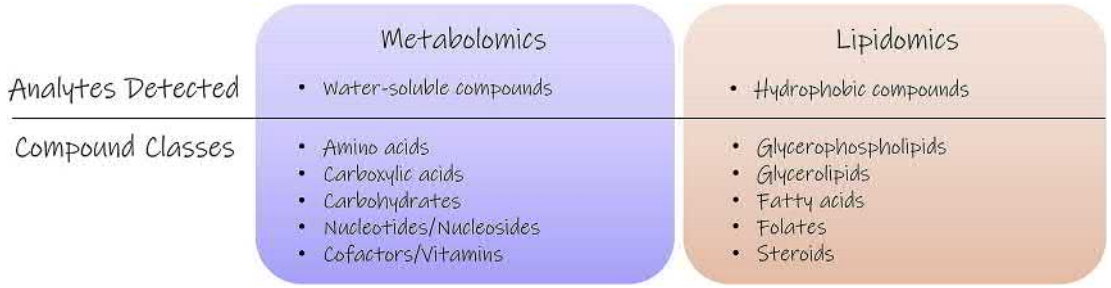

FIGURE 5.3 Overview of analyte types and typical compound classes measured in metabolomics and lipidomics experiments.

the most abundant compounds in a large variety of biological matrices, including biofluids, cells, or tissues, with minimal need for sample preparation. Structural isomers (or molecules with identical masses) can be differentiated and identified by NMR, whereas this is still challenging with MS. In addition, these techniques are nearly independent of the user or instrument used, allowing reproducibly and easy comparisons across platforms and studies (Emwas et al., 2019). Although NMR is a highly quantitative technique, it detects a fewer number of compounds due to metabolite signal overlap and the low-dynamic range of the instrument (Marshall and Powers, 2017).

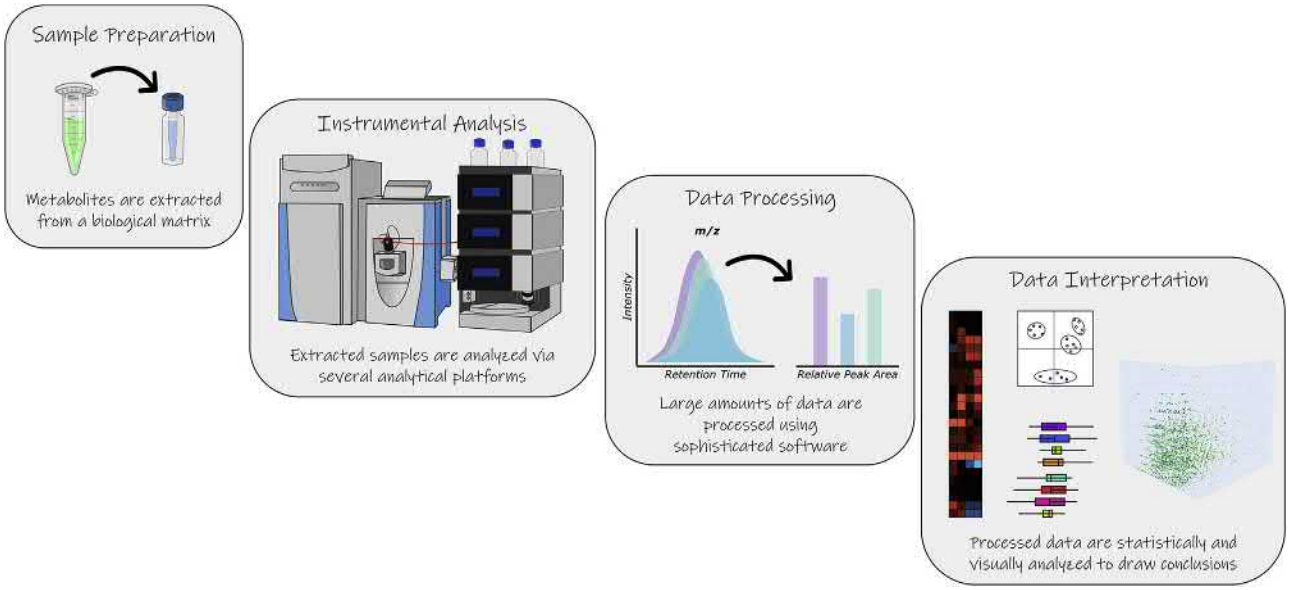

FIGURE 5.4 A simplified overview of the metabolomics experimental process. Samples are prepared via extraction of a diverse or specific set of analytes. The extracts are then analyzed by a variety of analytical platforms; a Thermo Fischer ® Orbitrap high-resolution mass spectrometer fitted with an liquid chromatography is shown. Processing consists of evaluating data for consistency and uniqueness. The final objective is to interpret data using various statistical or visualization options, such as heat maps, partial least squares discriminant analysis, multidimensional plots, and pathway maps.

NMR remains the analytical technique of choice for unknown structure identification, and the ability of two-dimensional (2D) NMR spectroscopy to correlate atoms belonging to the same compound greatly aids in these endeavors. Isotope tracing experiments that add metabolites or nutrients containing NMR active stable isotopes (typically ^{13}C or ^{15}N) to a sample allows the incorporation level of the isotope into metabolites to be measured and can also elucidate metabolic pathways as the dynamics of metabolite transformation can be traced (Tiziani et al., 2011). An interesting approach to isotope tracing is the combined analysis by NMR and MS. Detection of this type provides sensitive qualitative and quantitative information, exploiting the benefits of both detection methods (Bingol and Bruschweiler, 2015).

5.2.1.2 Mass spectrometry

MS-based metabolomics can detect many metabolites with a dynamic range of at least five orders of magnitude using a combination of chromatography, high-mass resolution, and/or tandem MS (Marshall and Powers, 2017). Each MS instrument consists of three main components: an ionization source, a mass analyzer, and an ion detector. These components allow the detection of various ions (i.e., molecules that have become charged), which are described by their mass-to-charge ratio (*m/z*). Based on its properties, a compound may ionize by the addition of a proton or loss of an electron to give a positive ion or vice versa to give a negative one. Modern instruments can switch between these two modes to cover a broader analytical range. Samples may undergo hard ionization, such as electron ionization (EI), which causes fragmentation of the molecule or soft ionization, such as electrospray or atmospheric pressure chemical ionization (APCI), which keeps the molecular structure intact. Of the available soft ionization sources, electrospray ionization (ESI) is most widely used because of its ability to generate intact ions via addition or removal of a proton and its analytical versatility over a broad range of compounds, i.e., small molecules (including metabolites), large molecules, surfactants, etc (Gross, 2004). In the event, ESI is not conducive for a particular analysis, for example, if ions formed during ESI are indicative of adducts or if the analytes being analyzed are low-polarity, APCI is often employed (Gross, 2004). Unlike ESI, APCI can generate ions from molecules that do not readily undergo acid-base reactions as ionization is accomplished by interactions with high-energy reactant gas species that are present in the corona discharge (Gross, 2004). As both sources operate at atmospheric pressure and are easily interchanged on most instruments, they are synergistic ionization techniques that are well suited for use with liquid chromatography (LC). On the other hand, most GC-MS utilize EI that results in fragmentation of analytes, although APPI and APCI sources for these instruments have been recently developed (Powers and Campagna, 2019). The fragmentation in most GC-MS metabolomics studies yields data that must be matched to existing spectral libraries or deconvoluted to predict structure and identify metabolites.

As many molecules possess similar *m/z,* the ability to distinguish between these compounds is necessary for

identification, and the chemical complexity of the metabolome highlights the utility of high-resolution mass analyzers and/or tandem techniques (see below). Low-resolution mass analyzers (such as quadrupoles or mass filters) are only capable of distinguishing ions ± 0.5 Da, which does not provide the resolution needed to distinguish among the thousands of compounds found a biological matrix (Jang et al., 2018). Conversely, high-resolution mass analyzers, such as ion cyclotron resonance, time-of-flight, and Orbitraps can routinely provide resolutions down to ±0.01−0.001 Da, which is sufficient to differentiate many molecules and isotopologues based on mass alone.

5.2.1.2.1 Separation

Despite its ability to resolve molecules based on mass, MS struggles as a stand-alone technique in the analysis of complex matrices due to the difficulty in ionizing and measuring many ions at once. Chromatographic separation is a synergistic technique that helps limit the complexity of the sample as it is introduced into the MS, which greatly aids in metabolite detection, quantitation, and identification (Johnson et al., 2016). Chromatography operates on a relatively simple basis: analytes dissolved in a *mobile phase* are allowed to interact with a *stationary phase*, and the affinity of a specific analyte for the stationary phase over the mobile phase leads to longer retention within the column. Differences in retention times among the metabolites are the foundation that provides separation. Though some alternatives such as capillary electrophoresis exist, the majority of metabolomics separation techniques rely on GC or LC (Lains et al., 2019). GC has been considered a workhorse in many laboratories since its implementation in the 1950s (Skoog et al., 2007). As expected, GC is particularly ideal for separation of thermally stable compounds that readily volatilize (i.e., molecules with low-boiling points). Therefore, GC analysis is generally used only for analyzing sugars, amino acids, fatty acids, or metabolites with compatible boiling points (Fiehn, 2016). Derivatization is necessary for many of these metabolite classes to aid in their volatilization to make them suitable for GC analysis (Fiehn, 2016).

LC instrumentation has seen significant advancement since its first use in the early 1900s, unlike GC which has largely remained the same (Skoog et al., 2007). The separation ability, sample efficiency, and broad applicability of modern LC instrumentation has made it an ideal choice for metabolomics analyses. Separations based on molecular size, polarity, hydrophilicity, and many other chemical properties are possible with modern columns. The most common columns used in metabolomics are those that separate a wide array of nonpolar and/or polar compounds, namely reverse phase (RP) and hydrophilic interaction liquid chromatography (HILIC), respectively. RP columns consist of a nonpolar stationary phase, often an alkane such as C_{18}, C_8, or C_4, attached to silica particles enclosed in a metal cylinder that can withstand high pressures (Huang et al., 2018). Compound separation is usually afforded by performing a gradient elution in which the mobile phase begins as a polar solvent and progressively becomes more nonpolar, thus allowing elution of compounds in decreasing order of polarity. HILIC stationary phases are generally more polar and rely on a mixture of chemical interactions to afford retention. Standard phase solvent gradients that progress from nonpolar to polar mobile phases are commonly used with HILIC separation, and studies have shown that the stationary phase particles surround themselves with a thin layer of water that interacts with the polar analytes to keep them retained longer that nonpolar molecules (McCalley, 2017).

Though not complete opposites, RP and HILIC methods of chromatography provide complementary separation chemistries to one another. Recent studies have utilized a technique called 2D-chromatography, in which two columns are used sequentially for separation in a single analysis. For example, this type of chromatography has been used for simultaneous detection of metabolites from both the metabolome and the lipidome, as well as metabolites that could not be separated using RP *or* HILIC alone (Wang et al., 2017). Despite its complex implementation, 2D-LC and 2D-GC have recently risen in popularity (Keppler et al., 2018).

5.2.1.2.2 Identification—targeted versus untargeted mass spectrometric analysis

Due to advancements in mass spectrometric capabilities, researchers can now either perform global analyses of the entire small molecule content of a sample (*untargeted metabolomics/lipidomics*) or focus on a predetermined set of molecules (*targeted metabolomics/lipidomics)* (Schrimpe-Rutledge et al., 2016; Bingol, 2018).Tandem MSs (e.g., the triple quadrupole) are used for targeted analyses. A target list of parent/fragment mass ions (i.e., knowns) is programmed into the instrument for these analyses that often rely on selective reaction monitoring to provide molecular identification. The use of a mass analyzer that selects for a parent ion and a second mass analyzer that selects for only fragments from a specific molecule affords separation in the mass domain and provides selectivity. These analyses are highly quantitative. However, they will not detect compounds for which the parent/fragment mass combination has not been programmed into the instrument, and these parameters are typically determined by injecting standards for each analyte of interest (Rabinowitz et al., 2011). This limits the ability of these methods to find novel biomarkers of biological activity, but data analysis is easier due to the lower number of metabolites detected (usually several hundred or fewer) and the high-confidence identifications.

Untargeted or global profiling experiments use a high-resolution MS (e.g., time-of-flight or Orbitrap

instruments) to detect parent ions with a high-mass accuracy to aid in metabolite identification, and tandem MS (MS/MS) is sometimes used to provide additional fragmentation data (Johnson et al., 2016). While global profiling experiments rarely increase the number of known compounds detected, they do allow for thousands of compounds of unknown structure and identity to be detected in a single analysis and provide an unbiased view of a larger portion of the metabolome (Su et al., 2017). However, compound identification can be difficult based on matching retention time, compound mass, and in some cases fragment mass, to a library of standards. This is further complicated due to differing performance among MS platforms and laboratories that often renders data incomparable among studies and facilities. Global profiling techniques are more labor- and analysis-intensive than targeted approaches; nonetheless, global metabolomics/lipidomics methods are the technique of choice for the discovery of novel metabolites and biomarkers (Vuckovic, 2018).

5.2.1.2.3 Data processing

Abundance of each detected metabolite is represented in raw data as a spectral peak, which must be aligned using known *m/z* and retention time information before being picked based on their intensities and peak shape. The *m/z*-retention time pair are used for metabolite naming or identification, and the intensity is proportional to concentration. Targeted analyses have become relatively streamlined, since metabolite identification is easier and more robust. Multiple software packages are available for data processing, and their usage varies depending on the approach (e.g., targeted vs. untargeted) (Jang et al., 2018).

5.2.2 Data analysis and interpretation

Regardless of whether NMR or MS is used, the core goal of metabolomics is to convert metabolite identifications and abundance to novel biological insight (Jang et al., 2018). The workflows used to accomplish this goal resembles those used for other 'omics platforms, in which biological signatures must be extracted from hundreds or thousands of data points. Clustering methods, such as hierarchical clustering and principle component analysis, are often used as a first analytical step to visualize distinctness of metabolite profiles between experimental groups (Heinemann, 2019). Univariate methods, such as t-tests and ANOVA, can be used to identify metabolites that differ statistically between experimental treatments (Ernest et al., 2012). Because of the hundreds of hypotheses that are typically tested simultaneously in these analyses, correction for multiple testing, for example using false discovery rate, should be included (Scheubert et al., 2017). Classical tools of statistics are often combined with multivariate analysis methods that reduce the dimensionality of the data and identify metabolites that most effectively discriminate groups. Supervised methods, such as partial least squares discriminant analysis (PLS-DA) and random forest, can be used to classify samples into groups based on patterns of metabolite abundance and to identify metabolites that are most effective at discriminating groups (Liebal et al., 2020, Figure 5.5).

Subsets of metabolites that emerge from these various winnowing methods can then be mined for biological insight and functional inference by mapping to known metabolic pathways. Bioinformatic resources such as the Kyoto Encyclopedia of Genes and Genomes Pathway Database (www.genome.jp), MAVEN, Metlin, and the Human Metabolome Database are highly valuable for functional interpretation of metabolite datasets (Xia et al., 2009; Clasquin et al., 2012; Guijas et al., 2018; O'Shea and Misra, 2020). A recent review of metabolomics tools, databases, and resources summarized over 100 published and nonpublished metabolomics tools and resources (O'Shea and Misra, 2020). Metaboanalyst (metaboanalyst.ca), a web server that contains a comprehensive set of analytical tools,

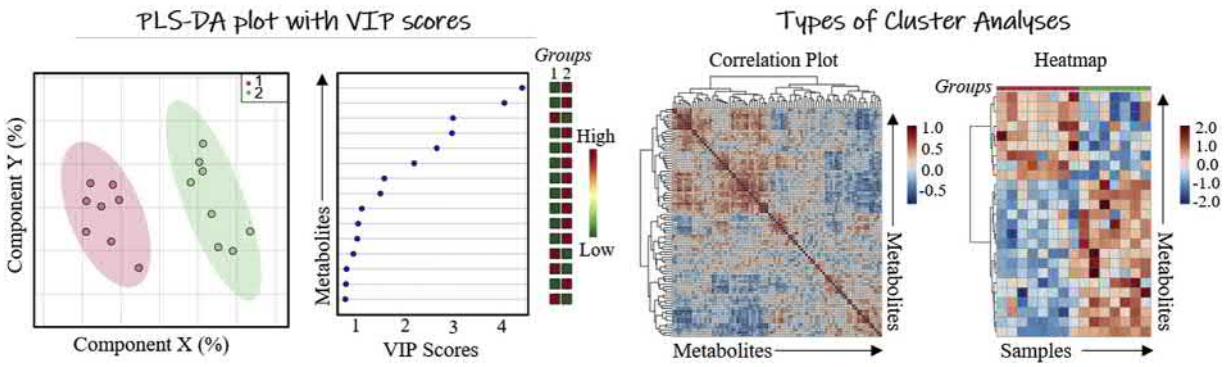

FIGURE 5.5 Examples of various visualization tools used in data analysis and interpretation. Partial least squares discriminant analysis (PLS-DA) plots, PLS-DA variable importance in projection scores, and cluster analyses including correlation plots and heat maps are common techniques to illustrate statistical significance and fold changes in large datasets. Illustrations were produced using the toolkit provided in Metaboanalyst (metaboanalyst.ca).

is particularly useful for quantitative and functional analyses of metabolomics datasets (Xia et al., 2009; Xia et al., 2012, 2015; Chong et al., 2018). Metabolomics data are often collected in the context of other physiological measurements, or alongside global measures of gene expression or other 'omics data types. Correlating metabolite abundance to other phenotypes can add additional insight into functional relationships and highlight metabolites that may be particularly relevant to a specific trait. As several studies that are summarized in the following section illustrate, connecting metabolome with transcriptome data yields synergistic insight that strengthens the biological value of both data types. Ultimately, metabolome data can be integrated into a systems biology approach, in which multiple types of 'omics data are integrated with phenotypic measurements using tools of correlation (Voy and Aronow, 2009; Voy, 2011). Genes, proteins, and metabolites are assembled into interconnected networks and mapped onto overlying phenotypes, providing mechanistic insight into pathways that underlie physiological functions. As discussed below, the emerging use of metabolomics and integration of metabolome data has begun to advance the study of avian physiology.

5.3 Applications of metabolomics to avian physiology

Although use of metabolomics is becoming more widespread, its application to avian physiology lags behind its role in more intensively studied areas, such as human disease. The majority of avian metabolomics studies to date have focused on issues relevant to the poultry industry, largely due to its economic importance and critical role in feeding a global population. A metabolomics toolkit is extremely well-suited to address these issues and physiological questions, as metabolism is inherently tied to growth and efficient utilization of feed that are critical for poultry production. In particular, modern broiler (meat-type) chickens are a metabolic marvel due to their incredible rates of growth and efficient conversion of dietary energy to tissue. The studies summarized below illustrate new insights into avian physiology that continue to emerge from use of metabolomics. In addition, they demonstrate the potential to use this platform to identify biomarkers of disease processes and desirable traits, using biological samples (e.g., serum) that are minimally invasive to collect yet can yield a global snapshot of a bird's physiological state.

5.3.1 Growth and efficiency

The ability to efficiently convert feed to lean tissue is a hallmark of modern broiler chickens. Commercial broiler lines have been produced by intensive selection for growth over the past several decades (Griffin and Goddard, 1994). As a result, growth rates of broilers increased approximately fourfold from 1957 to 2005 (Havenstein et al., 2003; Zuidhof et al., 2014). The efficiency with which broilers convert feed to tissue mass improved in parallel, cutting the amount of feed needed to support growth in half over the same time period (Havenstein et al., 2003; Zuidhof et al., 2014). Although the genetics and production environments of commercial broilers are tightly controlled, heterogeneity in feed efficiency still exists within flocks. Residual feed intake (RFI) is used to describe an individual bird's deviation in actual feed intake from what is predicted, based on the known relationship between weight of feed required per unit of weight gain (Romero et al., 2009). A negative RFI value reflects a higher than expected efficiency, while a positive value indicates reduced efficiency. RFI is heritable, making it a potential trait on which to select to improve efficiency. Circulating metabolites can feasibly be used as biomarkers of RFI, and some metabolites that are associated with higher feed efficiency in broilers have been identified. However, given that feed intake is a key component of RFI, it is difficult to discern metabolites that are affected by differences in feed intake per se from those that reflect intrinsic metabolic differences that underlie variation in efficiency.

To uncouple feed intake from RFI, Metzler-Zebeli et al. (2019) measured RFI and profiled serum metabolomes of broilers under both ad libitum and modestly restricted (85%) feeding. Serum metabolomes were profiled using a targeted ESI- LC/MS approach and a commercial kit (Absolute IDQ P180; BIOCRATES Life Sciences AG) that enabled absolute quantification of 188 known metabolites across various classes, including both small molecules and lipids. Using a mixed-model ANOVA, metabolites that were specifically affected by feed intake, RFI, and interaction of the two terms were identified. Feed efficiency was specifically associated with differences in serum amino acids. Levels of histidine, isoleucine, leucine, lysine, ornithine, proline, serine, threonine, and valines were lower, while tyrosine was higher, in birds with low RFI, independent of feed intake. Using a combination of PCA, regression modeling, and relevance networks, these authors identified metabolites that were specifically associated with RFI, feed intake, and total body weight gain. The amino acids isoleucine, lysine, valine, histidine, and ornithine were most closely associated with variation in RFI, while subsets of biogenic amines or glycerophospholipids were sufficient to discriminate birds based on feed intake and weight gain, respectively. This study illustrates the additional insight that can be gained when metabolomic data are integrated with other physiological measures.

Although improvements in feed efficiency over the past few decades have yielded remarkable advances in broiler growth, competing demands for soy, corn, and other major diet constituents make the cost of feed inputs increasingly

important. As for virtually any physiological trait, the ability to completely digest feedstuffs varies significantly between individual birds. Digestive efficiency contributes to RFI by affecting the amount of energy and nutrients that are extracted per unit of diet. Heritability estimates for digestive efficiency range from 0.33 to 0.47, making it an attractive target for genetic selection (Mignon-Grasteau et al., 2004). However, measuring efficiency is labor-intensive and low-throughput, requiring birds to be housed and fed individually. Metabolomics was used to identify biomarkers in serum that predict digestive efficiency, and to understand the metabolic relationships that contribute to efficiency in the digestive tract (Beauclercq et al., 2018).This study utilized two lines of chickens that had been derived through divergent selection for high (D+) or low (D−) digestive efficiency over eight generations, and for which various intensive measures of digestive efficiency (e.g., use of starch, lipids, dry matter) were measured from fecal samples. Metabolomes of both ileal and caecal contents, as well as serum, were quantified using NMR. Each sample type contained metabolites that contributed to a model predicting digestive efficiency. Although further effort is needed to validate biomarkers from this study, it provides foundational information about the metabolite pools that may reflect the capacity to fully digest feedstuffs in chicken.

Crude protein is both a costly component of poultry diets and an environmental concern due to emission and runoff of nitrogen. However, lowering the total crude protein content of diets without compromising growth is a significant challenge. Supplementing diets with glycine, a nonessential amino acid that can be reversibly metabolized to serine, has been shown to prevent compromised growth when crude protein levels are lowered, but the metabolic basis for this protection is poorly understood (Dean et al., 2006). To understand the metabolic basis for the growth supporting effects of glycine, broilers were fed a total of 12 diets containing varying levels of glycine and crude protein (Hofmann et al., 2019). Untargeted metabolomics of serum highlighted a somewhat unexpected association of phosphatidylcholine and sphingomyelin, rather than specific essential amino acids or glycine, with compromised growth under low crude protein intake. This study highlights the discovery potential of metabolomics when a platform capable of profiling broad classes of metabolites is used.

In addition to adequate total protein levels, specific amino acids must be optimized to support the unique physiological demands of rapid growth in broilers. Arginine is an essential amino acid that may have specific benefits for broiler physiology through its role as the precursor of nitric oxide (NO), an endogenous vasodilator. Improving basal levels of vasodilation may benefit broilers because tissue hypoxia contributes to development of breast muscle myopathies that currently challenge the broiler industry (Greene et al., 2019). Zampiga et al. (2018) tested the impact of dietary arginine supplementation on incidence of myopathies and profiled the effects on the breast muscle and serum metabolomes using NMR. Arginine supplementation significantly increased both circulating and tissue arginine content in broilers, confirming that local levels in muscle can be enhanced through the diet. Although incidence of breast myopathies was not affected by arginine supplementation, metabolite profiles indicated that arginine significantly enhanced both protein metabolism and energetic utilization of fatty acids, both of which are important for growth.

5.3.2 Consequences of selection

Many genes are pleiotropic, and the fundamental biochemical pathways that govern metabolism across tissues are inextricably linked. It is therefore not surprising that the intensive muscle growth of highly efficient broiler chickens has come with unintended physiological consequences (Griffin and Goddard, 1994). Metabolomics has proven useful for providing key insight into the metabolic tradeoffs that contribute to unintended and maladaptive traits in broilers.

5.3.2.1 Accretion of excess body fat

Although muscle and adipose tissue have divergent effects on body composition, selection for rapid growth inadvertently increased fat accretion in modern broiler chickens (Havenstein et al., 2003). Deposition of fat beyond what is physiologically necessary represents a waste of feed, the costliest component of production, and produces a byproduct with very little commercial value (Rauw et al., 1998; Baéza et al., 2015). Strategies to efficiently selected birds with a reduced tendency for fat accretion are therefore valuable to the poultry industry. Metabolomics (NMR) was employed to identify circulating biomarkers that could predict susceptibility to fat accretion (Baéza et al., 2015). Two lines of broilers (fat line and lean line) created using divergent selection were fed low and high-fat diets from three to nine weeks of age, creating a group of individuals with wide-ranging levels of adiposity. Chemometric methods identified metabolites that were associated with variation in adiposity, which were then used to develop regression models that predicted fat mass. A model containing free fatty acids, glutamine, methionine, phospholipids, cholesterol, and beta-hydroxybutyrate explained 74% of the variability in abdominal fat weight across the study population. Beta-hydroxybutyrate was inversely correlated with fat weight, indicating that increased levels of fatty acid oxidation contribute to leanness in broilers. Independent of diet, serum levels of glutamine, histidine, and betaine could discriminate between fat line and lean

line birds. This study demonstrates the biomarker potential of metabolites to predict fat accretion in broilers.

Mechanistic studies of susceptibility to accrete fat in broilers have largely focused on liver because of the clear contribution of hepatic delivery of triglyceride. As in humans, the liver is the primary site of de novo lipogenesis in avians (Leveille et al., 1968; O'Hea and Leveille, 1968), and divergent selection on serum VLDL levels yields birds with significant differences in adiposity (Hermier, 1997). Ji et al. investigated the role of adipose tissue in fat accretion using a combination of adipose tissue metabolomics and transcriptomics (Ji et al., 2014). To create a robust model of leanness, two genetically distinct lean lines of chickens (Leghorn (egg type) and Fayoumi (lean meat type)) were compared to a commercial broiler line. Untargeted tissue metabolomics using an LC/MS platform identified 47 (of 92 detected) metabolites that differed significantly in abundance between the three lines. Several components of the purine and pyrimidine metabolism pathway, which has been associated with resistance to obesity in mice (Tague et al., 2018), were significantly elevated in lean adipose tissue. In addition, tissue from both lean lines contained ~threefold more carnitine and acetylcarnitine than that of broilers, as well as increased levels of several amino acids. These changes in carnitine species corroborated parallel gene expression profiling which identified fatty acid oxidation in abdominal adipose tissue as a pathway associated with leanness. This relationship is also consistent with biomarkers of fatness identified by Baeza et al. (2015).

Insulin promotes adipocyte hypertrophy and fat accretion in many species, but its influence on avian adipocytes is unclear. Unlike in humans and most animals, the ability of insulin to stimulate glucose uptake and induce fatty acid synthesis in avian adipocytes is minimal (Tokushima et al., 2005). Metabolomics and transcriptomics were integrated in a study designed to clarify the effects of insulin in chicken adipose tissue (Ji et al., 2012). Broiler chicks (21 days of age) were fed ad libitum and administered an anti-insulin antibody, to neutralize circulating insulin, or vehicle for five hours. An additional group of chicks was fasted for five hours to serve as a metabolic control. Effects on the abdominal adipose tissue metabolome were determined using an untargeted LC/MS platform. No metabolites associated with glucose utilization were affected by insulin neutralization. However, tissue levels of free amino acids and their metabolites were significantly more abundant than in either the fed or fasted control groups. Fasting significantly decreased tissue amino acid levels, which was consistent with upregulation of genes that mediate amino acid metabolism in the fasted group. Relevance networks and hierarchical clustering demonstrated that many amino acids and their metabolites were closely correlated with expression of p85alpha, a regulatory subunit of phosphoinositide 3-kinase, which plays an important role in mediating insulin actions in adipose tissue (McCurdy et al., 2012). This use of metabolomics uncovered a potential role for insulin in regulating amino acid use, rather than glucose metabolism, in avian adipose tissue.

5.3.2.2 Muscle myopathies

The extremely rapid growth of breast muscle that characterizes modern broiler chickens may also be its Achilles heel. Highly efficient broilers are susceptible to develop degenerative muscle myopathies that compromise breast meat quality and consumer appeal (Mazzoni et al., 2015; Trocino et al., 2015; Kuttappan et al., 2016). Wooden breast (characterized by hardened, firm breast tissue) and white striping (fibrotic and lipid-laden regions that parallel muscle fibers) are the two most common lesions (Kuttappan et al., 2016). Both have arisen in the past decade, and they afflict flocks with a high rate of incidence worldwide (de Brot et al., 2016; Kuttappan et al., 2017). Histologically, lesions are characterized by signs of myodegeneration and regeneration, and by infiltration of fibroblasts, inflammatory cells, and adipocytes (Sihvo et al., 2014; Soglia et al., 2016; Chen et al., 2019). Myopathies are thought to develop in part when muscle growth outpaces vascular development, resulting in localized hypoxia and oxidative stress that disrupt cellular metabolism and damage myofibers (MacRae et al., 2006; Mutryn et al., 2015; Boerboom et al., 2018; Livingston et al., 2019). Several studies have used metabolomics to understand the metabolic basis for breast myopathies and to identify biomarkers that could be used to detect at-risk birds within a flock. An initial metabolomics investigation utilized a large library of commercially available annotated standards to quantify abundance of 282 compounds in breast muscle (Abasht et al., 2016). Birds affected or not with wooden breast were selected from two genetically distinct purebred broiler lines and from one commercial flock, creating a robust sample design. Random forest analysis was used to identify metabolites that most effectively discriminated affected from nonaffected tissue. The 30 top distinguishing metabolites mapped onto multiple metabolic pathways, including amino acid metabolism and oxidative stress. Affected tissue exhibited features of altered glycogen metabolism and glucose utilization. Tissue levels of glycolytic intermediates as well as lactate and pyruvate were significantly lower in affected birds, while components of the pentose phosphate pathway were increased compared to unaffected controls. The commercial platform that was used also queried lipids, which revealed that several fatty acids, phospholipids, signaling lipids (e.g., eicosanoids), and by-products of fatty acid oxidation were significantly elevated in affected wooden breast tissue. Changes in the circulating metabolome also support a role for aberrant fatty acid oxidation in this disorder. Both

carnitine and acetylcarnitine were among metabolites shown to be significantly elevated in serum of broiler affected with wooden breast compared to unaffected controls (Maharjan et al., 2019). These findings from use of metabolomics corroborate gene expression results and further implicate aberrant glucose and fatty acid metabolism as key factors in the etiology of wooden breast lesions (Mutryn et al., 2015; Zambonelli et al., 2016; Pampouille et al., 2018; Lake et al., 2019).

Breast muscle metabolomes have also been characterized in birds affected with white striping, the other major myopathy in broilers. Boerboom et al. (2018) classified white striping status of 51 broilers as either normal, moderate, or severe, based on examination of breast muscle at slaughter. Using a QTOF platform they measured abundance of 599 metabolites in breast muscle, including both lipids and small molecules. Upon comparing metabolomes of the three groups using ANOVA, 63 metabolites differed significantly between normal, moderate, and severe white striping status. Comparable to what was described for birds affected with wooden breast (Abasht et al., 2016), metabolome profiles highlighted fatty acid oxidation as a pathway linked to the disorder. Affected breast tissue contained higher levels of fatty acids and of certain carnitine esters, both of which are consistent with reduced fatty acid oxidation. Using pathway enrichment tools, they also found that the citric acid cycle, as well as glyoxylate, galactose, and taurine metabolism were affected in white striping. Wooden breast and white striping are described as distinct disorders, each with its characteristic histological features. However, both types of lesions can occur in the same muscle sample, which suggests that they may be different manifestations of the same underlying metabolic dysfunction in high-efficiency broilers (Lorenzi et al., 2014; Sihvo et al., 2014; Mutryn et al., 2015). In support of this concept, some metabolite changes (e.g., higher levels of taurine, malate, and certain fatty acids; imbalance in the TCA cycle) were found in both wooden breast and white striping. In addition, both studies related several of the disrupted pathways to hypoxia, which has been linked to extremely rapid growth in broilers (Livingston et al., 2019).

5.3.2.3 Ascites syndrome

Selection for rapid growth has also increased the susceptibility of modern broilers to ascites syndrome, in which excessive fluid accumulates in the peritoneal cavity from transudation of fluid from the vascular system (Peacock et al., 1989; Julian, 1993). In broilers, ascites is a consequence of right ventricular failure that is secondary to pulmonary hypertension. Pulmonary hypertension in broilers arises from a mismatch between oxygen demand and supply that is due to both metabolic demands of rapid growth and a relative reduction in heart and lung mass that developed over the course of selection (Kalmar et al., 2013). Eventually, right ventricular hypertrophy fails to compensate for hypoxemia, and the consequent increase in venous pressure drives fluid leak into the abdomen (Julian, 1993; Wideman et al., 2013). Mortality rates from ascites syndrome can be significant, and are exacerbated by production in low temperature or high-altitude environments (Ruiz-Feria and Wideman, 2001). Genetic background influences susceptibility/resistance to ascites, and heritability estimates (reaching 0.44) indicate the potential to select for resistance in commercial flocks (Lubritz et al., 1995). Serum metabolome profiling was used to identify biomarkers that could be used to identify birds resistant to ascites (Shi et al., 2017). Resistance was associated with increased abundance of various phospholipids. Species that discriminated susceptible from resistant birds contained choline, ethanolamine, serine, and inositol, and thus were not restricted to a specific class of phospholipids. Shao et al. used GC-MS to profile lung tissue metabolomes to gain new biochemical clues into the pathogenesis of pulmonary arterial hypertension in broilers (Shao et al., 2018). Affected birds were identified based on relative increase in right ventricular weight at slaughter. Clustering analyses indicated that lung metabolites clearly differentiated affected from unaffected birds. The set of metabolites with the highest discriminatory signals, based on variable importance in projection (VIP) values, was significantly enriched in components of amino acid metabolism, including increased lysine in lung tissue of birds affected with PAH. Lysine is notable because it inhibits uptake of arginine, which is the precursor for synthesis of the vasodilator NO. In addition, this metabolite set included ornithine and urea, which can limit NO production by competing with NO synthase for arginine. Insufficient synthesis of NO has been linked to development of pulmonary hypertension in broilers (Wideman et al., 2007). Interestingly, metabolome profiles also reflected differences in tissue fatty acid oxidation, just as hypoxia in breast muscle is associated with effects on this pathway (Mutryn et al., 2015; Abasht et al., 2016; Boerboom et al., 2018). Levels of the beta oxidation end-product beta-hydroxybutyrate were higher, and several fatty acids were lower, in lungs of affected birds (Shao et al., 2018). These similarities suggest that cellular hypoxia, through its impact on fatty acid metabolism, may be a common denominator to the consequences of rapid growth in broilers.

5.3.2.4 Heat stress/stress

Increased body size and the metabolic heat produced to accommodate rapid growth make modern broiler chickens more susceptible to heat stress (Deeb et al., 2002). Heat stress occurs when birds are no longer able to counteract elevated ambient temperatures and maintain a

thermoneutral body temperature. Paradoxically, heat stress suppresses feed intake but reallocates energy in a way that increases fat deposition (Geraert et al., 1996). Lu et al. used an experimental design that used pair-feeding to control for reduced feed intake and identify specific effects of heat stress on metabolism (Lu et al., 2018). Broilers were exposed to sustained heat stress (housed at 32°C) from 22 to 42 days of age. Pair feeding was used to create a control group that was housed under thermoneutral conditions (22°C) but with intake matched to heat stress birds. A total of 34 serum metabolites were identified as significantly altered by heat stress, based on a combination on ANOVA and OPLS-DA analyses. This set of metabolites was enriched in components of the TCA cycle, and in alanine, aspartate, glutamine, and tyrosine metabolism. Correlation analyses linked the circulating abundance of several amino acids, as well as pyruvate, with increased fat deposition in heat-stressed birds. Heat stress has been shown to rapidly alter hepatic lipid metabolism, which may contribute to increased fat accretion. Broilers were exposed to cyclical heat stress, in which ambient temperatures were increased for four hours/day, for one week (Jastrebski et al., 2017). Heat stress increased levels of glucose, glucose-6-phosphate, and fructose-6-phosphate, as well as components of gluconeogenesis, glycerol, and glycerol-3-phosphate. Most free amino acids were decreased by heat stress, which may be due to their use as substrates for gluconeogenesis. Effects of heat stress on glucose metabolism were corroborated by transcriptomics, which revealed differential expression of several enzymes in the glycolytic pathway. Stress in general has been shown to alter the metabolome profiles of poultry. Broilers consuming dexamethasone in their drinking water for four weeks exhibited significant increases in serum glucose, fatty acids, and amino acids, while components of the TCA cycle and beta-hydroxybutyrate were lower than in controls (Lv et al., 2018). In a related study, tissue metabolomes (liver, kidney, and breast muscle) were profiled in leghorn chickens consuming corticosterone in their drinking water for up to 12 days (Zaytsoff et al., 2019). This stress mimic significantly altered lipogenesis in the liver, and exerted tissue-specific effects on amino acid and glucose metabolism.

5.3.3 Mechanisms of antibiotic growth promoters

In addition to selective breeding, antibiotic growth promoters have contributed to the dramatic improvements in broiler chicken growth and performance (Dibner and Richards, 2005). When added to feed, subtherapeutic doses of certain antibiotics increase gain and feed conversion (Butaye et al., 2003). Despite their widespread use, the mechanisms through which antibiotics promote growth is not well understood. Because of the nature of antibiotics, an intuitively sound mechanism is that they increase availability of energy to the host by reducing the population of biota that scavenge nutrients in the gut (Visek, 1978). Evidence to date from both poultry and other species indicate that the mechanisms are more complex, and may result from a combination of selective metabolite enrichment and reduced gut inflammation, in addition to a net increase in energy (Engberg et al., 2000; Niewold, 2007; Lu et al., 2008; Khadem et al., 2014). Metabolomics as a platform is well-suited to yield insight into the mechanisms through which antibiotics promote growth. Gadde et al. (2018) utilized the breadth of untargeted metabolomics to characterize the effects of two widely used antibiotic growth promoters, virginiamycin, and bacitracin, on the intestinal metabolomes of broilers. Although both of these antibiotics are effective in promoting weight gain, their antimicrobial actions are distinct. Virginiamycin, a product of Streptomyces virginiae, inhibits bacterial protein synthesis by binding to the 50S ribosomal subunit (Butaye et al., 2003). Bacitracin is a combination of 10 peptides produced by two Bacillus species inhibits bacterial growth by disrupting lipid phosphorylation that is needed to synthesis of the bacterial wall (Butaye et al., 2003). Broiler chicks were fed either antibiotic from hatch to 21 days and compared to chicks receiving no growth promoters. Contents of the ileum were used for global metabolome profiling, and the composition of the microbiome was characterized by 16S sequencing. Both antibiotics had marked effects on the ileal metabolome. Of the 706 metabolites that were identified in ileal contents, 218 differed significantly between virginiamycin and controls, while 119 were significantly affected by bacitracin treatment. Although both increased weight gain to a comparable extent (10.1% for bacitracin and 7.9% for virginiamycin), gain was associated with distinct effects on the metabolome. The authors used random forest classification to identify the 30 metabolites with the most statistically significant ability to distinguish each treatment group. In comparison to controls, the metabolome of virginiamycin-treated birds was characterized by metabolites of amino acids (33%), fatty acids (30%), and nucleosides (23%). In contrast, lipid metabolites were the distinguishing feature of bacitracin metabolomes when compared to either controls (57%) or the virginiamycin group (66%). The lipid-enriched signature of bacitracin may reflect its interactions with cellular lipids, which confers its antimicrobial effects (Butaye et al., 2003). Despite these unique signatures, several metabolic pathways were commonly affected by both antibiotics, suggesting that there are some shared effects for growth promotion. Both bacitracin and virginiamycin significantly increased the levels of several lysine and tryptophan metabolites, including kynurenine, kynurenante, and quinolinate, which play important roles in regulation of inflammation (Chen et al., 2010). Changes in this pathway

also implicate effects on gut motility mediated through a reduction in serotonin. Serotonin is the main neurotransmitter used by the enteric nervous system, and a reduction in serotonin would be expected to increase gut transit time, allowing for enhanced nutrient and energy absorption from the diet. Several purine and pyrimidine metabolites were also commonly affected by both antibiotics, further supporting the concept that they share some outcomes on the intestinal metabolome.

A wide variety of plant-derived extracts show promise as alternatives to antibiotic growth promoters. Plant structural components can serve as probiotics, and endogenous phytochemicals can interact with the host immune and metabolic systems to influence energy utilization and gut health. Chen et al. (2020) combined microbial sequencing with metabolomics to compare the effects of virginiamycin to those of a plant essential oil (PEO) supplement in broiler chickens. Both supplements increased the relative abundance of bacteroidetes and decreased the abundance of Firmicutes in cecal samples, but each exerted unique effects at the genera level compared to control birds. Virginiamycin and PEO also exerted distinct influence on the cecal metabolome, with little overlap between the metabolites that were affected by each treatment compared to controls. However, both supplements significantly enriched the serum metabolomes in essential fatty acids, including linoleic and linolenic acids. Magnolia bark has shown promise in growth trials as a source of plant-derived chemicals that augment growth and feed utilization in broilers (Oh et al., 2018). Using a broad targeted metabolomics platform, Park et al. demonstrated diverse and relatively rapid effects of magnolia bark supplementation in broiler chicks (Park et al., 2020). Three weeks of supplementation (from hatch to 21 days of age) were sufficient to significantly alter the abundance of 278 metabolites in chick ileal contents. This set of metabolites spanned functional classes, including many components of macronutrient metabolism, as well as many more novel biochemicals and vitamin metabolites. Collectively, these studies illustrate the potential to exploit metabolome profiling to advance the search for new ways to enhance growth and health in poultry.

Across species, intrinsic variation in gut microbiomes influences growth and metabolism and is linked to inter-individual differences in body composition (Ridaura et al., 2013; Bergamaschi et al., 2020). Enterotype is used to describe distinct microbial community structures that can be detected in sets of individuals (Arumugam et al., 2011). Yuan et al. (2020) classified 206 broilers into three enterotypes, based on 16S RNA sequencing, and then used untargeted metabolomics to define and compare the resultant metabolomes in the duodenum. A total of 24 metabolites differed significantly between the three enterotype groups, reflecting the impact of different community structures on nutrients available to the host. This set included assorted sugars, as well as fatty acid metabolites and glutathione. Using correlation, the authors connected abundance of two specific genera, *Ochrobactrum* and *Rhodococcus*, which were more abundant in enterotype 2, with increased availability of simple sugars in the duodenum. Conversely, both were inversely correlated with beta-hydroxybutyrate, suggesting that provision of sugars by the microbiome may be associated with reduced oxidation of fatty acids. Interestingly, fat accretion was significantly higher in birds with this enterotype. The authors proposed that these two genera may contribute to increased weight gain by enhancing the bird's ability to utilize complex polysaccharides, which normally are poorly digested by chickens.

5.3.4 Toxicology

Many chemicals found in the environment (e.g., bisphenol A) can disrupt homeostatic metabolism and promote disease in both animals and humans (Heindel et al., 2017). The Deepwater Horizon oil spill exposed hundreds of avian species in the Gulf of Mexico to markedly increased levels of crude oil, resulting in large numbers of mortalities (Barron, 2012). In addition, sublethal exposures persisted for several months as the oil spread (Bursian et al., 2017). Follow-on, controlled studies demonstrated that exposure to sublethal levels of the same source of oil released during this spill affected function of multiple tissues and compromised energy balance (Bursian et al., 2017). Dorr et al. (2019) used metabolomics to identify specific metabolic pathways that are disrupted by sublethal oil exposure and may impact survivability of birds in the wild. Double-crested cormorants, a carnivorous aquatic bird that inhabits the Gulf, were experimentally housed in water containing oil collected from the Deep Water Horizon spill. Hepatic and plasma metabolomes of exposed and control birds were analyzed using NMR. Both sample types showed significant alterations in amino acid metabolism and use of fatty acids. Several branched chain, aromatic and essential amino acids increased significantly after seven days of exposure and remained elevated through completion at 22 days. Despite increased mobilization of amino acids, which cormorants normally rely on energetically as a fish-eating species, and sufficient glucose levels and feed intake, metabolomes suggested that oil exposure significantly increased fatty acid oxidation. Like amino acids, levels of beta-hydroxybutyrate, an end-product of fatty acid catabolism, increased significantly after only seven days exposure and remained elevated throughout the study. In addition, oil exposure altered the abundance of metabolites of bile acids in liver, further indicating effects on lipid metabolism. This use of metabolomics added a level of phenotypic granularity to understanding the consequences

of sublethal oil exposure in avians. Given the importance of lipid metabolism during seasonal adaptations, migration, and reproduction, this study provides an important foundation for studies of avian physiology in native environments.

Significant effects of environmental chemicals on avian lipid metabolism were also revealed in a separate study of laying hens and their offspring. Metabolome profiling was used to characterize the endogenous, tissue-specific metabolism of alpha-cypermethrin, a pyrethroid class insecticide, in laying hens (Liu et al., 2019). This class of compounds is lipid soluble and thus can thus be readily deposited in the yolk (Zheng et al., 2015). Avian embryos in the wild are therefore susceptible to its teratogenic effects (Uggini et al., 2012). Metabolome profiles of chicks that were newly hatched from hens exposed to alpha-cypermethrin exhibited significant effects on various lysophospholipids, as well as pantothenate. Tissue-specific differences in the time course and products of alpha-cypermethrin were also identified. This study highlights that metabolomics can serve dual purposes in toxicological studies by profiling both xenometabolites that are produced from breakdown of environmental chemicals and the corresponding disruptions to endogenous metabolomes.

5.4 Conclusions

Although metabolomics entered the 'omics field later than other players, rapid advances in technology and availability have accelerated its implementation in efforts to understand avian physiology. Its continued application to studies of both chickens and other species is expected to expand the global understanding of health, disease, and environmental adaptations? in avians.

Chapter 6

Mitochondrial physiology—Sturkie's book chapter

Walter Gay Bottje

Department of Poultry Science, Center of Excellence for Poultry Science, Division of Agriculture, University of Arkansas, Fayetteville, AR, United States

6.1 Overview of mitochondria

6.1.1 Introduction

Mitochondria generate 90% of the energy in the form of adenosine triphosphate (ATP) within a cell by oxidative phosphorylation earning it the title of "powerhouse of the cell." The process of oxidative phosphorylation from the respiratory or electron transport chain (ETC) activity was first reported by Kennedy and Lehninger (1949). Energy production, however, is just one of many roles orchestrated by mitochondria. Mitochondria are the only organelle outside the nucleus with a discrete pool of DNA (mitochondrial, mtDNA). This distinction lead to the accepted theory of endosymbiotic origin of mitochondria in which an α-Proteobacteria took up a commensal residence within a eukaryotic cell with more recent evidence of co-evolution of an extant eukaryotic cell (Gray et al., 1999). According to Lehninger (1965), Rudolf Albert van Kolliker, a Swiss cytologist, first described mitochondria in 1857 and gave them the name of sarcosomes having a distinct granular structure surrounded by a membrane. Later, (Benda, 1898) renamed the structure the mitochondrion; a derivation from Greek for thread (*mitos*) and grain (*chondrion*) and the standard name for the organelle since the 1930s (Lehninger, 1965). The synthesis and import of nuclear (n)-encoded proteins that represent 98% of all mitochondrial protein is tightly coordinated with the synthesis of mtDNA-encoded proteins that is followed by the coordinated assembly needed for fully functional mitochondria. Mitochondria play a vital role in programmed cell death (apoptosis) and mitochondrial generated reactive oxygen species (ROS) at low levels is important in signal transduction whereas higher ROS generation makes the mitochondria a major site of endogenous oxidative stress. Mitochondria are dynamic organelles that change morphology and composition in response to physiological signals, e.g., variations in nutrition, O_2 levels, and metabolic demand (Aw and Jones, 1989). Mitochondria are not static structures (Hoppins et al., 2007) and undergo fusion and fission processes that are driven in part by the energetic status of the cell, e.g., Liesa and Shirihai (2013). Mitochondria also possess hormone receptors that have profound relevance on mitochondrial function (see reviews by Wyrutniak-Cabello et al. (2001), Chen et al. (2005), Psarra et al. (2006)). The first report of mitochondrial hormone receptors in avian muscle cells was provided by Lassiter et al. (2018).

6.1.2 Physical description

Under the electron microscope, mitochondria appear bean-shaped with striations that are visible due to folding of the inner mitochondrial membrane called cristae, which is where the ETC is located. Electron tomography revealed mitochondria as long tube-like structures that weave throughout the cytosol (Mannella, 2000). Sections of the mitochondrial membrane are contiguous with the endoplasmic and sarcoplasmic reticulum that facilitate shuttling of molecules such as ATP and ADP between the mitochondria and cytosol (Scheffler, 1999; Sharma et al., 2000). Mitochondria have an inner membrane that surround the mitochondrial matrix and an outer membrane that encloses an intramembranous space (Figs. 6.1 and 6.2). Cytochrome *c*, located in the intramembranous space, is critical for cellular respiration and for initiating normal cell turnover (apoptosis). Most mitochondrial proteins are found in the matrix and are associated with (a) the Kreb cycle, (b) β-oxidation of fats, (c) synthesis of heme proteins, and (d) iron-sulfur proteins prevalent in the ETC. Mitochondrial DNA is also present in the matrix.

Sturkie's Avian Physiology. https://doi.org/10.1016/B978-0-12-819770-7.00043-8

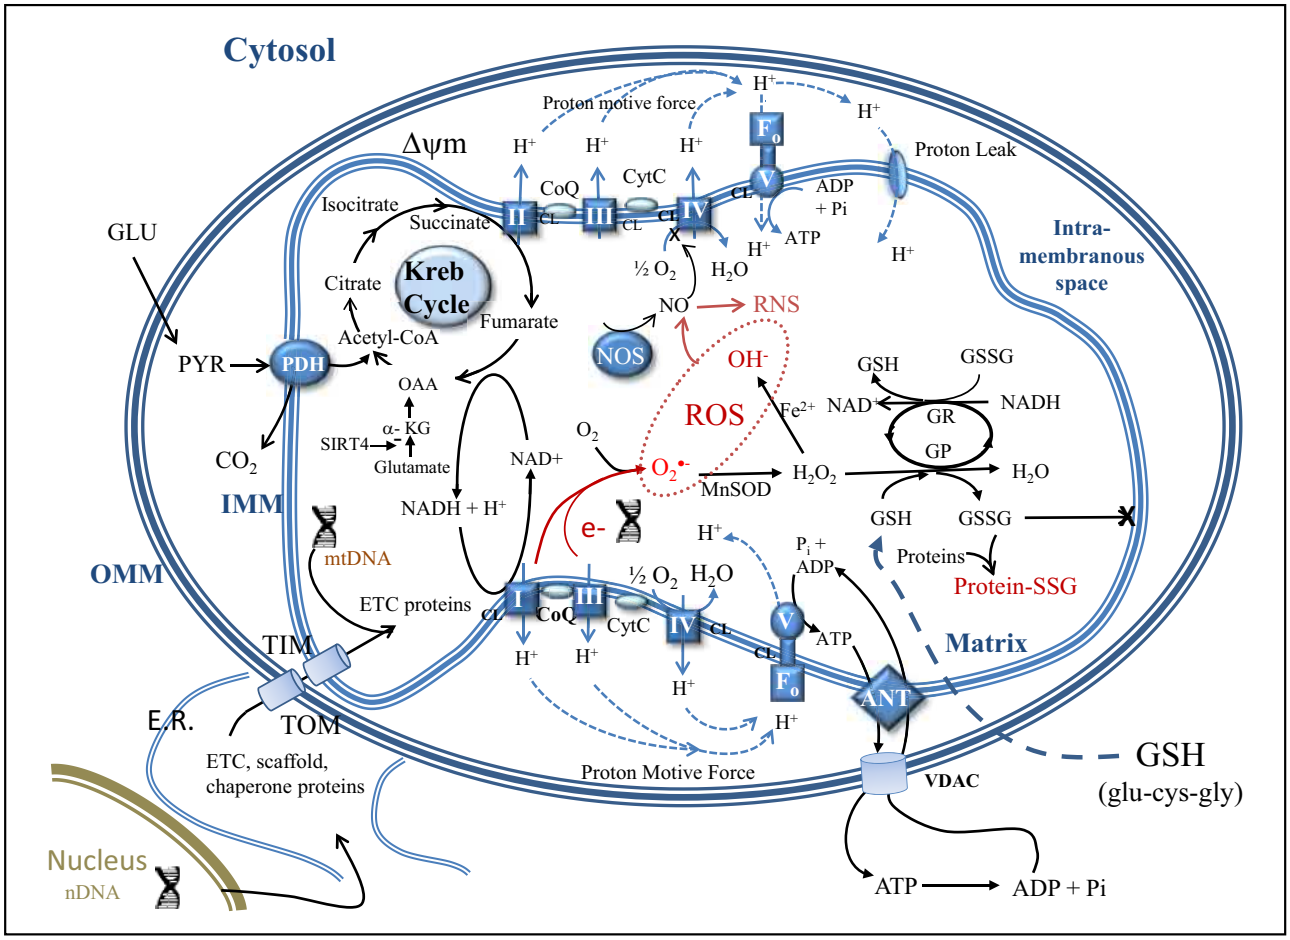

FIGURE 6.1 Overview of mitochondria. A stylized mitochondria with some of mitochondrial processes discussed in the text is presented. The mitochondria have both an outer (OMM) and inner (IMM) mitochondrial membrane with the electron transport chain (ETC) (I, II, III, IV, V) located on the IMM. The ETC toward the top shows electrons moving from succinate, an intermediate of the Kreb's Cycle, to Complex II, III, and IV. The ETC on the bottom shows NADH-linked energy substrates with electrons entering the ETC at Complex I. Electrons are passed between Complex II and III, and Complex I and III by coenzyme Q (CoQ). Cytochrome C (cyt *c*) shuttles electrons from complex III to Complex IV. The movement of electrons down the respiratory chain is accompanied by pumping of protons (H+), in the intramembranous space that sets up a proton motive force that drives ATP synthesis when protons flow through ATP synthase (Complex V). ATP is transported out of the mitochondria for use by the cell through the adenine nucleotide translocase (ANT) on the inner membrane and the VDAC on the outer membrane. A mitochondrial NOS produces NO that can compete with oxygen for the active site on cytochrome *c* oxidase. Protons may also move through the membrane at sites other than the ATP synthase in a process called proton leak. Proton leak dissipates the proton motive force without synthesis of ATP but can also attenuate formation of reactive oxygen species (ROS). Electrons (e−) that leak from the ETC can react with oxygen to form superoxide (O_2^-) that is normally converted to hydrogen peroxide (H_2O_2) by manganese superoxide dismutase (MnSOD). In the presence of free metal ions, H_2O_2 can be converted to the highly reactive hydroxyl radical (OH^-). Collectively, superoxide, H_2O_2 and OH^- are called ROS and can cause oxidative damage to cellular structures (e.g., proteins, lipids, DNA). ROS can react with NO to produce reactive nitrogen species that can damage these structures also. Glutathione (GSH) is an important endogenous antioxidant that is imported from the cytosol into the mitochondria. The active thiol in GSH is used to reduce lipid peroxides or H_2O_2 to water or lipid alcohols with the concomitant formation of oxidized glutathione (GSSG) that can be recycled to GSH reductase (GR) that utilizes reducing equivalents from NADH. Unlike cells, mitochondria cannot export GSSG and elevations in GSSG in mitochondria can lead to protein disulfides (protein-SSG) formation. This can be particularly detrimental to ETC activity due to the presence of reactive thiol groups in these proteins. The ETC is comprised of nuclear and mitochondrially encoded (mtDNA) proteins. The nuclear encoded proteins must be transported into the mitochondria which is facilitated by both outer membrane translocase (TOM) and inner membrane translocase (TIM) proteins. *This figure was adapted from Wallace (1999).*

The outer mitochondrial membrane is a simple phospholipid bilayer whereas the inner mitochondrial membrane is highly convoluted forming cristae that greatly increase its surface area. Due to the presence of the multiprotein complexes of the ETC, the inner mitochondrial membrane contains 70% protein and 30% lipid compared to a 50:50 ratio of proteins to lipids that is typically found in membranes. The inner mitochondrial membrane also contains cardiolipin, a unique lipid found primarily in mitochondria (Hatefi, 1985).

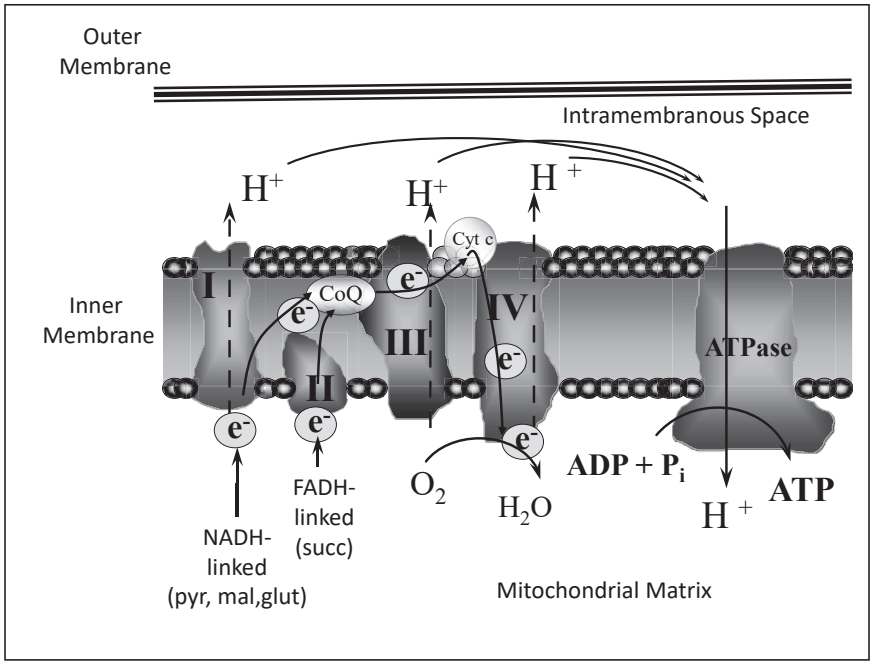

FIGURE 6.2 **Diagrammatic representation of the mitochondrial electron transport chain.** The respiratory chain consists of five multiprotein complexes (Complex I, II, III, IV, and V). Electrons (e−) enter the electron transport chain (ETC) either through Complex I from NADH-linked energy substrates (e.g., pyruvate, malate, glutamate), or at Complex II from FADH-linked substrates (e.g., succinate). The electrons are passed down the ETC (*solid arrows*) to the terminal electron acceptor, oxygen that is reduced to water. Coenzyme Q (CoQ, ubiquinone) is responsible for the transfer of electrons from Complex I and II to Complex III. Associated with the movement of electrons along the ETC is the movement of protons (H^+, *dashed arrows*) from the mitochondrial matrix into the intramembranous space, setting up a proton motive force. The movement of protons through the adenosine triphosphate synthase (ATP synthase, Complex V) provides the energy to support ATP synthesis. *Based on Lehninger et al. (1993).*

6.1.3 Mitochondrial and nuclear DNA interaction for assembly and function

Mitochondrial DNA, a circular molecule with over 16,000 base pairs, contains roughly 37 genes that code for two ribosomal RNA's, 22 transfer RNA's, and 13 proteins that combine with over 70 other n-encoded proteins to form the respiratory chain (Anderson et al., 1981). Transcription, translation, and mtDNA replication including synthesis of ribosomal proteins are all under nuclear regulation. Consequently, mitochondrial function depends upon the tightly coordinated interaction between nDNA and mtDNA-encoded proteins, protein assembly factors, and chaperone proteins involved in protein folding, protein scaffolding, and structural support (Nijtmans et al., 2002; Rabilloud et al., 2002; Ryan and Hoogenraad, 2007).

Nuclear encoded proteins destined for the mitochondria must be unfolded prior to transport through the outer (TOM) and inner (TIM) membrane translocase proteins (Ryan and Hoogenraad, 2007). After transit through these protein channels, the proteins are refolded within the mitochondria by chaperone proteins, e.g., heat shock proteins 70 (Hsp70), Hsp 60/10 (also called Chaperonin 60/10), Hsp78, and a number of proteases. Chaperone protein expression increases during stress (e.g., heat, oxidative, toxin-mediated) when they are particularly important in stabilizing and repairing damaged proteins.

The D loop of mtDNA contains regulators of mitochondrial transcription and replication. Differences in D loop mtDNA have been used to identify animals with different mitochondrial types. Some proteins are part of the mitochondrial import machinery, whereas others are needed for expression of the mitochondrial genome and metabolism. Other proteins are required for mitochondrial roles in apoptosis (Liu and Kitsis, 1996), redox cell signaling, and homeostasis (Bogoyevitch et al., 2000; Levonen et al., 2001; Droge, 2002). Rabilloud et al. (2002) indicated that "… *mitochondrial function in general, and mitochondrial protein synthesis in particular, depend on the conjugated and coordinated expression of both mitochondrial and nuclear genomes.*" A complex communication network between mitochondria and the nucleus also exists to coordinate mitochondrial biogenesis and function (Poyton and McEwen, 1996).

6.1.4 The respiratory chain and adenosine triphosphate synthesis

The ETC, first reported by Kennedy and Lehninger (1949), consists of five multiprotein enzyme complexes: Complex I (NADH: ubiquinone oxido-reductase), Complex II

(succinate: ubiquinone reductase), Complex III (ubiquinol: cytochrome *c* oxido-reductase), Complex IV (cytochrome *c* oxidase), and the F_1F_0 ATP synthase or ATPase (Complex V), and two mobile electron carriers, ubiquinone (Q) and cytochrome *c* (cyt *c*) (Figs. 6.1 and 6.2). Electrons enter the respiratory chain at Complex I for NADH-linked substrates (e.g., malate and pyruvate), or at Complex II for succinate, an $FADH_2$-linked substrate (Fig. 6.2). Ubiquinone carries electrons from Complex I and II to Complex III while cyt *c* shuttles electrons from Complex III to Complex IV. Electron transfer to O_2 (the terminal acceptor) results in full reduction of O_2 to water. Electron movement coincides with proton pumping to establish a proton motive force consisting of a membrane potential ($\Delta\psi_m$) and pH (proton) gradient that provide energy for ATP synthesis as protons flow back into the matrix through ATP synthase (Complex V). Protons can also cross the inner mitochondrial membrane at sites other than the ATP synthase due to anion carrier proteins (e.g., adenine nucleotide transporter, glutamate transporter), uncoupling proteins (UCPs), and intrinsic membrane characteristics (Brown and Brand, 1991; Brand et al., 1994, 2005; Rolfe and Brand, 1997; Brookes et al., 1997). Proton leak therefore consumes O_2 and dissipates the membrane potential without ATP synthesis. Uncoupling represents an inefficiency of mitochondrial function, but minimizes ROS production (see below). While mitochondrial uncoupling is important in heat generation in brown adipose fat tissue in mammals, brown adipose tissue has not been reported in any avian species and appears to have been lost early in evolution of the avian lineage from a common ancestor of birds and mammals (Mezentseva et al., 2008).

6.1.4.1 Ubiquinone (coenzyme Q)

Electron transfer from Complex I to Complex III and from Complex II to Complex III is carried out by ubiquinone (coenzyme Q; e.g., CoQ_9 and CoQ_{10}). Autooxidation of CoQ is a major source of mitochondrial ROS production (Chance et al., 1979; Turrens et al., 1985; Turrens and Boveris, 1980). Animals with relatively more CoQ_{10} had lower mitochondrial ROS production than those with higher CoQ_9 levels (Lass and Sohal, 1999), and CoQ content is highly correlated with Complex I and II activities (Ernster and Forsmark-Andree, 1993; Forsmark-Andree et al., 1997).

6.1.4.2 Cardiolipin

Cardiolipin (tetra-acyl-diphosphatidyl-glycerol) is a unique phosphorglyceride with four long-chain fatty acids compared to two side chains in typical phospholipids that is essential for membranes involved in coupled (oxidative) phosphorylation (Hoch, 1992). Full activity requires the interaction of each complex (I to V) with cardiolipin. Yeast lacking cardiolipin exhibit impaired mitochondrial function (Koshkin and Greenberg, 2000). Exogenously added cardiolipin depressed respiratory chain coupling but increased ATP synthase activity in isolated liver mitochondria (Bobyleva et al., 1997).

6.1.5 Assessing mitochondrial function

6.1.5.1 Polarographic method

A standard method of assessing mitochondrial function utilizes an O_2 electrode in a Warburg apparatus to measure O_2 consumption with different respiratory states in freshly isolated mitochondria (Estabrook, 1967). In the presence of NADH- and FADH-linked energy substrates, mitochondria exhibit an initial slow rate of O_2 consumption (State 2 respiration). The addition of ADP stimulates ETC activity and initiates rapid O_2 consumption that is followed by a slower rate of O_2 consumption (State 4 respiration) when ADP levels decline (i.e., ADP is limiting) due to oxidative phosphorylation and synthesis of ATP (from ADP and inorganic phosphorus). Functional indices calculated from these data include the respiratory control ratio (RCR) and ADP:O ratio (Estabrook, 1967). The RCR represents the degree of coupling or efficiency of respiratory chain activity and is calculated as State 3 (active respiration) divided by State 4 (resting) respiration rate. The ADP:O ratio is the amount of ADP phosphorylated per nanoatom of monomeric oxygen consumed during State 3 respiration and is an index of oxidative phosphorylation. Electron movement down the transport chain is coupled to proton pumping, setting up the proton motive force that synthesizes ATP as protons flow through the f_1f_0ATPase. The ADP:O ratio, an index of oxidative phosphorylation, is determined as ADP used per nmol monomeric oxygen during State 3 respiration. Theoretical ADP:O ratios are 2 (for succinate) and 3 (for malate) that enter at Complex I and II, respectively. ATP synthesis is not 100% efficient due in part to electron and proton leak. Decreases in the ADP:O ratio (increased O_2 use that is uncoupled from ATP synthesis) occur by (a) proton leakage across the inner mitochondrial membrane at sites other than the F_1F_0 ATPase (Brand et al., 1994) or (b) electron leakage from the respiratory chain that react with O_2 to form ROS such as superoxide and H_2O_2 (Boveris and Chance, 1973; Chance et al., 1979, see Section 6.1.5.2 below).

6.1.5.2 Flux analysis

A relatively new approach to assess mitochondrial function in intact cells using flux analysis of oxygen consumption rate was reported by Wu et al. (2007). The advantage of this method is that mitochondrial function can be assessed within intact cells which eliminates any artifacts (e.g., sheer

stress) that might be introduced from stirring that is a requirement of the polarographic method of Estabrook (1967). Assessment of glycolytic activity can also be determined simultaneously by assessment of extracellular acidification rate. Metabolic inhibitors will stimulate glycolytic activity.

Flux analysis was used to assess bioenergetic in response to 4-hydroxy 2-nonenal (4-HNE) induced oxidative stress in chicken embryo fibroblast (CEF) cells and a spontaneously immortalized CEF cell (DF-1) (Lassiter et al., 2014). It was determined that senescent CEF cells (passage 19) were more susceptible to 4-HNE-induced oxidative stress than younger (passage 8) CEF cells, but surprisingly, the immortal DF-1 cells were more sensitive to oxidant challenge than the CEF cells. Greater sensitivity to oxidant challenge following 4-HNE treatment may have been due to an inability of DF-1 cells to increase proton leak in comparison to CEF cells.

6.1.6 Mitochondrial role in apoptosis

Mitochondria are critical in initiating programmed cell death or apoptosis (Wallace, 1999). Between the inner and outer mitochondrial membranes are cytochrome *c*, apoptosis-inducing factor, and caspases (proteases) that contribute to apoptosis. Apoptosis is initiated by formation of the mitochondrial permeability transition pore (mtPTP) on the inner membrane. The mtPTP forms by the coalescing of the voltage-dependent anion channel (VDAC), adenine nucleotide translocase (ANT), BCL-2-associated X protein, and cyclophilin D. When the mtPTP is formed, the mitochondrial membrane potential is dissipated followed shortly thereafter by mitochondrial swelling and release of caspases and apoptosis initiating factor. The proteolytic caspases released into the cytoplasm degrades the cytoskeletal architecture. Events that trigger the opening of the mtPTP include (a) a decrease in energetic capacity of the mitochondria, (b) excessive influx of ionic calcium, and (c) increased ROS generation.

6.2 Mitochondrial inefficiencies, oxidative stress, and antioxidants

6.2.1 Electron transport defects and oxidative stress

6.2.1.1 Reactive oxygen species

Mitochondria are a major source of endogenous oxidative stress; 2−4% of O_2 used by mitochondria may be converted to ROS by univalent reduction of O_2 to form superoxide ($O_2\cdot^-$) following electron (e−) leak from the respiratory chain (Boveris and Chance, 1973; Chance et al., 1979; Turrens and Boveris, 1980). Superoxide dismutase (SOD) converts $O_2\cdot^-$ to H_2O_2 that is reduced to H_2O by GSH peroxidase (GPx). The relatively nonreactive H_2O_2 is converted to the highly reactive hydroxyl radical (•OH) in the presence of Fe^{2+} and Cu^{2+}, and due to its lipid solubility, is able to cross membranes and oxidize proteins, DNA, lipids, and carbohydrates throughout the cell (Yu, 1994, See Figs. 6.1 and 6.3).

6.2.1.2 Identification of site-specific defects in electron transport

Fig. 6.3 shows sites of e-leak that are accentuated by treatment with various chemical inhibitors. The use of these chemicals for identifying e−transport defects were pioneered by Boveris and Chance (1973), Chance et al. (1979), Turrens and Boveris (1980). Numerous reports followed that confirmed Complex I and III as predominant sites of mitochondrial e−leak and associated with numerous metabolic diseases in humans including Alzheimer, cancer, diabetes, and aging (Yu, 1994).

A criticism of the use of chemical inhibitors used in studies such as those mentioned above is that they cause maximum ROS production that can greatly exceed actual rates relative to basal noninhibited states (Goncalves et al., 2015; Brand, 2016). In their studies a total of 10 sites of electron leak were revealed in muscle mitochondria when media was used that mimicked skeletal muscle during rest and exercise states; generation of ROS was much greater in media mimicking muscular rest than in mild or intense exercise.

6.2.1.3 Nitric oxide and reactive nitrogen species

Nitric oxide (NO) produced by mitochondrial nitric oxide synthase (NOS) near the site of the ETC (Giulivi et al., 1998; Giulivi and Oursler, 2003) competitively inhibits cytochrome oxidase thus regulating mitochondrial O_2 consumption. The release of NO in the presence of ROS can produce a large number of reactive nitrogen species (RNS, e.g., peroxynitrite) that damage proteins by nitrosylation. Peroxynitrite was reported to be responsible for decreased activities of Complex I and II in mitochondria (Riobo et al., 2001).

6.2.1.4 DNA damage and respiratory chain complex activities

A correct balance of mtDNA- and nDNA-encoded proteins is needed for functional integrity of mitochondria (Nijtmans et al., 2002). Due to its proximity to the respiratory chain and a lack of protective histones, mtDNA is more susceptible to mitochondrial ROS-mediated oxidation than nDNA, and mtDNA oxidation can lead to mitochondrial

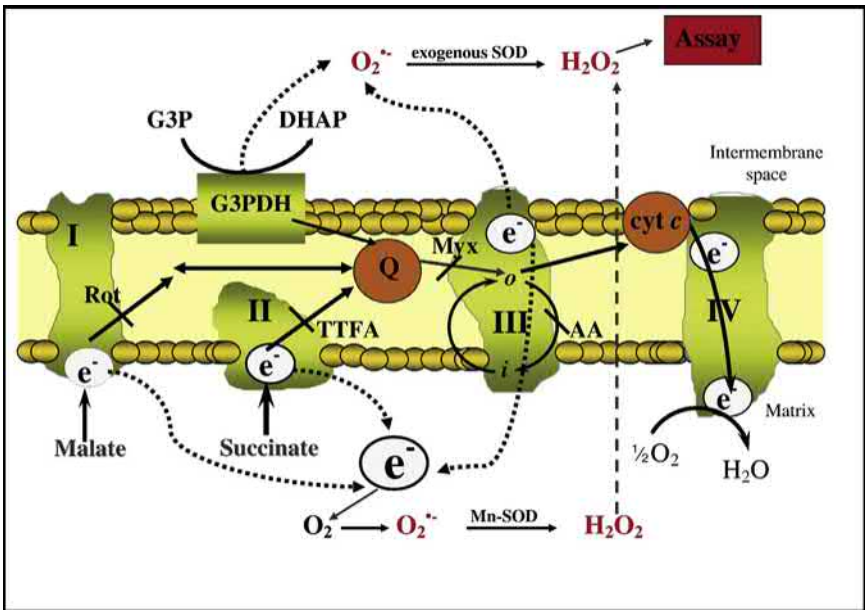

FIGURE 6.3 Diagrammatic representation of identification of site-specific defects in the electron transport chain using chemical inhibitor. The movement of electrons (e−) along the respiratory chain is shown by *solid arrows* from Complex I or Complex II to Complex III by the e−carrier, Coenzyme Q (Q) and to complex IV by cytochrome *c* (cyt *c*). The terminal step of electron transport is the full reduction of oxygen (O_2) to water by cytochrome *c* oxidase. Chemicals used to block e−transport and identify site-specific defects are rotenone (Rot) at Complex I, thenoyltrifluoroacetone (TTFA) at Complex II, and Myxothiazol (Myx) (at the outer membrane [*o*]) and antimycin A(AA) (at the inner membrane [*i*]) within Complex III. If a site-specific defect exists at any of these sites following chemical inhibition, e−leak (*dotted arrows*) results in the univalent reduction of O_2 to superoxide ($O^{\bullet}-$) that is reduced by hydrogen peroxide (H_2O_2) by superoxide dismutase (SOD). Topology of H_2O_2 formation (as in index of reactive oxygen species, ROS) can be determined by adding exogenous SOD to the media in isolated mitochondrial preparations that distinguishes it from endogenous ROS that is for by the mitochondrial located MnSOD (see Miwa et al. (2003)). Extramitochondrial e−leak can also occur when glyceraldehyde three- phosphate (GSP) is converted by G3P dehydrogenase (G3PDH) to dihyroxyacetone phosphate (DHAP). *Reprinted by permission Ojano-Dirain et al. (2007a).*

dysfunction (Kristal et al., 1994; Wei, 1998). Oxidant-medicated repression of mitochondrial transcription can exacerbate mitochondrial dysfunction by inhibiting respiratory protein synthesis (Kristal et al., 1997). Restricted availability of mt-encoded subunits or damaged proteins can lead to diminished complex activities and cell respiration (Wallace, 1999). There are also specific thiols in proteins of Complexes I, II, and IV that are particularly susceptible to oxidation that decrease complex activity upon exposure to oxidants (Lin et al., 2002b). Inverse relationships between oxidative stress and complex activity were noted in animals with low-feed efficiency (Ojano-Dirain et al., 2005; Bottje and Carstens, 2009).

6.2.1.5 Specific protein targets of mitochondrial reactive oxygen species

Mitochondrial ROS produced by Complex I (rotenone sensitive site) are exclusively released into the mitochondrial matrix whereas ROS produced at the ubiquinone-CIII site are confined to the intermembranous space (Han et al., 2001; St Pierre et al., 2002; Muller et al., 2004). Bleier et al. (2015) hypothesized that ROS generated at CI, which is in close proximity to mitochondrial DNA and redox sensitive proteins in the ETCs, would cause oxidation, whereas ROS from CIII would primarily participate in signal transduction reactions. Using two-dimensional gel electrophoresis with fluorescent detection, Bleier et al. (2015) identified specific proteins that were oxidized by ROS produced at CI (by reverse electron transport [RET] described below) differed from proteins oxidized by ROS generated at CIII (by forward electron transport) in isolated rat heart mitochondria. They concluded that there was a distinct difference in the proteins that were oxidized depending on the site of ROS production. Bleier et al. (2015) hypothesized that these proteins could " … *serve as biomarkers to study the generator-dependent dual role of mitochondrial ROS in redox signaling and oxidative stress*".

6.2.1.6 Mitochondrial reactive oxygen species generation in avian species

The use of chemical inhibitors shown in Fig. 6.3 has been used to assess mitochondrial ROS production in birds. In broilers, site-specific defects in e-leak at Complex I and III were identified in liver, lung, skeletal, and cardiac mitochondria obtained from birds exhibiting fulminant pulmonary hypertension syndrome (Cawthon et al., 2001; Iqbal et al., 2001; Tang et al., 2002). Greater ROS production due to site-specific defects in e−transport was also identified in

Complex I and III skeletal muscle, liver, and duodenal mitochondria associated with low-feed efficiency in broilers (Bottje et al., 2002; Iqbal et al., 2004; Ojano-Dirain et al., 2004, 2007a) as well as Complex II in duodenal tissue (Ojano-Dirain et al., 2004). Greater ROS production was likely responsible for higher oxidative stress and lower respiratory chain complex activities consistently observed in animals exhibiting a low-feed efficiency phenotype (Bottje and Carstens, 2009; Ojano-Dirain et al., 2007b) and may have been involved in differential gene expression in feed efficiency in broilers (Bottje and Kong, 2013). Mitochondrial ROS production has also been shown to play a role in heat stress (Abe et al., 2006; Mujahid et al., 2006, 2007, 2009).

Mitochondrial ROS production is generally lower in avian compared to comparable size mammalian species with an inverse relationship between longevity and mitochondrial ROS production (Herrero and Barja, 1997, 1998). Fig. 6.4 presents data of heart mitochondrial ROS production in comparable sized mammals and birds (Herrero and Barja, 1997, 1998) in the presence or absence of ETC inhibitors shown in Fig. 6.3. This species difference is even more remarkable since birds have a number of characteristics that should favor heightened mitochondrial radical production such as higher body temperatures, metabolic rates, and blood glucose concentrations (Holmes and Austad, 1995; Holmes et al., 2001). The fact that birds have much lower mitochondrial ROS production has been hypothesized to explain lower mitochondrial DNA diversity in avian compared to mammalian species (Hickey, 2008).

6.2.2 Mitochondrial uncoupling and attenuation of oxidative stress

Proton motive force provides the power that "drives" ATP synthesis when protons flow back into the matrix through ATP synthase (Complex V). However, protons that flow into the mitochondrial matrix at sites other than the ATP synthase (proton leak) dissipates proton motive force, diminishes mitochondrial membrane potential, and short circuits ATP synthesis (Brand et al., 1994). Oxygen consumption from proton leak can represent 25% of total basal metabolic rate in animals (Rolfe and Brand, 1997). Basal proton leak (or conductance) is facilitated by intrinsic characteristics of membranes and the presence of intramembranous proteins (e.g., UCPs, adenine nucleotide translocase [ANT]) (Brown and Brand, 1991; Rolfe and Brand, 1997; Brookes et al., 1997, 1998; Brand et al., 2005; Dilger et al., 1979). Free fatty acids enhance proton-translocating activities of ANT, UCPs, and phosphate and glutamate carrier proteins (Andreyev et al., 1988, 1989; Echtay et al., 2001; Samartsev et al., 1997; Jaburek et al., 1999). Proton leak is also stimulated by hyperthyroidism and diminished by hypothyroidism (Hafner et al., 1990).

Proton leak represents an energetic inefficiency, but plays an important role in attenuating mitochondrial ROS production and endogenous oxidative stress. A self-limiting

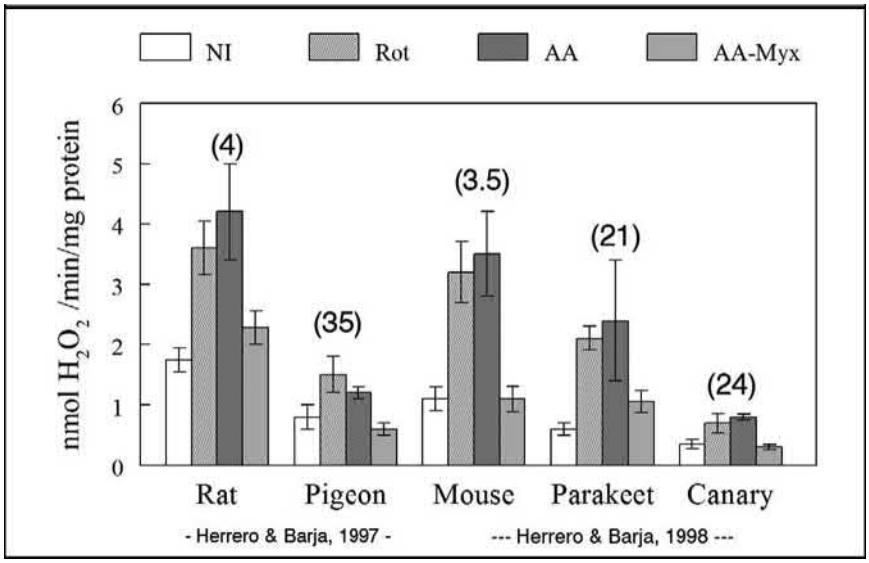

FIGURE 6.4 Hydrogen peroxide (H_2O_2) production rates (expressed as nmol/min/mg protein) in heart mitochondria isolated from mammals and birds of comparable body weights (rat vs. pigeon; mouse vs. parakeet and canary). Rates of H_2O_2 production are shown for mitochondria treated with no-inhibitor (NI, basal rate), and for mitochondria treated with inhibitors of Complex I (rotenone, Rot), and two inhibitors of Complex III (antimycin A, AA and myxothiazol, Myx, alone and in combination). The maximum life span for each animal species is shown in parentheses. *Data were obtained from Herrero and Barja (1997, 1998).*

feedback of superoxide on mitochondrial ROS production (Skulachev, 1996, 1997) is due to increased expression and activity of UCPs and ANT (Echtay et al., 2002; Murphy et al., 2003; Brand et al., 2004). This mechanism is depicted in Fig. 6.5 which is a composite of Figs. 6.1 and 6.2 from Brand et al. (2004).

Uncoupling to reduce mitochondrial ROS generation has been clearly demonstrated in several avian species. In birds, the initial sequencing of the avian uncoupling protein (avUCP) was reported by Raimbault et al. (2001) and confirmed shortly after by Toyomizu et al. (2002). Uncoupling of mitochondria represents an important physiological response to attenuate oxidative stress during both cold and heat stress conditions. Toyomizu et al. (2002) reported that ANT and UCP mRNA were upregulated in cold stressed chicken skeletal muscle. Increased UCP and ANT expression has been observed in skeletal muscle of chickens (Toyomizu et al., 2002), king penguins (Talbot et al., 2003, 2004), and in cold-acclimated ducks (Rey et al., 2010) that attenuates cold-induced increases in mitochondrial ROS production. Increased mitochondrial ROS and oxidative stress has also been observed in heat-stressed chicken skeletal muscle (Mujahid et al., 2007a,b). It was determined that olive oil attenuated mitochondrial ROS production during heat stress (Mujahid et al., 2009). The increased ROS production during heat stress was due to a combination of down-regulation of avUCP expression and an increase in inner mitochondrial membrane potential (Mujahid et al., 2006; Kikusato and Toyomizu, 2013).

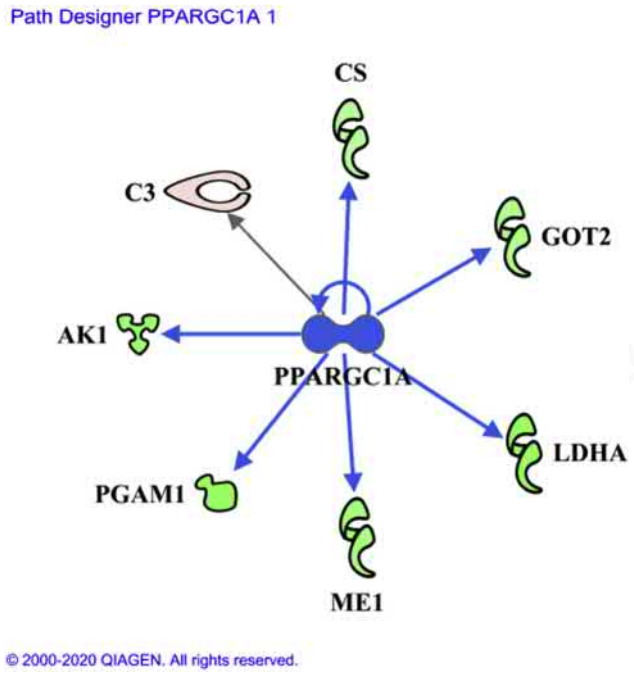

FIGURE 6.5 Attenuation of mitochondrial reactive oxygen species formation by increased uncoupling activity of adenine nucleotide translocase (ANT) and uncoupling protein (UCP). Shown in the figure are the outer and inner mitochondrial membranes (OMM and IMM) and intramembranous space (IS) within which proton motive force is generated by pumping of protons from the matrix into the IS. Proton leak occurs when protons move across the IMM at sites other than the ATP synthase. Electron leak from flavin and iron-sulfur centers in proteins of complex I, and from co-enzyme Q into the mitochondrial matrix causes univalent reduction of oxygen to superoxide ($O\cdot-$). In the presence of free iron (Fe^{2+}) that can be released from oxidative damage of matrix proteins (e.g., aconitase) results in the formation of hydroxyl radical ($\cdot OH$) that abstracts an electron from polyunsaturated fatty acid to form a carbon-centered fatty acid radical (FA radical) and an FA peroxyl radical in the presence of oxygen. This leads to the formation of a stable reactive alkenal, 4-hydroxy 2-nonenal (4-HNE) that stimulates uncoupling activity (proton leak) by ANT and UCP. Increased proton leak in turn dissipates proton motive force and mitochondrial membrane potential that reduces electron leak and mitochondrial reactive oxygen species formation. *Based on Echtay et al. (2002), Murphy et al. (2003), Brand et al. (2004).*

Differences in proton leak and mitochondrial membrane potential have also been linked to the phenotypic expression of feed efficiency in broilers (Ojano-Dirain et al., 2007a; Bottje et al., 2009). Enhanced ROS production was observed in muscle, liver, and duodenal mitochondria of broilers with low-feed efficiency compared to broilers with high-feed efficiency due to site-specific defects in electron transport (Ojano-Dirain et al., 2004; Bottje et al., 2004; Iqbal et al., 2005). Using a number of different chemical treatments, it was observed that proton leak in broilers with a high-feed efficiency phenotype exhibited proton leak that was either lower or equal to, but never higher than proton leak in broilers exhibiting a high-feed efficiency phenotype (Bottje et al., 2009). Observations of increased (<0.06) expression of avUCP and lower membrane potential in low feed efficiency mitochondria (Ojano-Dirain et al., 2004, 2007) are consistent with the model presented in Fig. 6.5 to minimize or attenuate mitochondrial ROS formation.

6.2.3 Antioxidants

It is difficult to discuss oxidation without also discussing antioxidants. Oxidative stress develops when the generation of ROS overwhelms antioxidant protection (Yu, 1994). Repair of damaged structures (e.g., lipids, proteins) is energetically expensive requiring considerable input of ATP to either repair or recycle materials within the cell. Mitochondrial ROS are normally metabolized by the enzymatic antioxidants, SOD, and glutathione peroxidase, as well as by nonenzymatic antioxidants GSH and α-tocopherol (Yu, 1994).

Glutathione is the major endogenous antioxidant system both in the cytosol and within mitochondria (Meister, 1984; Griffith and Meister, 1985; Martensson et al., 1993). Glutathione exists in either a reduced (GSH) or oxidized (GSSG; glutathione disulfide) form, and the GSSG:GSH ratio is used as an indicator of oxidative stress. The glutathione reduction-oxidation (redox) system consists of GSH

and the GSH recycling enzymes, GPx, and GSH reductase (GR) (Meister, 1984). The enzyme GPx metabolizes peroxides (e.g., H_2O_2) using reducing equivalents from GSH and catalyzes the reaction shown in Eq. (6.1):

$$2\ GSH + H_2O_2 \rightarrow GSSG + 2\ H_2O \quad (6.1)$$

Low levels of GSSG are maintained by GR, which utilizes nicotinamide adenine dinucleotide phosphate ($NADPH_2$) to reduce GSSG to GSH as shown in Eq. (6.2):

$$GSSG + NADPH_2 \rightarrow 2\ GSH + NADP^+ \quad (6.2)$$

The glutathione redox system is a vital defense mechanism of mitochondria against free radical damage as mitochondria lack catalase (Martensson et al., 1990), γ-glutamyl synthetase (the rate limiting enzyme in GSH synthesis) (Meister, 1984), and the ability to export GSSG (Olafsdottir and Reed, 1988). Martensson et al. (1990) noted that the mitochondrial GSH transport system might be designed to efficiently conserve mitochondrial GSH at the expense of cytosolic GSH.

During oxidative stress, toxic levels of GSSG can accumulate within mitochondria (Olafsdottir and Reed, 1988; Cawthon et al., 1999). Unlike cells, mitochondria are unable to export GSSG from the mitochondria leading to thiolation of critical proteins in the ETC and diminished activities for the respiratory chain complexes. Augustin et al. (1997) reported that mitochondria are not damaged by ROS as long as the mitochondria are in an energized state in which ROS production is minimized. Other research indicates that GSH levels are critical in maintaining or protecting respiratory chain complex activity from oxidation and positive correlations between GSH and respiratory chain activity have been reported (Ojano-Dirain et al., 2005; Bolanos et al., 1996; Cardoso et al., 1999).

6.3 Signal transduction and reverse electron transport

6.3.1 Low mitochondrial reactive oxygen species levels

Whereas high levels of ROS are detrimental, low levels of mitochondrial ROS act in signal transduction processes that are recognized as being vital for normal cell function processes (e.g, Giulivi and Oursler (2003), Crawford et al. (1997), Carper et al. (1999), Greiber et al. (2002), Li et al. (2002), Kemp et al. (2003)). Baughman and Mootha (2006) hypothesized "… *a homeostatic role for ROS in maintaining stable respiratory phenotypes across genetic variants of the mitochondrial genome.*" Finkel (2011) proposed that H_2O_2 stimulated several signaling pathways by oxidizing cysteine moieties of key regulatory proteins that are modulated by antioxidants such as peroxiredoxin (Rhee et al., 2005). Low levels of mitochondrial ROS contribute to mitochondrial-mediated signal transduction mechanisms (Finkel, 2011; Murphy et al., 2011) in a process designated as "mitochondrial hormesis (mitohormesis)" (Barbieri et al., 2013). Furthermore, whereas mitochondrial ROS generated from Complex I is associated with oxidative stress, ROS generated from Complex III is primarily involved in signal transduction (Sena and Chandel, 2012; Bleier et al., 2015). RET in the mitochondria is now recognized to be vital to a number of physiological conditions (see review by Scialo et al. (2017)).

6.3.2 Cellular nutrient utilization

Guaras et al. (2016) demonstrated that RET enables mitochondria to efficiently use different energy sources entering the transport chain. In this mechanism, the ratio of reduced coenzyme Q ($CoQH_2$) to oxidized CoQ[1] is a sensor that functions to optimize energy use by stimulating RET. The ETC is composed of five multiprotein complexes (see above) that can be arranged into supercomplexes consisting of CI + CIII + CIV and CI + CIII (Acin-Perez et al., 2008; Enriquez, 2016). It is proposed that these supercomplex arrangements creates two functional pools of CIII; one associated and another not associated with CI (Lapuente-Brun et al., 2013). When the energy source switches from glucose to fatty acids, ROS produced by RET degrade CI, the result of which increases mitochondrial fatty acid β-oxidation. Thus, remodeling of the ETC is a response to ubiquinone acting as a metabolic sensor that positions the mitochondria to efficiently oxidize different nutrients as they become available in the cell.

6.3.3 Macrophage function

Mitochondria enable macrophages to quickly shift from "attack and destroy" to a "heal and rebuild" cell needed for tissue repair after the initial foreign invasion or insult. In a bacterial infection, the ETC reorganizes resulting in a decrease in CI activity and an increase in CII activity (Garaude et al., 2016). The ability of macrophages to switch between these very different functional phenotypes occurs through a shift in mitochondrial energy production (from OXPHOS to glycolysis) concomitant with an increase in membrane potential that helps drive RET-derived ROS production and proinflammatory cytokine production (Mills et al., 2016). This redirection of mitochondrial function is a result of succinate accumulation with increased succinate dehydrogenase activity. Inhibition of proinflammatory cytokines in macrophages was achieved by (a) treating cells with dimethyl malonate to prevent succinate oxidation, (b) treating cells with rotenone to

1. CoQ transfers electrons from CI to CIII and CII to CIII.

block reverse electron flow from succinate, and (c) preventing CoQ reduction. RET from succinate is therefore essential for initiating an inflammatory response in macrophages.

6.3.4 Ischemia-reperfusion injury

When blood supply is interrupted (e.g., heart attack, stroke, or severe blood loss) and followed by blood flow restoration, oxidative damage of tissues occurs from a hyperimmune response and a burst of mitochondrial ROS production. Mitochondrial ROS generated during reperfusion was considered mainly a nonspecific response to increased oxygen levels (e.g., Murphy and Steenbergen (2008)). However, Chouchani et al. (2014) demonstrated that succinate accumulation during ischemia drives mitochondrial ROS generation during reperfusion due to RET from Complex II to Complex I. Ischemic damage of heart and brain tissue was prevented by rotenone (that blocks RET from CII to CI) and by inhibition of succinate dehydrogenase with dimethyl malonate.

6.3.5 Muscle differentiation

Many myogenic regulatory factors promote satellite cell differentiation to form myoblasts and myotubes in avian species (see Velleman and McFarland (2015)). Hydrogen peroxide produced by NADPH oxidase is instrumental for cardiac and muscle cell differentiation (Piao et al., 2005; Buggisch et al., 2007). Since H_2O_2 is lipid soluble, it readily crosses membranes in the various cell compartments. Using mitochondria specific antioxidants (MitoQ and MitoTEMPOL), it was determined that suppression of muscle differentiation was concomitant with decreased mitochondrial ROS production (Lee et al., 2011). This response was not due to inhibition of electron transport or ETC activity since these antioxidants had no effect on ATP production. During differentiation, there was an increase in mitochondrial content and increased expression and activity of CI. Treating cells with small inhibitory RNA or blockade of electron transport in CI inhibited muscle cell differentiation. It was concluded that superoxide produced by RET at CI was converted to H_2O_2 by MnSOD that stimulated muscle differentiation in response to NF-kB activation (Lee et al., 2011).

6.3.6 Aging and longevity

Examination of the mitoproteome that focused on CI assembly and stabilization produced a new insight into the role of mitochondria in aging (Miwa et al., 2003). CI is the largest complex of the respiratory chain containing ~40 proteins with two arms; one that extends into the mitochondrial matrix and a second arm that is found primarily within the inner mitochondrial membrane. The mitoproteome of young animals had reduced abundance of proteins in the matrix arm of CI in long-lived animals, but there was no difference in the abundance of the membrane arm of CI between short-lived and long-lived groups. Disruption of CI assembly reduced oxidative metabolism and elevated mitochondrial ROS production. Disruption of CI assembly resulted in premature senescence in primary hepatocytes. Miwa et al. (2003) hypothesized that decreased abundance of proteins in the catalytic component of CI improves assembly of the enzyme complex, improves substrate utilization while reducing mitochondrial ROS production and increasing longevity.

6.4 Matching energy production to energy need

6.4.1 Mitochondrial dynamics

Initial electron micrographs of mitochondria suggest that kidney shaped image of mitochondria as being a static organelle (Lehninger et al., 1993, p.39). Electron tomography (Mannella, 2000) provided a three-dimensional view of a sausage-like appearance of mitochondria extending through the cytosol with intimate connections to endoplasmic reticulum that could facilitate communication with the rest of the cell, protein transfer, and signaling. It is now apparent that mitochondrial fission and fusion events regulate mitochondrial function over a broad spectrum of available energy sources that can serve to cull defective organelles from the "mitochondrial herd" (see reviews by Hoppins et al. (2007), Archer (2013), Liesa and Shirihai (2013), Rambold and Pearce (2018)). In addition, it is clear that intimate connections of mitochondria with other organelles in the cell including the nucleus, endoplasmic reticulum, and lysosomes help in movement of proteins and as pathways for cell signaling to optimize cell function (Rambold and Pearce, 2018).

Liesa and Shirihai (2013) provided a review of fission and fusion events in a mitochondrial life cycle that is depicted in Fig. 6.6. In a nutrient limiting environment (e.g., starvation), mitochondria become elongated (fuse) and more efficient in producing ATP from energy substrates. In the face of excess nutrient availability, mitochondria divide (fragment) to become less efficient in oxidative phosphorylation and burning off excess fuel supply in the cell. In this fragmentation process, the endoplasmic reticulum targets the mitochondria with proteins, including mitofissin, dynamin, and dynamin-like 120 kDa—protein (**OPA-1** short) that split the mitochondria in two. Fission is part of the mitochondrial life cycle that allows mitochondria to adapt to different amounts of available nutrients. In the life cycle,

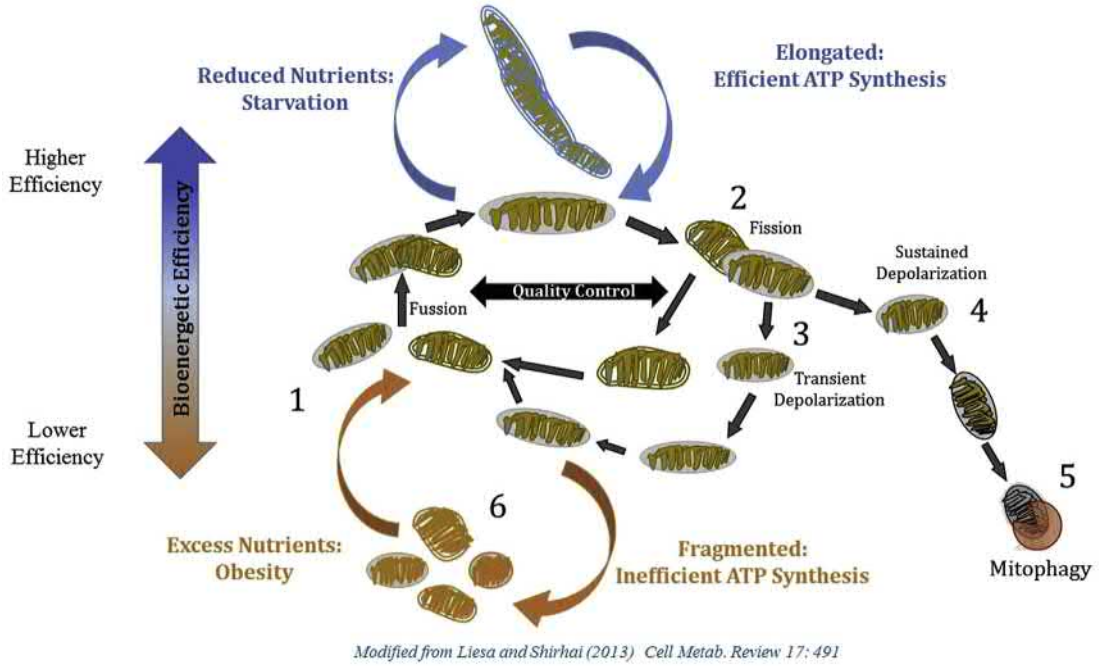

FIGURE 6.6 **Life cycle of mitochondria.** A mitochondrial life cycle was described by Liesa and Shirihai (2013). In this life cycle, mitochondria raise or lower energetic efficiency through biochemical and conformation changes in response to low or excess nutrient levels. In fusion events (1) two daughter cells can combine to form a single mitochondria. With nutrient limiting conditions (e.g., starvation, or possibly high energy demand such as muscle activity or rapid growth), mitochondria elongate and become more efficient in utilizing available substrate. Once nutrient levels are no longer limiting, the mitochondria return to normal size. Parts of the mitochondria may experience oxidative damage and increased mitochondrial reactive oxygen species (ROS) production with concomitant oxidation of mt-DNA. When this occurs, the endoplasmic reticulum will present specialized proteins (mitofissin, OPA-1, dynamin) to initiate mitochondrial fission (2). In this quality control process, the damaged or poorly functioning mitochondria with depolarized inner mitochondrial membrane will split from the optimal functioning mitochondria. If the mitochondria recover from depolarization, it will return to the mitochondrial life cycle (3). If mitochondria experience sustained membrane depolarization (4), it will be targeted for degradation by mitophagy (5). In response to excess nutrients (e.g., obesity), mitochondria fragment (6) and become less efficient in oxidative phosphorylation. Fragmentation is accompanied by increased mitochondrial ROS production that can have deleterious consequences to the cell. When cell nutrients levels decline, the mitochondria will return to the mitochondrial life cycle.

dysfunctional mitochondria are destined for removal by mitophagy (Fig. 6.6), thereby raising the collective function of the remaining mitochondrial population ("mitochondrial herd") in cells.

Regulation of mitochondrial dynamics by the orexin system in avian muscle cells was provided by Lassiter et al. (2015). After showing that orexin was secreted by quail muscle 7 (QM7) cells, it was determined that treating the cells with recombinant orexin A (rORX-A) and orexin B (rORX-B) down-regulated and upregulated mtDNA expression, respectively, indicating inhibition and stimulation of mitochondrial biogenesis. Furthermore, rORX-A inhibited genes associated with mitochondrial fusion (MFN1, OPA-1, and OMA1) and stimulated genes associated mitochondrial fission (MTFP1 and DNM1 and MTFR1) whereas rORX-B stimulated mitochondrial fusion by upregulating MFN2, OPA1, and OMA1. The findings by Lassiter et al. (2015) presented the first evidence of a physiological role of the orexin system in avian cells in regulating mitochondrial dynamics that could be hypothesized to play an important role in growth and development in birds if similar relationships occurred between orexin and mitochondria in vivo.

6.4.2 Mitochondrial biogenesis

Whereas mitochondria divide during mitosis to insure daughter cells are provided a full complement of functional mitochondria, mitochondrial biogenesis is stimulated in response to increased energy demand. An early demonstration of mitochondrial biogenesis was provided by Paul and Sperling (1952) who observed that there were more mitochondria in breast muscle from pigeons that are more active than the relatively sedentary commercial chicken. One of the first factors identified to increase mitochondrial biogenesis was peroxisome proliferator-activated gamma coactivator 1-alpha (PGC-1α) (Puigserver et al., 1998; Wu et al., 1999). Cold exposure increased the mRNA expression of PGC-1α that in turn increased the expression of several mitochondrial proteins including ATP synthase and cytochrome c-oxidases II and IV. PGC-1α as well as PGC-1β stimulate nuclear respiratory factors (NRF-1 and

NRF-2) and mitochondrial transcription factor A (TfamA) (Nisoli et al., 2003, 2004) that up-regulate mitochondrial transcription factor A (mtTFA) by independent mechanisms (Meirhaeghe et al., 2003; Lin et al., 2002a). NRF1 and NRF2 stimulate mitochondrial protein synthesis, e.g., ETC proteins, whereas mtTFA stimulates mitochondrial DNA transcription that is instrumental in synthesis of mitochondrial proteins during mitochondrial biogenesis. Because of its role in mitochondrial biogenesis, PGC-1α has been termed the master regulator of mitochondrial protein synthesis (Nisoli et al., 2003, 2004).

6.4.3 Adenosine monophosphate–activated protein kinase

Adenosine monophosphate (AMP)-activated protein kinase (AMPK) is critical for (a) sensing cellular energy (AMP/ATP) status and stimulating mitochondrial biogenesis (Zhou et al., 2001; Hardie et al., 2003; Hardie, 2007; Carling, 2004, 2005) and (b) in regulating animal food intake and overall energy balance (Minokoshi et al., 2004). Once AMPK is phosphorylated by serine-threonine kinase 11 (LKB1) (Hardie, 2005), the activated AMPK phosphorylates several proteins involved in carbohydrate, lipid, and protein metabolism (Kemp et al., 2003; Hardie, 2004, 2007). In general, AMPK reduces ATP-utilizing (anabolic) pathways (e.g., fatty acid synthesis) and increases ATP-generating (catabolic) pathways (e.g., fatty acid oxidation, glycolysis). AMPK is required for stimulating glucose uptake and glycolysis in skeletal muscle cells and astrocytes (Zhou et al., 2001; Almeida et al., 2004). AMPK also up-regulates PGC-1α expression (Ojuka, 2004) and therefore presumably plays a role in mitochondrial biogenesis. In conjunction with thyroid hormone receptor activation, PGC-1α up-regulates ANT and avUCP expression in chickens that uncouple mitochondrial oxidative phosphorylation (Masatoshi et al., 2005). Choi et al. (2001) presented evidence that AMPK and the AMPK cascade mechanisms are sensitive to ROS, particularly H_2O_2. Colombo and Moncada (2009) provided evidence that mitochondrial ROS-mediated upregulation of AMPK was associated with increased of several cellular antioxidants. Thus, AMPK is very important in sensing energy status in cells and could be a pivotal component in growth, development, and is responsive to mitochondrial generated ROS production. The expression of AMPK was higher in chickens exhibiting a high-feed efficiency phenotype (Bottje and Kong, 2013).

6.4.4 Sirtuins

The sirtuins are a family of conserved NAD-dependent deacetylases that regulate many cellular activities including stress response and energy metabolism (Haigis and Sinclair, 2010). SIRT4 is located mainly in mitochondria (Haigis et al., 2006) where it inactivates glutamate dehydrogenase by ADP-ribosylation. The inactivation of glutamate dehydrogenase that converts glutamate to α-ketoglutarate indicates that SIRT4 regulates entry of energy substrates into the Krebs cycle. Knockdown of SIRT 4 increased gene expression of mitochondrial and fatty acid metabolism enzymes in hepatocytes and myocytes, and changes in gene expression were associated with SIRT1-dependent fatty acid oxidation (Nasrin et al., 2010). Chau et al. (2010) reported that fibroblast growth factor 21 regulates energy homeostasis in adipocytes through phosphorylation and activation of AMPK by increasing cellular NAD + levels as well by deacetylation and activation of PGC-1α and histone 3. Activation of AMPK maintains energy balance by enhancing mitochondrial biogenesis and oxidative metabolism (Hardie, 2007). AMPK increased SIRT1 (NAD + -dependent type III deacetylase sirtuin 1) by increasing NAD + levels that modulate several downstream SIRT1 targets (Canto et al., 2009). AMPK and SIRT1 act in concert with PGC-1α to regulate energy homeostasis in response to differences in nutritional and environmental factors (Hardie, 2007; Reznick and Shulman, 2006).

Acknowledgments

I want to thank all of my students, postdocs, and collaborators that I have been so lucky to have come through my lab. None of this would have been possible without your hard work. I want to acknowledge funding sources especially USDA-NIFA and Arkansas Biosciences Institute. Finally, I want to thank you Jax William Bottje for teaching me so much about life in the short six months you were here with us—and his amazing parents, Kelsey and Tyler, who have taught me a lot about inner strength and grace.

Chapter 7

Evolution of birds

Daniel T. Ksepka
Bruce Museum, Greenwich, CT, United States

7.1 Introduction

Birds are the most diverse major clade of tetrapods, and also the youngest. From our human perspective, birds are intimately associated with concepts like feathers and flight, eggs and nests, and beauty and song. Understanding how birds evolved flight, survived one of the worst mass extinctions in Earth history, and ultimately radiated into the >10,000 species that exist today truly requires combining paleontological and neontological perspectives. This chapter provides an overview of major patterns in avian evolution with a focus on the fossil record. The relationships of modern birds, which are increasingly well resolved, thanks to genomic data, are touched on only briefly.

To appreciate the remarkable evolutionary journey that resulted in modern birds, it is best to begin with a cursory discussion of their place within the larger context of vertebrate evolution. Birds descended from theropod dinosaurs. Within a phylogenetic context, birds *are* dinosaurs, and so the term "nonavian dinosaur" is often employed to specify all dinosaurs except for birds, for example, in stating that nonavian dinosaurs went extinct at the end of the Cretaceous Period. For simplicity, "dinosaur" and "theropod" are used to refer only to the nonavian subset of those clades in this chapter.

7.2 The dinosaur–bird transition

7.2.1 Theropod dinosaurs

The dinosaur–bird transition has been reviewed in great detail elsewhere (e.g., Ostrom, 1975; Gauthier, 1986; Prum, 2002; Norell and Xu, 2005), and so will only be briefly summarized here. The closest theropod relatives of birds were small, feathered predators (Figure 7.1). Major branching patterns within the evolutionary tree of theropod dinosaurs are relatively well understood, though the precise relationships of certain taxa remain the subject of active research. Most recent analyses place birds within the clade Paraves, which unites the sickle-clawed dinosaur clades Dromaeosauridae and Troodontidae with Aves. Sequentially, the branches of the tree below Paraves are occupied by the beaked and crested Oviraptorosauria, the secondarily herbivorous Therizinosauria, the aberrant short-armed Alvarezsauridae, the ostrich-like Ornithomimosauria, and the small predatory Compsognathidae (Figure 7.2) (e.g., Turner et al., 2012; Brusatte et al., 2014). Debate remains over the relationships of the enigmatic bat-winged Scansoriopterygidae, which may represent relatives of Oviraptorosauria or the sister taxon of Paraves (Brusatte et al., 2014; O'Connor and Sullivan, 2014; Wang et al., 2019).

Many features closely associated with birds first arose within dinosaurs. These include feathers, the loss of digits resulting in a three-fingered hand, fusion of the clavicles into a furcula ("wishbone"), increasing hollowness of the limb bones, bipedal posture, and small body size. A great deal of convergent evolution took place in advanced theropods, and many seemingly key features evolved multiple times in distantly related theropods and birds. One such feature is the loss of teeth, which occurred independently in ornithomimosaurs, oviraptorosaurs, and multiple times in birds. Another is the shortening of the tail via fusion of multiple vertebrae into a pygostyle, which arose independently in oviraptorosaurs, scansoriopterygids, and birds.

7.2.2 Feathers first

The evolution of feathers was long linked with the origin of flight. The unveiling of the small feathered compsognathid dinosaur *Sinosauropteryx* (Figure 7.1A) rocked the paleontological and ornithological communities, effectively ending debate over the dinosaurian ancestry of birds and raising new questions about why feathers first evolved (Chen et al., 1998). The "proto-feathers" covering *Sinosauropteryx* are often described as unbranched monofilaments, but it is more likely that each feather was

composed of multiple filaments joined either at a common base or a slender central shaft (Currie and Chen, 2001; Xu, 2020). A steady stream of new discoveries has confirmed that filamentous feathers were present in many other theropods (Norell and Xu, 2005; Qiang et al., 1998; Xu et al., 2003). More recent discoveries of ornithischian dinosaurs and pterosaurs with filamentous integument suggest that feathers have a deep history, extending back at least to the last common ancestor of all dinosaurs and possibly to the last common ancestor of dinosaurs and pterosaurs (Zheng et al., 2009; Yang et al., 2019).

Filamentous feathers would have failed miserably in forming an airfoil, but were useful for thermoregulatory insulation, especially in small dinosaurs. They also likely served to enhance display and camouflage patterning, functions that would have formerly been fulfilled by colored scales (Koschowitz et al., 2014). One major recent advance in paleobiology is the recognition that melanosomes, subcellular structures that store pigment, are often preserved in fossils and indeed may be largely responsible for feather preservation (Vinther et al., 2008). Melanosome aspect ratio can be used to infer melanin-based colors in extinct species, and has revealed display striping and countershading camouflage in dinosaurs (Zhang et al., 2010; Vinther et al., 2016).

Filamentous feathers differ markedly from the vaned pennaceous feathers we tend to imagine when we think of "a feather." These more complex feathers have a large central rachis and branching barbs, which are in turn held in place by smaller interlocking barbules, allowing them to form an airfoil in modern birds. The most basal theropods with pennaceous feathers were the clearly earthbound oviraptorosaurs. This suggests pennaceous feathers originally served a nonaerodynamic function, perhaps providing a more ordered "canvas" for display colors, as well as opening the door to structural color and complex ornamental feathers (Foth et al., 2014; Koschowitz et al., 2014). Paravian dinosaurs such as *Microraptor* and *Caihong* show

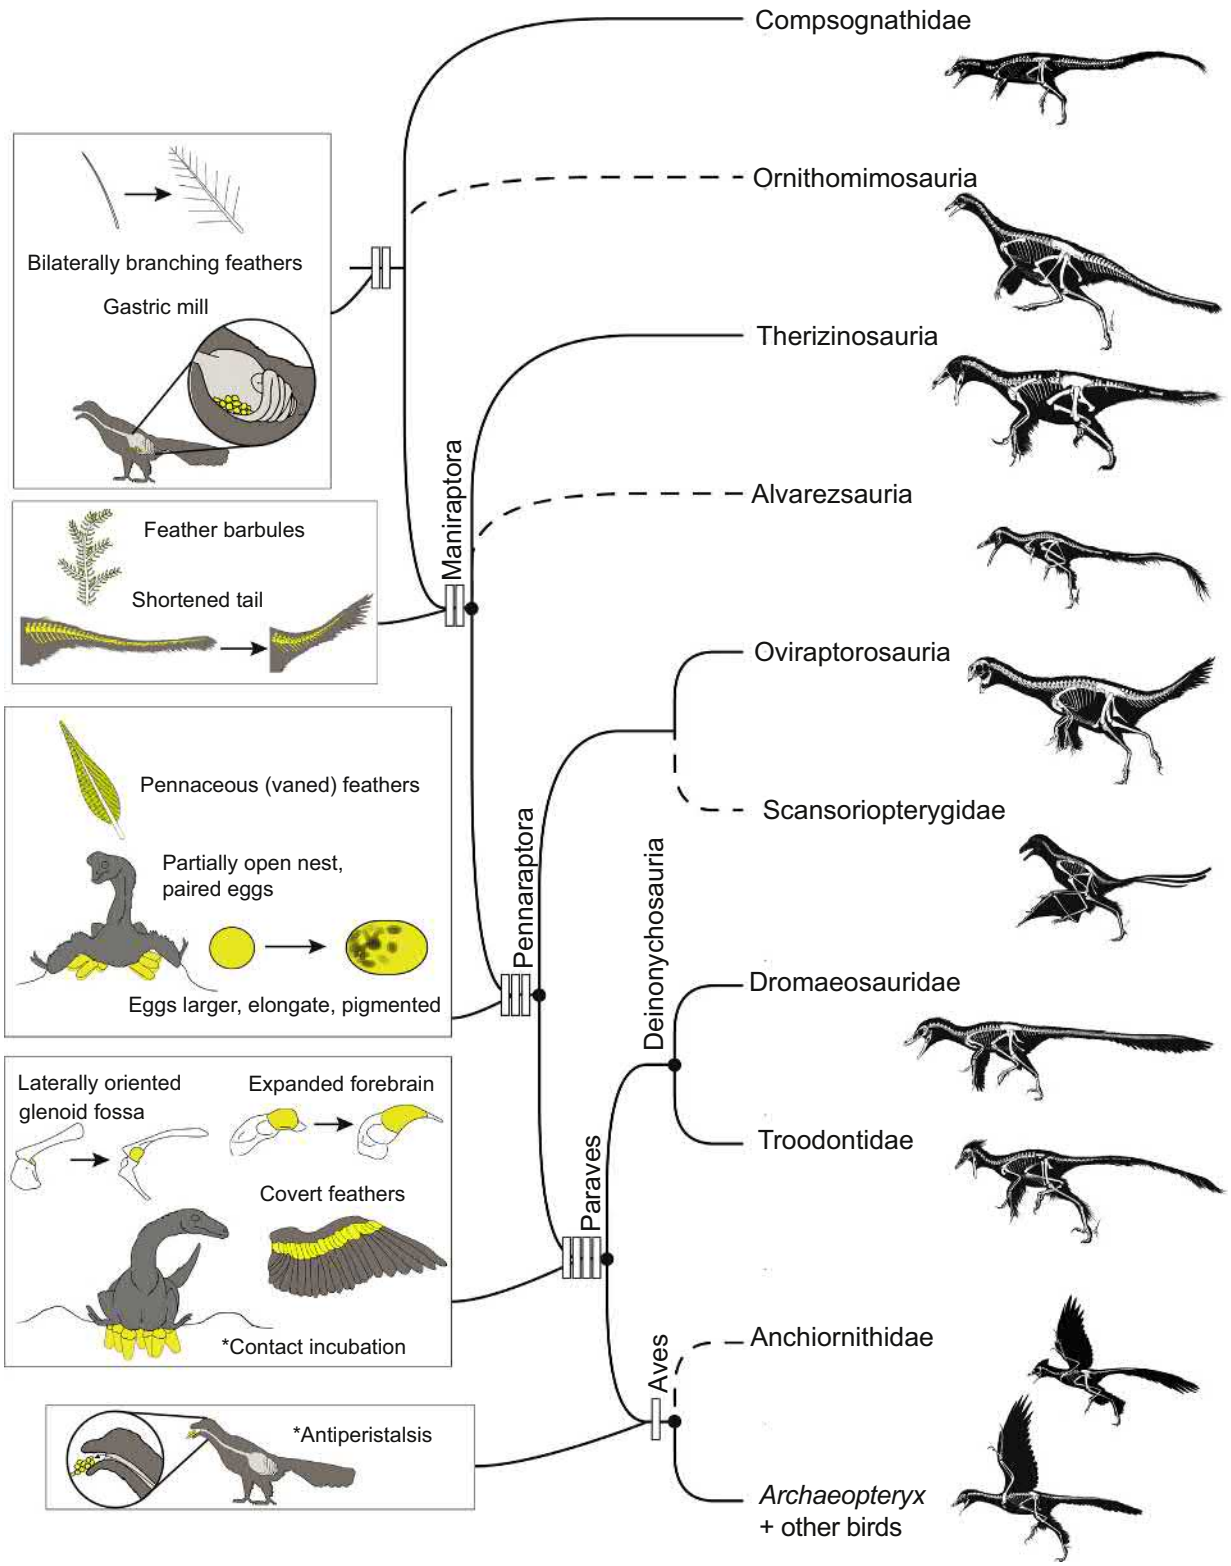

FIGURE 7.2 Phylogenetic tree depicting the relationships of birds to their theropod relatives. *Dashed lines* indicate uncertainty. Key synapomorphies discussed in this chapter are indicated. *Asterisks* indicate characters that evolve multiple times or for which placement remains uncertain. evidence of iridescent pennaceous feathers, indicating such structural coloration arose in theropods by the Late Jurassic (Li et al., 2012; Hu et al., 2018). Interlocking barbules have not yet been identified in theropod feathers, and their earliest occurrence is in *Archaeopteryx*. Plumulaceous (noninterlocking) barbules are known from feathers attached to a dinosaur tail preserved in amber which probably represents a basal maniraptoran (Xing et al., 2016).

Feathers with asymmetrical vanes arose in Paraves. The narrow leading vane and wide trailing vane of asymmetrical feathers aid in the formation of a lift-generating airfoil. Asymmetrical feathers occur universally in the wings and tails of volant modern birds. Thus, the presence of asymmetrical feathers in extinct species has been interpreted as evidence of flight capacity (Feduccia and Tordoff, 1979). However, the "flight" feathers of secondarily flightless birds typically retain asymmetrical vanes, reverting to symmetry only in birds with highly atrophied wings such as "ratites" (McGowen, 1989). Asymmetrical feathers have been reported in the wings of the dromaeosaurid *Microraptor* (see below) and the tail of the troodontid *Jianianhualong* (Xu et al., 2003, 2017). However, many other paravians appear to have had only symmetrical feathers (Lefèvre et al., 2017). This complex distribution suggests symmetrical feathers arose multiple times in concert with gliding ecology.

7.2.3 Taking wing

The earliest diverging theropod clade showing compelling evidence for some form of flight is Scansoriopterygidae. Scansoriopterygids can only be described as bizarre, and the discovery of "bat-winged" species ranks as one of the most startling fossil discoveries of the 21st century. The hyperelongate third finger of these small theropods initially puzzled paleontologists. Subsequently, the discovery of a specimen of *Yi xi* with preserved soft tissue revealed that the elongate finger combined with a novel rod-shaped wrist bone, dubbed the "styliform element," to anchor and control a membranous wing (Xu et al., 2015). Subsequent discovery of a second bat-winged species, *Ambopteryx longibrachium*, revealed that at least some scansoriopterygids had a pygostyle (Wang et al., 2019).

It is particularly remarkable that scansoriopterygids formed their wing from a membrane rather than feathers. Despite being nested within a clade of theropods that had pennaceous feathers, scansoriopterygids had only simple shaft-like wing feathers. The microstructure of these feathers suggests they represent a secondary simplification, with the role of potentially airfoil-forming pennaceous feathers made redundant by the membranous wing (Wang et al., 2019). *Yi* and *Ambopteryx* were well suited to gliding flight, though the lack of robust flight muscle insertions on the wing bones suggests they had little if any capacity for flapping (Xu et al., 2015). Marvelous as the scansoriopterygids were, they represent a now-extinct side branch of the theropod evolutionary tree and thus reveal little about the origin of avian flight.

Hints of what would later become a true bird wing (i.e., a feathered airfoil) first appear in large, flightless theropods. Although perplexing at face value, this simply suggests that incipient wings served no aerodynamic function, and were coopted for flight only later. The earliest diverging taxon to show potential evidence of a wing-like forelimb is the ornithomimosaur *Ornithomimus edmonticus* (Zelenitsky et al., 2012). In this species, juveniles show only filamentous feathers, whereas adults preserve carbonized markings that represent larger, potentially pennaceous feathers. However, because only shaft traces remain, it is uncertain whether these feathers were in fact branching, and they may instead represent broad monofilaments (Xu, 2020). More conclusive evidence for a wing-like forelimb is present in Oviraptorosauria. Several species are known to have had incipient wings, thanks to excellent fossil specimens with intact feathering (Ji et al., 1998). Oviraptorosaurians were clearly flightless, suggesting a nonaerodynamic function for the forelimb feathering, such as display or covering clutches during brooding (Hopp and Orsen, 2004).

The earliest "true" wing occurs in the dromaeosaurid *Microraptor* (Xu et al., 2003). This diminutive theropod possessed elongate asymmetrical wing feathers, as well as elongate pennaceous hind limb feathers (Figure 7.1B). This unexpected feather arrangement gave *Microraptor* the appearance of a dinosaurian biplane. Modeling suggests *Microraptor* was a proficient glider and this remarkable "four-winged" fossil provides perhaps the most compelling evidence for an intermediate gliding stage prior to the evolution of powered flight (Dyke et al., 2013). Once thought to be unique to *Microraptor*, feathered "trousers" extending from the hind limbs have since been reported in the dromaeosaurid *Sinornithosaurus* as well as early birds including *Archaeopteryx* and *Confuciusornis* (Ji et al., 2001; Longrich, 2006; Foth et al., 2014). Whether they served an aerodynamic or display function in these taxa remains debatable.

In modern bird wings, the elongate remiges are overlapped above and below by layers of shorter feathers called coverts. The incipient wings of oviraptorids appear to have lacked coverts, and thus to have been formed by a single layer of elongate feathers. Coverts have been identified in the *Microraptor* and the dromaeosaurid *Zhenyuanlong* (Lü and Brusatte, 2015), suggesting paravians shared a multilayered wing with improved airflow smoothing capabilities. The morphology of the coverts is poorly known in dromaeosaurids and troodontids, but those in *Anchiornis* differ from modern bird coverts in being poorly differentiated from the remiges (Longrich et al., 2012). This resulted in a

wing formed by stacked layers of relatively short feathers. *Archaeopteryx* was previously though to share this primitive arrangement, but new specimens reveal that it had short coverts and long primaries like modern birds (Foth et al., 2014). The combined presence of asymmetrical wing feathers, interlocking barbules, and elongate primaries suggests *Archaeopteryx* had substantially more advanced flight capabilities than the anchiornithids.

In summary, the balance of evidence suggests that although multiple theropod lineages acquired a capacity for gliding flight, *Archaeopteryx* is the earliest known taxon with the potential for powered flight. Nonetheless, drawing a bold line between *Archaeopteryx* and closely related groups in terms of flight capacity may never be possible to do with confidence, given phylogenetic uncertainty and the limits of inferring behavior in long-extinct species.

7.2.4 *Archaeopteryx*, the first bird?

For well over a century, there was little debate over the identity of the first bird. Originally named based on a single feather in 1861, *Archaeopteryx* is now known from 11 skeletons preserved in varying states of completeness (Rauhut et al., 2019). *Archaeopteryx* quickly became a linchpin of support for Darwin's theory of evolution—its status enhanced by the stunning quality of the "Berlin specimen," arguably the most beautiful fossil ever discovered. *Archaeopteryx* lived in an archipelago environment ~150 million years ago, when much of Europe was inundated by shallow ocean waters. Known specimens span a large range of sizes, from that of a small magpie to a large raven, contributing to debate over how many species are represented and whether the largest specimens should be placed in a separate genus (*Wellnhoferia*) (Elzanowski, 2001; Mayr et al., 2005; Rauhut et al., 2019).

Archaeopteryx long remained the key reference point for understanding the origin of birds because no serious challengers to its position at the base of the avian evolutionary tree arose for over a century. The brief promotion of the Triassic *Protoavis texensis* as an older rival to *Archaeopteryx* (Chatterjee, 1991) was nothing short of a debacle, with problems ranging from the veracity of reconstructed skeletal features to the chimeric nature of the type specimen (Witmer, 2001). The loneliness of *Archaeopteryx* ended dramatically when Mesozoic birds began to be unearthed in previously unfathomable numbers from eastern China near the turn of the 21st century. Thousands of individual fossils have emerged, revealing dozens of new species, ranging in age from roughly 110 to 160 million years old. As the floodgates opened, debate has started to swirl over candidates for the title of "first bird." Several small feathered theropods from the family Anchiornithidae (e.g., Figure 7.1C) have been proposed to occupy a branch one step below *Archaeopteryx* in some studies (Godefroit et al., 2013; Rauhut et al., 2019), which would make them the oldest and most primitive members of the bird line. However, the placement of these taxa remains controversial, and the possibility they instead represent small troodontid theropods or basal paravians is also plausible (Brusatte et al., 2014).

Other recent studies have called into question the placement of *Archaeopteryx* itself, shunting it off the bird branch to an alternate placement as sister taxon to Deinonychosauria (Mayr et al., 2005; Xu et al., 2011; Wang et al., 2019). This placement would imply *Archaeopteryx* was not a true bird, but rather an undersized cousin of *Velociraptor*—leaving the Early Cretaceous *Jeholornis* to inherit the title of first bird. The fact that each new study seems to yield a new reshuffling of advanced theropods, *Archaeopteryx*, and other primitive birds reflects the fact that these taxa split from one another in a relatively short time, making it likely we will always have some degree of uncertainty as to the branching patterns near the origin of birds. For purposes of this chapter, we will adopt the working hypotheses that anchiornithids occupy the branch immediately below *Archaeopteryx*, but that *Archaeopteryx* was the first bird with the potential for powered flight.

7.2.5 Flight in *Archaeopteryx*

The flight capabilities of *Archaeopteryx* have been subject to endless inquiry. Pectoral girdle morphology clearly indicates that *Archaeopteryx* was not capable of the same level of flight efficiency as modern birds. The absence of a bony sternum, which anchors the largest of the flight muscles in modern birds, immediately draws attention. However, this single feature cannot be considered surefire evidence against powered flight, as the sternum of *Archaeopteryx* may have been cartilaginous and thus not preserved in fossils (Bock, 2013). In addition, the pectoralis and supracoracoideus muscles may have attached primarily to the coracoid and/or furcula (Olson and Feduccia, 1979; Elzanowski, 2002), and so could have been well developed even in the absence of a bony sternum. However, other features, such as the lack of a triosseal canal and the lateral orientation of the shoulder joint, suggest a much weaker ability to elevate the wing than in modern birds (Ostrom, 1976; Senter, 2006).

The morphology of the wing is more congruent with powered flight. Recent data from wing bone cross-sectional geometry support the capacity for flapping flight (Voeten et al., 2018). Asymmetry of the flight feathers likewise suggests they served an aerodynamic function. On the other hand, lower trailing edge barb angles suggest the flight feathers of *Archaeopteryx* may have been less flexible than those of more advanced birds and thus less suited to maintaining a coherent airfoil under powered flight (Feo et al., 2015). Overall, skeletal and feather data suggest *Archaeopteryx* could fly, but surely lacked the sustained

flapping and sophisticated aerial maneuvering capabilities of modern birds.

7.3 The Mesozoic avifauna

7.3.1 Basal birds

Before attempting to summarize the early history of avian evolution, it is helpful to introduce the major groups of Mesozoic birds (Figure 7.3). Provided Anchiornithidae (provisionally eight species) ultimately prove to represent the branch on the avian tree below *Archaeopteryx*, they suggest the first birds were at best gliders. Anchiornithids were mostly crow-sized predators which retained teeth, had relatively long forearms, and lacked an ossified sternum. They possessed vaned feathers along both the forelimbs and hind limbs, but these appear to have largely been symmetrical and "shaggy" with limited aerodynamic efficiency (Saitta et al., 2018). The "silky" texture of the feathers in *Serikornis sungei* suggests the feathered "trousers" of anchiornithids served a display rather than aerodynamic function (Lefèvre et al., 2017). Display structures are also documented in the unique anchiornithid *Caihong juji*, which had both a pair of bony cranial crests and iridescent feathers (Hu et al., 2018).

After *Archaeopteryx,* the Jeholornithidae (three species) occupy the next branch of the evolutionary tree (Figure 7.4). These crow-sized birds had just six teeth, and at least one species, *Jeholornis prima*, consumed seeds and/or fruit (Zhou and Zhang, 2002a; O'Connor and Zhou, 2020). *Archaeopteryx* and *Jeholornis* retained a long bony tail like their theropod ancestors. Both had frond-like branching tail feathers, though in *Jeholornis* these were restricted to the distal part of the tail and a proximal fan of feathers was also present (O'Connor, 2020). Unlike *Archaeopteryx*, *Jeholornis* had a fused mandibular symphysis and partially fused carpometacarpus. The recently described short-tailed *Fukuipteryx prima* was proposed to represent an even more basal lineage than Jeholornithidae, which would require independent loss of the long bony tail in this species and more advanced birds (Imai et al., 2019). *Fukuipteryx* is known only from an incomplete skeleton representing an immature individual, so additional specimens are desirable before considering its phylogenetic placement resolved.

Confuciusornithidae, Jinguofortisidae, and *Sapeornis* occupy the next branches of the avian tree, though debate remains over their precise relationships. These groups differed from more basal birds in having a short bony tail ending in a pygostyle. Confuciusornithidae (five species) are the oldest birds that completely lacked teeth, though this loss occurred independently from the loss in crown birds (Chiappe et al., 1999). Confuciusornithids retained three long, clawed fingers like *Archaeopteryx* and Jeholornithidae, whereas in all other birds, the third digit is highly reduced. However, they were advanced in having a fully reversed hallux, which provided improved perching capabilities. The pigeon-sized species *Confuciusornis sanctus* is by far the best-represented Cretaceous bird, with thousands of specimens known. Because not one of these specimens preserves gut contents or gizzard stones, confuciusornithids likely consumed soft-bodied invertebrates (O'Connor and Zhou, 2020).

The recently named Jinguofortisidae unites two crow-sized species: *Jinguofortis perplexus* and *Chongmingia zhengi*. Jinguofortisidae show an unusual mix of features such as the fusion of the scapula and coracoid (also observed in many theropods and in Confuciusornithidae) and a strongly bowed minor metacarpal (resembling that of many crown birds but also Jeholornithidae). The low aspect ratio and low wing loading of *Jinguofortis* suggest this taxon had high maneuverability and occupied dense forest habitats (Wang et al., 2018). *Jinguofortis* at least had close-packed teeth in both the upper and lower jaws, and presence of gizzard stones in both *Jinguofortis* and *Chongmingia* suggests a plant-based diet for these birds (Wang et al., 2016, 2018).

Although a number of species have been assigned to *Sapeornis*, all are best considered junior synonyms of *Sapeornis chaoyangensis*. With a wingspan of approximately 1 m, this species was among the largest Cretaceous birds. *Sapeornis* retained a small number of teeth and lacked an ossified sternum. The large wingspan, primitive feather barb arrangement, and lack of an ossified sternum in *Sapeornis* suggest a soaring ecology, which would have allowed it to travel long distances via passive gliding (Zhou and Zhang, 2002b; Feo et al., 2015). Like *Jeholornis*, *Sapeornis* consumed seeds and/or fruits as at least part of its diet (O'Connor, 2019).

7.3.2 Enantiornithes: the opposite birds

While the abovementioned families were successful, the true diversification of birds is marked by the radiation of the Ornithothoraces, a clade that unites the extinct Enantiornithes and the Ornithuromorpha, which includes modern birds and their extinct relatives. Enantiornithes are known from nearly 100 named species (though some poorly defined species may prove invalid). They attained a global distribution and were the dominant birds of the Cretaceous, both in terms of abundance and ecological diversification. Enantiornithes are often referred to as "opposite birds" because their shoulder joint was formed by a convex ball on the coracoid inserting into a concave socket on the scapula, whereas the reverse is true in modern birds (Chiappe and Walker, 2002). With the exception of the toothless *Gobipteryx*, enantiornithines retained teeth. Most species were songbird sized and had more advanced flight capabilities than earlier birds based on their enlarged

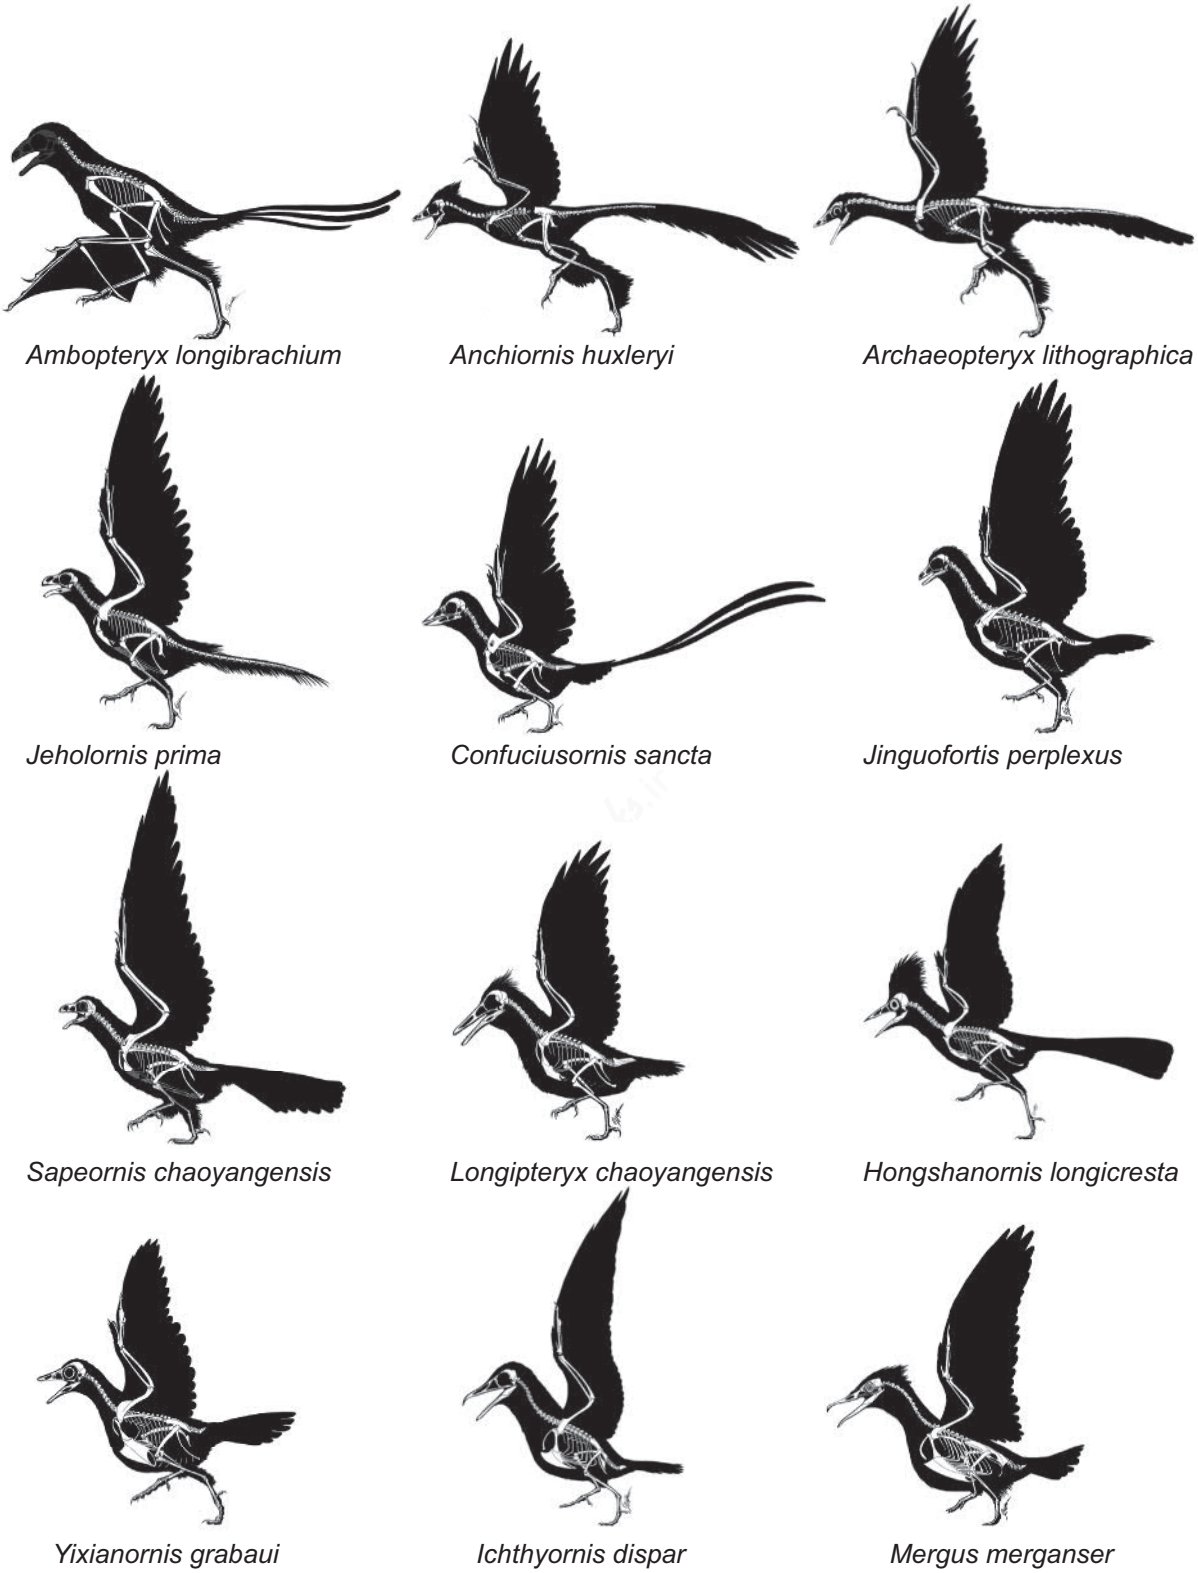

FIGURE 7.3 Reconstructions of the bat-winged scansoriopterygid *Ambopteryx longibrachium* and key avian taxa. *Credit: Artwork by Jaime Headden.*

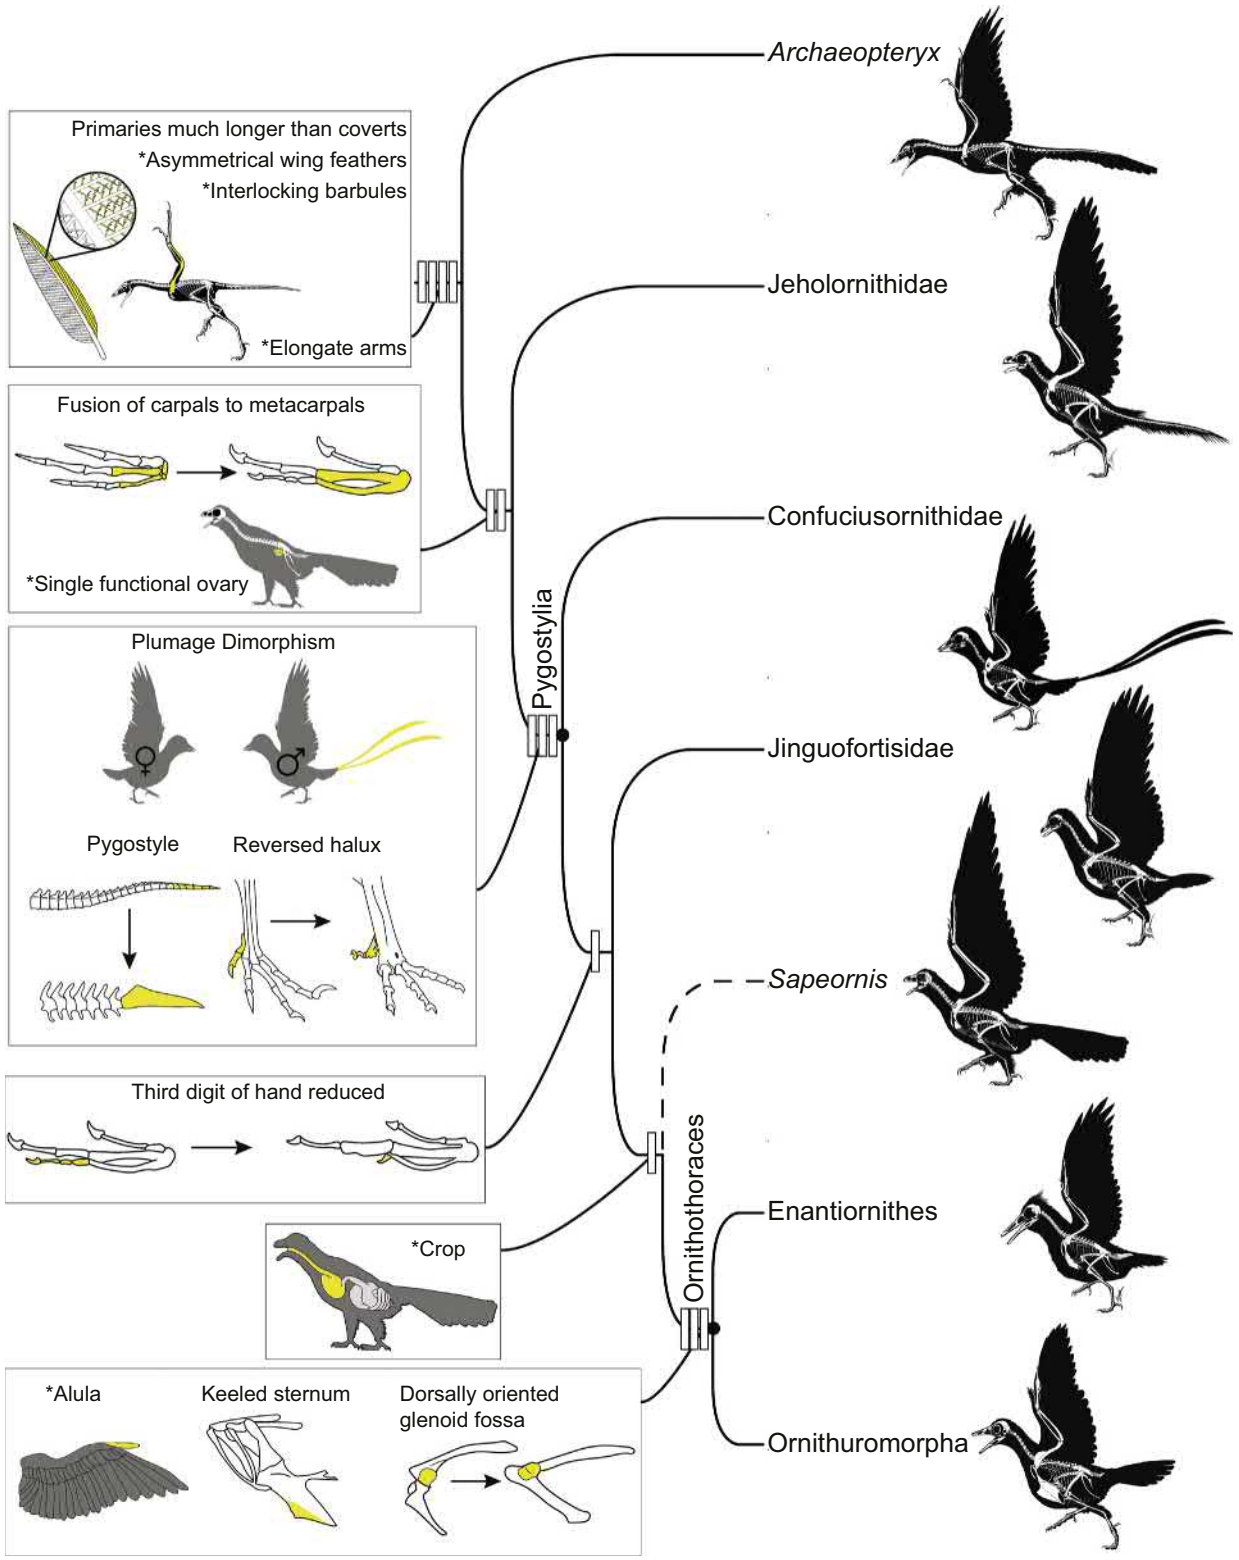

FIGURE 7.4 Phylogenetic tree depicting the relationships of early birds. *Dashed lines* indicate uncertainty. Key synapomorphies discussed in this chapter are indicated. Skeletal silhouettes, top to bottom: *Archaeopteryx lithographica*, *Jeholornis prima*, *Confuciusornis sanctus*, *Jinfengopteryx elegans*, *Sapeornis chaoyangensis*, *Longipteryx chaoyangensis*, and *Yixianornis grabaui*. *Credit: Silhouette artwork by Jaime Headden, character illustrations by Kate Dzikiewicz.*

sternum, wing bone proportions, and the presence of an alula (Chiappe and Walker, 2002). Together, these features suggest the capacity for sustained strong flapping and finer aerodynamic control. Enantiornithes were, for the most part, arboreal, as evidenced by a well-developed perching foot. Frustratingly, despite the wide array of tooth morphologies in Enantiornithes, fossilized gut contents are limited to single occurrence: fragments of a small crustacean in the rib cage of *Eoalulavis* (Sanz et al., 1996). The near-total lack of fossil gut contents in Enantiornithes suggests most species consumed prey with poor preservation potential, such as soft-bodied invertebrates (O'Connor, 2019).

The phylogeny of Enantiornithes is not yet fully resolved, but a few small clades are recognized. Pengornithidae (four species) represent one of the most basal enantiornithine families. They had many small teeth, stout legs, and a stubby pygostyle. The crow-sized *Pengornis houi* had blunt teeth suited for crushing soft arthropods (Zhou et al., 2008). The unique pygostyle of pengornithids helped anchor stiff, elongate tail feathers. *Parapengornis eurycaudatus* in particular may have used its tail feathers to prop itself against trees like a woodpecker (Hu et al., 2015).

Bohaiornithidae (six species) had robust beaks with an infratemporal bar, strong teeth, and stout feet with large claws on the middle toes. *Sulcavis geeorum* further had striations that presumably strengthened the enamel (O'Connor et al., 2013). These features suggest a tough diet, though the ecology of bohaiornithids remains the subject of debate. A raptorial ecology was proposed for the blunt-toothed *Bohaiornis guoi* (Figure 7.6B) in one study (Li et al., 2014), whereas others suggest bohaiornithids fed on hard-shelled invertebrates such as beetles and snails (O'Connor and Chiappe, 2011).

Longipterygidae (conservatively six species) were long-beaked enantiornithines. *Longirostravis* resembled a modern sandpiper except for the presence of a few small teeth near the tip of the beak, and may have had a similar probing ecology (O'Connor and Chiappe, 2011). *Longipteryx*, in contrast, bore several large blade teeth near the tip of its beak (Figure 7.6A). These powerful teeth would have been useless while probing, and instead appear to have been used to grasp slippery prey such as invertebrates and small fish (Chiappe and Qingjin, 2016).

The Late Cretaceous Avisauridae (conservatively six species) are an enigmatic group, with many species known only from a single bone. Whereas most enantiornithines were of modest size, a few avisaurid species reached the size range of turkeys (Atterholt et al., 2018). At least some avisaurids independently evolved features associated with advanced flight, such as a deep sternal keel and strong ulnar feather papillae, which are otherwise only seen in Ornithuromorpha (Atterholt et al., 2018) (Figure 7.4).

7.3.3 Cretaceous Ornithuromorpha: forerunners of modern birds

Ornithuromorpha include all modern birds along with their early relatives (Figure 7.5). Cretaceous ornithuromorphs show little evidence of arboreality: most species are inferred to have occupied ground-foraging or marine niches. Ornithuromorpha were a relatively minor part of the Cretaceous avifauna compared to the Enantiornithes, but the few ornithuromorphs that survived the Cretaceous–Paleogene (K-Pg) mass extinction gave rise to the >10,000 species of birds that live today. Space precludes a detailed survey of Cretaceous ornithuromorphs, but a few key taxa are mentioned briefly.

Archaeorhynchus spathula is the most primitive known ornithuromorph. The keeled sternum, short hind limb, and reduced hallux together suggest that, while *Archaeorhynchus* was a capable flier, it was unable to perch effectively and likely had a ground-feeding ecology. The toothless beak and spatulate lower jaw, along with the presence of gastroliths, suggest this species may have been herbivorous (Zhou et al., 2013) (Figure 7.6E). Hongshanornithidae (five species) represent another early branch of the ornithuromorph tree. These slender-beaked, plover-sized birds had elongate legs and toes that suggest a wading ecology (O'Connor et al., 2010). Though not the most basal member of Ornithuromorpha, the hongshanornithid *Archaeornithura meemannae* is the geologically oldest known representative of the clade at ~130 million years in age. Songlingornithidae (five species) are another shore-dwelling ornithuromorph clade. *Yanornis martini*, one of the best-known species, was a gull-sized bird with a moderately elongated beak, sharp teeth, and partially webbed feet. Many specimens of *Yanornis* preserve fish bones within the rib cage, providing direct evidence that this species was one of the earliest fish-eating birds (Zhou et al., 2002).

Gansus yumenensis and *Apsaravis ukhaana* each occupies branches of their own with no immediate relatives, intermediate between Songlingornithidae and more crownward birds. *Gansus* was the size of a small diving duck and likely had a similar foot-propelled diving ecology based on the prominent cnemial crest of the tibiotarsus and webbed toes (You et al., 2006). In contrast, the dove-sized *Apsaravis* provides an example of a presumably terrestrial Cretaceous ornithuromorph based on the discovery of the type specimen in a dune environment (Norell and Clarke, 2001).

Ichthyornis dispar merits special mention as the best-known volant species that occurs near the transition point between stem and crown birds (Clarke, 2004). This tern-sized bird had a skeleton that closely resembled modern birds with the notable exception of toothed jaws and a theropod-like adductor muscle chamber (Field et al., 2018b).

Skeletal morphology, along with its shallow marine fossil environment, suggests *Ichthyornis* likely had a gull-like ecology, reinforcing the hypothesis that modern birds arose from shore-dwelling ancestors (Feduccia, 1995). Finally, the most fully aquatic Cretaceous birds were the diverse foot-propelled diving Hesperornithes, which occurred in freshwater and marine environments throughout the Northern Hemisphere in the Late Cretaceous, even extending north of the Arctic Circle (Wilson et al., 2016). Derived members of this clade reached large sizes (body lengths >1 m) and had wings reduced to only a small, splint-like humerus. Like modern grebes, hesperornithines had a massively expanded patella, mediolaterally compressed tarsometatarsus, and lobed toes. Despite these similarities, morphometric analyses suggest a diving ecology more similar to cormorants (Bell et al., 2019).

7.4 Assembling the modern bird

7.4.1 Freeing the tail for flight

With the Mesozoic aviary introduced, we can now trace the evolution of avian anatomy. Rather than moving from beak to tail, this section will proceed roughly from the root to the tip of the avian evolutionary tree. Although the evolution of the wing has historically commanded more attention, the pelvis, legs, and tail also underwent an earlier major transformation during the theropod–bird transition. Early theropods anchored the primary retractor muscle of the limb (caudofemoralis) to the base of their long muscular tails (Gatesy, 1990). Tail length accounts for roughly half of overall body length in early theropods, and thus appears to have played a major role in balance (Gatesy and Dial, 1996). Derived theropods evolved shorter and less robust tails, but a bony tail was still present in the earliest birds. In more advanced birds, the tail is reduced to a few vertebrae ending in a fused pygostyle, and plays little role in terrestrial locomotion. The caudofemoralis muscle is reduced or lost, with the function of retracting the hind limb taken over by the "hamstring" muscles, which anchor to the pelvis. This transition was accompanied by a shift from femoral retraction to knee flexion as the primary movement of the hind limb, which results in the nearly horizontal orientation of the femur in birds (Gatesy, 1990).

The decoupling of the tail and hind limb can be considered a major preadaptation for advanced flight. This freed the tail to take on the new role of aiding aerial

maneuvering, via the development of a fan-like spread of rectrices controlled by the musculature of the rectricial bulb system (Gatesy and Dial, 1996). In most Cretaceous birds, the pygostyle was rod-like and lacked a central dividing lamina, which, together with preserved feather evidence, suggests these taxa lacked a precisely controlled tail fan (Clarke et al., 2006; Wang and O' Connor, 2017). In contrast, ornithuromorphs exhibit a more ploughshare-shaped pygostyle, indicating the presence of left and right rectricial bulbs (Clarke et al., 2006). These would have anchored aerodynamic rectrices, imparting an important flight advantage to ornithuromorphs over their enantiornithine contemporaries.

7.4.2 Perfecting the wing

As detailed above, incipient feathered "wings" evolved in theropods prior to the advent of flight. Paravians, at least some of which had gliding flight, show some skeletal adaptations that are necessary for a true wing, including lengthening of the forelimb and reorientation of the glenoid fossa (articulation for the head of the humerus) to a more lateral position. This lateral orientation permitted a fuller range of forelimb elevation in Paraves, a capability that was further enhanced by the more dorsal glenoid orientation in Ornithothoraces (Jenkins, 1993; Senter, 2006). Interestingly, the sternum remained cartilaginous in *Archaeopteryx* and *Sapeornis*, despite being ossified in many theropods. All other birds (even flightless species) have an ossified sternum. A weakly developed midline ridge is present in some *Confuciusornis* specimens. Most enantiornithines possessed a true (albeit low) keel that was restricted to the caudal part of the sternum, and in these taxa, the pectoralis musculature may have attached in part to the furcula (Olson and Feduccia, 1979). In ornithuromorphs the keel extends to the cranial margin of the sternum and becomes progressively deeper, culminating in the powerfully developed keel of crown birds (Mayr, 2017a). Theropods and early birds had numerous gastralia ("belly ribs") caudal to their sternum, which are lost in advanced ornithuromorphs, possibly as a weight-reducing adaptation. The coracoid is plate-like in theropods but becomes progressively more elongated and strut-like in advanced birds. This culminates in the formation of the triosseal canal, an opening at the juncture of the furcula, coracoid, and scapula that serves as a pulley allowing the supracoracoideus muscle to lift the wing. The triosseal canal was once thought to be present in all Ornithothoraces, but recent fossil discoveries suggest enantiornithines lacked a true triosseal canal (Mayr, 2017a).

The distal wing elements were among the last features of the wing to evolve their modern form. The carpals and proximal ends of the second and third metacarpals remain free in theropods and *Archaeopteryx*. These became fused into an incipient carpometacarpus in Pygostylia, with further fusion of the metacarpals to one another within Ornithuromorpha. In *Apsaravis* and more advanced birds, the first metacarpal has a strongly projected extensor process for insertion of the ligaments that help automate the extension of the distal wing during the flight stroke (Norell and Clarke, 2001). Finally, the distal claws become modified into flattened phalanges in crown birds (a small alular claw remains in some species).

7.4.3 Neuroanatomy

Endocasts (natural or virtual casts of the inside of the braincase) provide a window into the sensory capabilities and cognition of extinct taxa. Theropod endocasts have revealed that the enlargement of the forebrain that characterizes modern birds first began in theropods (Larsson et al., 2000; Balanoff et al., 2013). Our understanding of early avian brain evolution is greatly hindered by the fact that almost all known Mesozoic bird skulls are preserved flattened on slabs. Thus, study of the early bird brains relies heavily on endocasts from *Archaeopteryx* and *Cerebavis*, a 93-million-year-old ornithuromorph bird. The holotype of *Cerebavis* was first described as a natural endocast (Kurochkin et al., 2007). Later recognized to be a skull, it was CT scanned to reveal the true endocast (Walsh et al., 2016). *Archaeopteryx* retained a theropod-like degree of forebrain expansion, whereas *Cerebavis* shows greater inflation, placing the latter within the range of modern birds (Balanoff et al., 2013; Walsh et al., 2016). It remains controversial whether early birds possessed a "Wulst," a mesopallial, and hyperpallial outgrowth of the forebrain associated with information processing and motor control (Balanoff et al., 2013; Beyrand et al., 2019). The primitive neuroanatomy of *Archaeopteryx* suggests that it either lacked a "flight-ready" brain or that, more plausibly, some theropods already had the neuroanatomical architecture necessary for flight (Balanoff et al., 2013).

Large relative brain sizes arose in crown birds. Early diverging crown birds such as Palaeognathae, Galloanserae, and basal Neoaves share the same ancestral brain–body size scaling pattern as advanced theropods, but within Neoaves, many shifts in the brain–body scaling relationship occurred rapidly after the K-Pg mass extinction (Ksepka, 2020). Relative brain sizes in some crows and parrots can rival those of primates, and it is interesting to note that the largest brained birds evolved only in the latter part of the Cenozoic.

7.4.4 Respiration and vocalization

The avian respiratory system consists of paired static lungs that serve as gas exchange surfaces and a system of connected air sacs that ventilate the lungs in a bellows-like fashion. This system allows unidirectional airflow, with oxygenated air passing over the gas exchange surfaces of

the lungs during both inhalation and exhalation. Unidirectional airflow was long thought to be associated with flight in birds, but recent work has shown it also occurs in crocodilians and lizards (Farmer and Sanders, 2010; Schachner et al., 2014). Air sacs, which are absent in living reptiles, have long been hypothesized to have been present in dinosaurs based on pneumatic fossae and foramina on the vertebrae. These features suggest dinosaurs possessed a dorsally immobile lung, which was divided into gas-exchanging and ventilating regions (Brocklehurst et al., 2020). Theropods likely had flexible air sacs, and at least some advanced taxa potentially had a fully decoupled lung and air sac system similar to modern birds (Brocklehurst et al., 2020). When this system evolved remains uncertain, as no theropod fossil preserves the lung structure. Remarkably, one specimen of the basal ornithuromorph bird *Archaeorhynchus* does preserve fossilized lung tissue. The intact tissue suggests the lungs were directly attached to the wall of the body cavity, indicating the respiratory system of early birds was similar to that of modern birds (Wang et al., 2018).

Modern bird vocalizations range from the simple grunts of emus to the intricate melodious songs of passerines. Whereas most tetrapods produce sound using the larynx, birds instead vocalize using a unique organ, the syrinx, which is located closer to the lungs. The syrinx is rarely preserved in fossil birds, and only two specimens have been reported to date (Clarke et al., 2016). Because both belong to crown birds, they shed little light on the timing of syrinx evolution. Cartilaginous (ossified in a few species) tracheal and bronchial rings support the passageways that connect the syrinx to the mouth and lungs in most birds. In contrast to the syrinx, these structures are relatively common in articulated fossil birds. Thus, the absence of preserved rings likely indicates the lack of a syrinx, and hence lack of song capabilities, in dinosaurs (Clarke et al., 2016).

Given the poor preservation potential of the syrinx, determining when and why this structure evolved remains a difficult question. One hypothesis holds that the elongation of the neck in birds, made possible by their derived respiratory system, created a situation in which a source of sound generation located closer to the lungs was more efficient (Riede et al., 2019). This would favor a transition from the larynx to the syrinx as the primary sound-generating organ, which begs the question of whether there was a stage in avian evolution during which both organs overlapped in function, or less plausibly a "quiet" phylogenetic interval during which dinosaurs lacked a functional larynx but had not yet evolved a syrinx (Kingsley et al., 2018).

While the timing of the origin of song remains a mystery, one innovation that appears restricted to crown birds is vocal learning. Most birds have an innate ability to perform their characteristic vocalizations, and will produce the same calls and songs even if raised in isolation (Kroodsma, 1984). Hummingbirds, parrots, oscine passerines (and perhaps a few suboscines), in contrast, are vocal learners: young birds learn specific vocalizations by listening to adults of their species (Nottebohm, 1972; Kroodsma, 2015). Vocal learning opens the door to mimicry. This is taken to the extreme in parrots, which can learn and utilize human words—obviously a most recent development (Pepperberg, 2009).

7.4.5 Teeth and beaks

Bird skulls resemble paedomorphic theropod skulls, with large orbits and short snouts that are likely ancestral juvenile traits carried into adulthood (Bhullar et al., 2012). Over the course of avian evolution, the skull became more consolidated. Theropod and early bird skulls retained visible sutures, whereas in crown birds, most of the cranial sutures are obliterated by adulthood. The avian beak is perhaps the most recognizable morphological hallmark of birds aside from feathers. Yet, the first birds lacked a true beak. Early birds retained premaxillary, maxillary, and dentary teeth. Reduction of the dentition occurred repeatedly, with independent losses of teeth in Confuciusornithidae, the enantiornithine *Gobipteryx*, several ornithuromorph lineages, and in crown birds.

The modern avian beak evolved within Ornithuromorpha, a process that began prior to the complete loss of teeth. In ornithuromorphs, loss of the premaxillary teeth preceded loss of maxillary and dentary teeth. Many ornithuromorphs possessed a small predentary ossification, interpreted as a biomechanically induced sesamoid, which articulated with the rostral tip of the mandible (Bailleul et al., 2019). The loss of premaxillary teeth and the evolution of this predentary ossification together played a crucial role in the origin of the modern avian beak, as the toothless, keratin-covered tips of the premaxilla and predentary together formed a pincher-like structure for fine manipulation (Field et al., 2018b). Theropods retained an upper temporal fenestra to accommodate the jaw adductor muscles, which are greatly reduced in modern birds. Somewhat surprisingly, this fenestra appears to have been retained in the near-crown bird *Ichthyornis*, demonstrating that the evolution of a transitional beak preceded reduction of the temporal musculature in the lineage leading to modern birds (Field et al., 2018b).

7.4.6 Digestive system

Lacking teeth, modern birds rely almost entirely on their digestive tract to process food. Most modern birds possess a crop for storing food, and all have a two-part stomach comprising a proventriculus and ventriculus (gizzard). Food swallowed directly or passed on from the crop enters

the proventriculus, where digestion is initiated via stomach acids and enzymes. The partially digested food then passes into the muscular gizzard where it is physically processed, often with the help of gastroliths (gizzard stones).

A two-chambered stomach with a gastric mill was present in theropods, as evidenced by gastroliths documented in Ornithomimosauria, Oviraptorosauria, and Scansoriopterygidae (Ji et al., 1998; Wang et al., 2019) (Figure 7.6C and D). Gastroliths have also been observed in some early bird lineages including Jeholornithidae and *Sapeornis*. They are conspicuously absent in Confuciusornithidae and Enantiornithes, suggesting these groups lacked a thick-walled gizzard capable of providing a gastric mill (O'Connor and Zhou, 2020). In modern birds, the gizzard varies in development from a thick-walled chamber capable of pulverizing tough food material to a thinly lined pouch incapable of accommodating gastroliths. The available evidence suggests a gizzard was ancestrally present in birds but that its development varied widely throughout avian evolution.

The crop is a more recent innovation. *Sapeornis* is the most primitive bird preserving a crop (Zheng et al., 2011) (Figure 7.6G and H), though the association of large numbers of undigested seeds preserved in some *Jeholornis* specimens suggests a crop could have been present in that taxon as well (Zhou and Zhang, 2002a). This timing suggests the crop may have evolved to increase food storage capacity beyond the limited stomach volume allowed by a rigid rib cage required for flight (O'Connor and Zhou, 2015).

Many modern birds can regurgitate difficult-to-digest material, such as bones and fur, in the form of pellets. Bone fragments in *Tyrannosaurus* coprolites suggest that theropods passed indigestible material completely through their digestive tract like modern crocodilians (Chin et al., 1998). The earliest evidence of antiperistalsis (the ability to regurgitate pellets) comes from intact, unexpelled pellets containing fish and lizard remains in *Anchiornis* (Zheng et al., 2018). Antiperistalsis may potentially have evolved earlier, given that pellets are unlikely to be preserved in the fossil record.

7.5 Reproduction and development

7.5.1 Sexual dimorphism

Birds provide some of the most striking examples of sexual dimorphism in the vertebrate world. Bony cranial ornamentation occurred in many theropods, but appears to have been present in both sexes. Bony ornaments occur in many modern birds, in which they may be identically developed in both sexes or more pronounced in males (Mayr, 2018). Convincing evidence for skeletal or size-based sexual dimorphism in dinosaurs is currently lacking (Mallon, 2017), though it remains possible dimorphism was manifested in a way not yet detected from the fossil record, such as dimorphic feather coloration or the presence of fleshy ornaments.

In modern birds, male-biased plumage dimorphism is common, whereas female-biased plumage dimorphism occurs only in a few groups (e.g., phalaropes). The earliest example of plumage dimorphism in birds occurs in the Confuciusornithidae, in which some individuals possess a pair of elongate ornamental rectrices (Figure 7.7A). The presence of putatuve ovarian follicles in one unornamented individual of *Eoconfuciusornis* suggests it was an adult female (Zheng et al., 2017). Thus, it seems likely that male-biased dimorphic plumage arose very early in the evolution of birds.

Males tend to be larger in bird species with size-based dimorphism, though some species show the opposite pattern (e.g., many falcons). The most remarkable example of size dimorphism occurs in the historically extinct moa *Dinornis*, in which females weighed almost three times as much as males (Bunce et al., 2003). Paternal brooding (see below) may have contributed to this wild size disparity, as males would have been restricted from attaining the same enormous sizes as females by the competing need to brood eggs without damaging them (Huynen et al., 2010).

7.5.2 Eggs

Major shifts in egg production and nesting occurred along the theropod—bird transition, spanning the full process from oogenesis to hatching. Dinosaurs, like most vertebrates, possessed two functional ovaries—a feature confirmed by the discovery of a pair of unlaid eggs within an oviraptorid dinosaur skeleton (Sato et al., 2005). Early dinosaurs laid large numbers of eggs per clutch, but derived theropods laid a single pair at a time, leading to clutches being completed via several discrete laying events. In modern birds, only the left ovary is typically functional. Reduction of the right ovary has been interpreted as an adaptation for reducing weight in egg-carrying females so as to maintain flight capacity (Taylor, 1970). Circular structures preserved in clusters near the life position of the left ovary in one specimen of *Jeholornis* and several enantiornithines have been identified as fossilized ovarian follicles, suggesting that the right ovary first became nonfunctional in early birds (Zheng et al., 2013) (Figure 7.7D and E). The nearly identical diameters of the follicles suggest simultaneous maturation, which is unexpected, as early bird body size would suggest only one egg could be stored in the body at a time (Zheng et al., 2013). However, the identity of these structures remains controversial and others have argued they instead represent plant propagules (Mayr et al., 2020).

Maniraptoran theropod eggs were elongate and small relative to body size compared to modern bird eggs. Rather than serving a specific function, the elongate shape may be

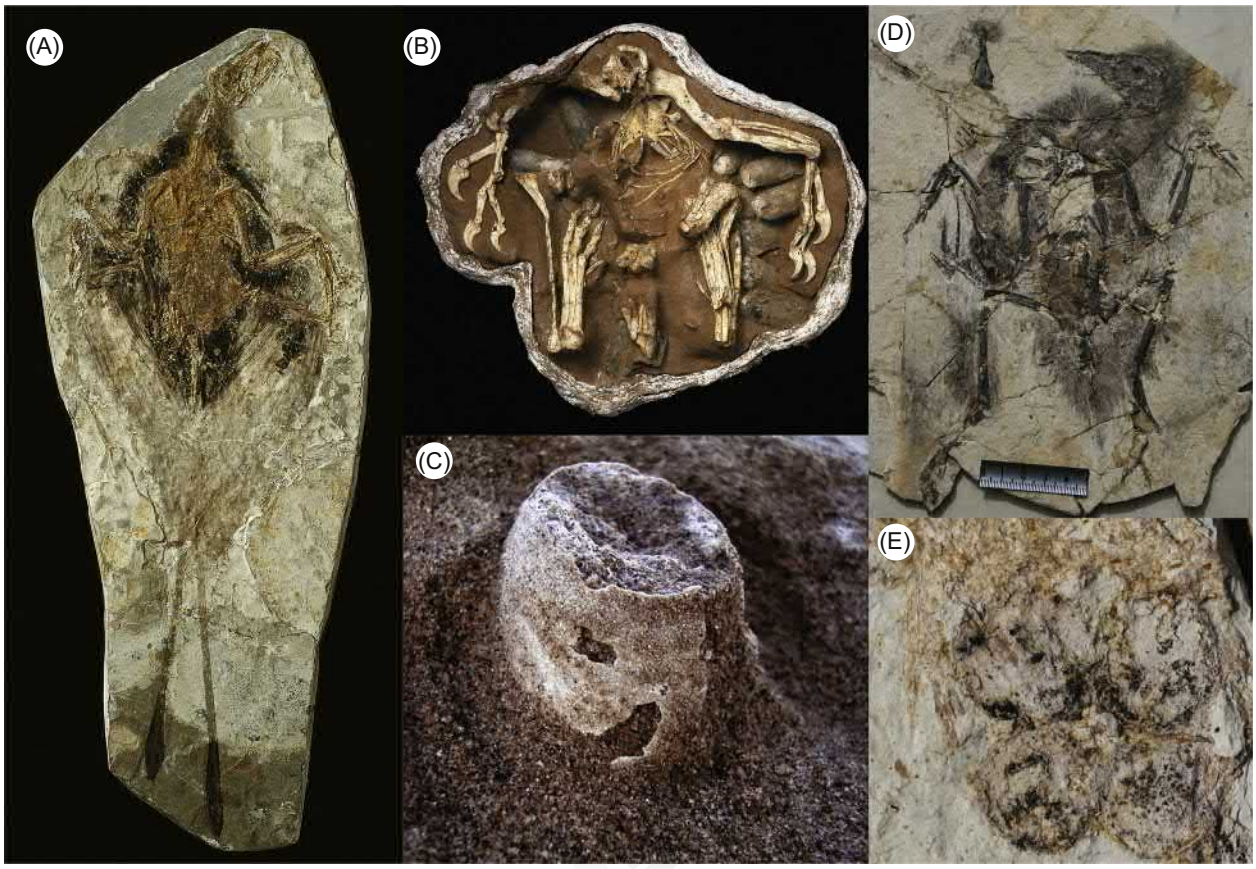

FIGURE 7.7 Fossil evidence for the evolution avian reproduction. (A) Sexually dimorphic tail plumage in a male specimen of *Confuciusornis sanctus* (GMV-2150). (B) Nesting oviraptorid *Citipati osmolskae* with eggs (IGM 100/979). (C) Partially buried enantiornithine egg (see Fernández et al., 2013). (D) Enantiornithine bird with putative ovarian follicles (STM29-8). (E) Close-up of putative ovarian follicles from another enantiornithine bird (STM10-45). *Credit: Photos in (A) and (B) by Mick Ellison, American Museum of Natural History, photo (C) courtesy Dr. Mariela S. Fernández, photos (D) and (E) courtesy of Dr. Jingmai O'Connor.*

a product of the ova being constricted in the oviduct as they expanded prior to shelling while absorbing the water required for development (Deeming and Ruta, 2014). At present, no eggs are known from the earliest birds. Enantiornithine eggs, however, are relatively well known, and were intermediate between theropods and modern birds in both size and shape (Varricchio and Jackson, 2016). Early ornithuromorph eggs have not yet been identified in the fossil record. However, osteology hints that larger egg sizes evolved relatively late in ornithuromorph history. The distal ends of the left and right pubis contact one another in basal birds and enantiornithines, constraining maximum egg diameter. In *Apsaravis* and more crownward birds, the pubes are widely separated, allowing for the passage of a larger egg (Dyke and Kaiser, 2010).

Like bird eggshell, theropod eggshell was hard and calcitic. Crocodilians mobilize calcium for shelling eggs directly from structural bone, whereas birds deposit an ephemeral layer of medullary bone to provide a rapidly accessible reservoir of calcium. Medullary bone appears to have first arisen in dinosaurs (Schweitzer et al., 2005; Lee and Werning, 2008). However, tissue resembling medullary bone may be deposited in non-egg-laying individuals for a variety of reasons including pathologies. One recent study considered nearly all reports of medullary bone in dinosaurs to be unconfirmed, due to the absence of one or more morphological characteristics (O'Connor et al., 2018). While these disparities should indeed raise caution, it must also be considered that medullary bone in dinosaurs may not have formed in exactly the same way as in modern birds. In particular, the much smaller egg size to body size ratio of large dinosaurs suggests that a smaller proportion of overall skeletal calcium needed to be mobilized to shell a clutch, in which case medullary bone may have had a more restricted skeletal distribution or lined a smaller region of a given bone's medullary cavity.

An overall trend toward smaller clutches occurs over the theropod–bird transition. Troodontid and oviraptorid clutches comprised 22–30 eggs (Varricchio et al., 1997). Given that theropods appear to have laid only two eggs

per cycle, such large clutches require either a greatly extended laying period or communal nesting (Horner, 1987). Intact clutches have not yet been uncovered from early birds, but the presence of 20 putative ovarian follicles in *Jeholornis* would suggests a very large clutch size (Zheng et al., 2013). Enantiornithine clutch size appears to have varied widely, based on evidence from putative follicles (5–14 as minimum estimates from two specimens) and an estimate of 8 eggs in one partial nest (Zheng et al., 2013; Varricchio and Barta, 2014). Clutch size varies tremendously in living birds, ranging from a single egg in many species such as albatrosses to over 20 eggs in gray partridges.

One fascinating recent discovery is the recovery of color patterns in dinosaur eggs. Birds are the only living amniotes that lay colored eggs. Modern bird eggs come in a variety of colors and patterns, ranging from plain white, to speckled, to the brilliant glossy eggs of some tinamous. In contrast, crocodilians lay plain, unpatterned eggs. Mass spectroscopy studies have revealed the presence of the pigments protoporphyrin and biliverdin in oviraptorid, troodontid, and dromaeosaurid eggs. This indicates some theropods laid blue-green eggs, and some laid eggs with speckled or spotted patterns (Wiemann et al., 2017). Sauropod and ornithischian dinosaur eggs lack evidence of color, suggesting colored eggs first evolved within theropods (Wiemann et al., 2018).

7.5.3 Nesting

Many dinosaurs buried their eggs in closed nests and so could not have brooded or manipulated them directly, whereas all modern birds, except for megapodes and brood parasites, directly incubate their eggs. Brooding, partially open nesting, contact incubation, and egg manipulation appear to have evolved in sequence across the theropod–bird transition.

Parallel pairing of eggs in oviraptorid nests corresponds to discrete laying events accommodating one egg from each ovary. Any subsequent movement would disrupt pairing, so it is unlikely that theropods manipulated their eggs (Varricchio et al., 1997). Nonetheless, the spectacular discovery of a "nesting oviraptorid" preserved at the center of a ring of eggs provides evidence for brooding in pennaraptoran theropods (Norell et al., 1995). The posture of the adult, with its arms (feathered in life) wrapped around the eggs, shows it was shielding the clutch when it perished (Figure 7.7B). Troodontids also brooded their eggs, and had a more advanced nest structure, with the eggs tightly positioned so that an adult could have covered the entire clutch with its abdomen (Varricchio et al., 1999). Because the eggs remained partially buried, it remains controversial whether nesting oviraptors and troodontids practiced true contact incubation or were only guarding their eggs (Deeming, 2006). An intermediate possibility is that adults raised egg temperatures somewhat via proximity and insulation, even without extensive direct contact. Indeed, oxygen isotope data indicate oviraptorid eggs were maintained at a temperature of 35–40°C, which, if accurate, implies at least some form of incubation (Amiot et al., 2017).

Intact enantiornithine nests show that at least some species partially buried their eggs vertically in sediment (Fernandez et al., 2013) (Figure 7.7C). Whether enantiornithines contact-incubated their eggs remains debated. Adult bones associated with a fossil clutch have been interpreted as belonging to brooding parents (Varricchio and Barta, 2014). However, estimates of enantiornithine egg strength and body mass have been used to argue that many species laid eggs too weak to support the weight of a brooding adult (Deeming and Mayr, 2018). Caution should be taken here, as these safety factor estimates apply to isolated eggs, whereas partially buried eggs would have been reinforced around their circumference by the presence of substrate and therefore able to resist greater stress. Dense concentrations of eggshells preserved alongside bones of nestlings and adults from Romania suggest colonial nesting was practiced by at least some enantiornithines (Dyke et al., 2012).

No direct fossil evidence exists for the presence or absence of chalazae, the membranes that anchor the yolk within an egg. However, because theropods and early birds appear not to have manipulated their eggs, chalazae may have been absent. If so, the evolution of chalazae may have allowed more open nesting strategies by protecting the embryo during egg movement and rotation (Varricchio and Barta, 2014). The evolution of colored eggs coincides with the evolution of partially open nests, and so may in turn have been driven by new selective pressures such as camouflage from predators or brood parasites (Wiemann et al., 2017).

Modern birds have a dazzling array of nest types. The shift from partially open to fully open nests occurred somewhere along the ornithuromorph lineage and likely played a major role in the radiation of crown birds by allowing them to brood their eggs in a variety of environments (Mayr, 2017b). Indeed, the inordinate success of passerines, which comprise the majority of extant bird species, may be due as much to nesting flexibility as complex song (Olson, 2001).

7.5.4 Development and growth

Increased contact incubation likely improved the efficiency of embryonic development along the theropod-to-bird transition. Incubation times in dinosaurs have recently been estimated based on growth lines preserved within teeth of embryos (Erickson et al., 2017; Varricchio et al., 2018). These data suggest troodontid eggs had an incubation time

of ~74 days, representing an intermediate condition between the long incubation times predicted by a crocodilian model (107.3 days) and the short incubation times predicted by an avian model (44.4 days) based on egg size (Varricchio et al., 2018).

Hatchlings of modern birds range from superprecocial (well-developed chicks needing no parental care) to superaltricial (weakly developed chicks hatching with closed eyes, few or no feathers, and capable of little movement aside from begging for food). Theropod hatchlings were well developed, at least from a skeletal perspective. Evidence of brooding, discussed above, suggests theropods practiced parental care. Thus, theropod hatchlings would most likely fall within the precocial category. Remarkable fossils of enantiornithine embryos suggest that enantiornithines were likewise precocial or superprecocial, exhibiting well-ossified skeletons, erupted teeth, and feather sheets (Elzanowski, 1981; Zhou and Zhang, 2004). The presence of flight feathers, along with early midline ossification of the sternum, suggests that enantiornithines may have been able to fly soon after hatching (O'Connor and Zhou, 2015). It has been hypothesized that the shift from arboreal to predominately aquatic or terrestrial habits in ornithuromorph birds facilitated a shift from fully independent superprecocial hatchlings to precocial hatchlings requiring some parental care (Mayr, 2017b). However, whether enantiornithine chicks were superprecocial *sensu stricto* (i.e., fully independent of parents) cannot be established or refuted based on available evidence. It is quite possible that chicks with strongly developed locomotor capabilities nevertheless relied on parents for protection, imprinting, or provisioning. Indeed, chicks of many extant bird species pursue their parents begging for food even after attaining flight capacity.

Crown birds likely shared a common ancestor exhibiting precocial development, as nearly all members of the early branching Palaeognathae and Galloanserae have precocial chicks, with the exception of the superprecocial Megapodiidae. Megapode chicks emerge from buried nests unassisted and astoundingly can fly the day that they hatch. Many shifts toward the altricial end of the spectrum occur within Neoaves, culminating in superaltricial chicks in at least eight clades (Botelho et al., 2015). Shifts in the opposite direction appear to be rare, with perhaps the most compelling example being loons, whose chicks can dive after just 2 or 3 days, though they often prefer to ride on their parents' backs.

Surprisingly, recent work suggests that paternal care characterized most early birds. Although direct evidence is lacking for the relative roles of males and females in theropod brooding, large clutch volume, lack of medullary bone in sampled nesting adults, and phylogenetic reconstructions all support the inference that males brooded eggs (Varricchio et al., 2008). Because paternal care also predominates in extant Palaeognathae, it is likely this was the primitive condition for crown birds (Moore and Varricchio, 2016). Thus, the shift to a predominantly biparental mode of care, which confers the advantage of additional protection and provisioning for chicks, may be considered a major innovation in Neognathae.

Theropods took several years to reach adult body size, and began breeding well before reaching maximum size (Lee and Werning, 2008). Extant birds grow much more rapidly, and almost all species reach their adult size in a matter of weeks or months. Moreover, most modern birds do not breed until after completing growth, in some cases delaying breeding until several years after reaching maximum size. Early birds like *Archaeopteryx* and *Confuciusornis* retained a slower growth curve, and thus grew in a manner similar to small dinosaurs. They reached maturity after 2 or 3 years with annual pauses in growth recorded by lines of arrested growth (LAGs), demarcations that are visible in thin sections of long bones (Erickson et al., 2009). The transition to more rapid maturation occurred within ornithuromorphs. The bone microstructure of the basal-most ornithuromorph *Archaeorhynchus* indicates it grew slowly like its enantiornithine contemporaries (Wang and Zhou, 2017). In contrast, the late Cretaceous *Ichthyornis* and Hesperornithes show more richly vascularized bone tissue and lack LAGs, suggesting they grew more rapidly and reached adult size in a single year (Chinsamy et al., 1998).

7.6 The rise of modern birds

7.6.1 The shallow Cretaceous roots of crown birds

By the end of the Cretaceous, crown birds (Neornithes) had evolved. When the crown bird radiation began remains a subject of perpetual debate, due to a sparse fossil record of Late Cretaceous birds and conflict between recent molecular divergence dating analyses. Regardless of when they first appeared, early crown birds were "modern" in that they had given up teeth once and for all, evolved a deep sternal keel for the pectoral muscles and precisely controlled tail fan, and acquired a development system in which they hatched from large eggs and achieved adult size rapidly. Despite these advantageous features, crown birds made up a relatively small proportion of the latest Cretaceous avifauna (Longrich et al., 2011).

The fossil record suggests that all crown birds descend from a handful of extinction boundary-crossing lineages, perhaps as few as four. Only a few convincing Cretaceous records of crown birds are known, all from very close to the K-Pg boundary. The oldest of these is the "wonder chicken" *Asteriornis maastrichtensis*, known from a 66.7–66.8-million-year-old skull and partial skeleton that

preserve features found in the otherwise disparate Galliformes (landfowl) and Anseriformes (waterfowl) (Field et al., 2020). *Asteriornis* was a small bird, about the size of the modern gray partridge, with a short, rounded beak, and large nostrils. This species probably branched off the avian evolutionary tree shortly before Galliformes and Anseriformes split from one another (Field et al., 2020).

Vegavis iaai is a slightly younger (~66.5 Ma) crown bird. Originally described from a partial postcranial skeleton, *Vegavis* was considered to be closely related to magpie geese and ducks, and thus the oldest species of crown Anseriformes (Clarke et al., 2005). However, the discovery of more complete material, together with the application of different phylogenetic models, has led to alternative hypotheses that *Vegavis* may instead represent a stem member of Anseriformes, or perhaps fall just outside the crown bird radiation (O'Connor et al., 2011; Worthy et al., 2017; Field et al., 2020). *Vegavis* possessed a strongly bowed femur, well-developed cnemial crests, and greatly enlarged patella (notably absent in most waterfowl, with the exception of a few diving taxa such as *Thalassornis*), which strongly suggest a diving ecology.

The putative Cretaceous Antarctic loon *Polarornis gregorii* shares numerous hind limb features with *Vegavis*, suggesting they are close relatives. However, the long and pointed bill of *Polarornis* would be unexpected if both taxa were nested within Anseriformes. Frustratingly, *Polarornis* remains an enigma despite being known from one of the most complete Late Cretaceous bird fossils. The type specimen was illustrated in great detail in a series of line drawings, which depict many fine details such as the location of cranial nerve foramina (Chatterjee, 2002). Regrettably, the skull has been so heavily reconstructed that few if any of these features can actually be observed in the fossil, begging the question of whether they were even there in the first place. Inexplicably for such a critical fossil, several bones described in the original monograph can no longer be located (see Clarke et al., 2016), leaving *Polarornis* to be considered by many avian paleontologists more of a cautionary tale than a keystone fossil.

Under a conservative phylogenetic framework considering *Asteriornis* to be a stem galloanserine and *Vegavis* to be a stem anseriform, the fossil record provides evidence that four major crown bird lineages diverged by the end of the Cretaceous, and thus survived the mass extinction: Palaeognathae ("ratites" and tinamous), Anseriformes, Galliformes, and Neoaves (all other crown birds). Whether any major groups of Neoaves had already diverged prior to the mass extinction remains unresolved—molecular divergence dating analyses yield conflicting results, and in most cases, the confidence intervals for multiple early splits overlap the K-Pg boundary, indicating statistical uncertainty (Ksepka and Phillips, 2015). Nonetheless, when the biological plausibility of a rapid radiation immediately prior to a mass extinction is weighed against that of a rapid radiation immediately following a mass extinction, it is hard to justify the former (Berv and Field, 2018).

7.6.2 Survival and extinction

A major asteroid impact at the end of the Cretaceous caused global devastation and wiped out close to 75% of all species (Alvarez et al., 1980). Following the impact, global wildfires caused by molten debris reentering the atmosphere burned a large proportion of existing forests, while smaller dust and soot particles remained suspended in the atmosphere leading to the temporarily shutdown of the photosynthesis-based food chain (Robertson et al., 2004). A few key factors set birds aside from their theropod relatives, which perished during the mass extinction. Small size would have been advantageous in the immediate aftermath of the asteroid impact, imparting lower energy requirements that would have been helpful in a resource-poor environment. However, large birds and small theropods overlapped in size, so this factor cannot fully explain differential survival. It is likely that the advanced beak and digestive system of birds played an important role, potentially allowing birds to sustain themselves with food sources such as seeds that remained available despite the temporary collapse of photosynthesis-based food chains (Larson et al., 2016). Flight may also have allowed birds to travel to less devastated areas, or to have occupied remote and less affected areas in the first place.

Perhaps a more compelling question is not why birds survived at all, but why some birds survived and others did not. As far as can be determined, the K-Pg mass extinction completely wiped out all stem birds, most notably the enantiornithines, leaving only crown birds to inherit the new landscape. Habitat preference provides the most plausible explanation for the survival of modern birds. Enantiornithes dominated arboreal ecosystems in the Cretaceous (O'Connor et al., 2011). Widespread deforestation during the extinction event may have led to the demise of birds that relied on canopy for feeding (Mayr, 2017c; Field et al., 2018a). Cretaceous crown birds, which preferred aquatic or ground-dwelling habitats, appear to have been less susceptible to the decimation of global forests (Field et al., 2018a, b). Notably, early crown birds presumably possessed a gizzard, whereas no known enantiornithines preserve evidence of gastric milling capacity, suggesting they may not have been able to access nonperishable food resources like seeds (O'Connor, 2019). While crown birds undoubtedly also suffered greatly during the mass extinction, their ancestral ecology ensured that a few lineages were able to hang on.

7.6.3 An explosive Paleogene radiation

Although avian fossils remain poorly sampled from early Paleocene localities, emerging evidence supports not only an explosive phylogenetic diversification but also a rapid ecological diversification. The two oldest Paleocene neoavians are indeed about as different from another as can be imagined. *Tsidiiyazhi abini*, a ~62.5-million-year-old mousebird, was a tiny species with a semizygodactyl grasping foot representing the oldest crown bird adapted to an arboreal existence (Ksepka et al., 2017). In contrast, the ~61-million-year-old *Waimanu manneringi* was a large penguin that had already made the transition to a flightless aquatic lifestyle (Slack et al., 2006). Molecular divergence analyses support an even wider radiation than the fossil record hints at, implying almost every order of modern birds had split from their sister taxa by the Eocene (Jarvis et al., 2014; Prum et al., 2015).

The mass extinction appears to have opened an array of new niches for crown birds by removing existing competitors. The most important of these was the complete opening of forest ecosystems vacated by enantiornithines. Crown birds rapidly diversified into arboreal niches, with an amazing variety of specialized groups ranging from owls to frogmouths and from rollers to passerines well represented in early Eocene lake deposits. Two major marine reptile groups, the plesiosaurs and mosasaurs, perished in the extinction along with the previously widespread and successful diving bird clade Hesperornithes. It is tempting to posit a link between the loss of these secondarily aquatic tetrapod clades and the rapid appearance of penguins shortly after the mass extinction. Likewise, the fact that Late Cretaceous pterosaurs tended toward very large sizes suggests that the dominance of pterosaurs may have prevented Cretaceous birds from moving into large soaring niches. Giant marine soaring forms first arose in crown birds, including the extinct bony-toothed Pelagornithidae and modern albatrosses, though the earliest representatives of both clades had relatively modest wingspans compared with their later descendants.

The closest that crown birds came to converging on the body plans of their extinct theropod relatives was in the terrestrial realm. Numerous lineages including the extant "ratites," the extinct giant waterfowl families Gastornithidae and Dromornithidae, and the extinct "terror bird" group Phorusrhacidae, all attained large sizes and reverted to flightlessness (Worthy et al., 2017). Ecologically, these groups essentially reoccupied niches vacated by theropod groups, e.g., with true ostriches converging on the Ornithomimosauria and terror birds converging on Deinonychosauria, with hooked beaks instead of serrated teeth.

7.7 The shape of modern bird diversity

For nearly a century and a half, ornithologists struggled to reconstruct the evolutionary tree of modern birds. Over time, morphological and molecular data led to support for three major divisions that are now recognized: Palaeognathae, Galloanserae, and Neoaves. Today, the rapidly advancing capacity for genomic-level sequencing is actively improving our understanding of finer level relationships within these clades (Jarvis et al., 2014; Prum et al., 2015; Reddy et al., 2017). It is beyond the scope of this chapter to provide more than a cursory review of the interrelationships and evolution of the >10,000 species of crown birds. Below, the three major branches are introduced with brief comments on patterns of diversity.

7.7.1 Palaeognathae

The basal split among all living birds separates the Palaeognathae and Neognathae (Galloanserae + Neoaves). These two branches led to wildly different evolutionary histories: Palaeognathae represent less than 1% of extant avian species as opposed to Neognathae accounting for more than 99%. Yet, Palaeognathae includes some of the most unusual birds ever to have lived, such as the nocturnal ground-probing kiwi and the enormous wingless moa. The long-held theory that "ratites" (ostrich, rhea, emu, cassowary, and kiwi) formed a clade guided hypotheses about palaeognath biogeography and flight loss for much of the 20th century. Surprisingly, molecular data have converged on a topology that nests the volant tinamous well within Palaeognathae (Phillips et al., 2010). Combined with geographical distribution, this requires a remarkable six losses of flight to have occurred in palaeognaths, with all but one leading to subsequent shifts to gigantism (Sackton et al., 2019).

The extinct volant Lithornithidae occurred in North America and Europe during the Paleogene. Controversy remains over whether Lithornithidae represent stem palaeognaths, crown palaeognaths, or even late-surviving stem birds (Houde, 1988; Livezey and Zusi, 2006; Nesbitt and Clarke, 2016). Olfactory bulb impressions in the skulls of lithornithids indicate they had a powerful sense of smell, and thus may have probed shoreline environments for food with their long beaks (Houde, 1988; Zelenitsky et al., 2011).

Ostriches are familiar as the largest living birds, but they would have been dwarfed by two major lineages of flightless palaeognaths that were wiped out by humans in the last millennium. The New Zealand Dinornithiformes (moa) and the Madagascar Aepyornithiformes (elephant birds) each attained gigantic sizes, with the aepyornithid

Vorombe titan believed to be the largest bird ever to have lived at ~650 kg (Hansford and Turvey, 2018). Remarkably, both of these clades of enormous birds are closely related to much smaller birds, with moa paired with tinamous, and elephant birds paired with kiwi in molecular phylogenies (Phillips et al., 2010; Mitchell et al., 2014). It is particularly perplexing that despite once occurring side by side in New Zealand, kiwi and moa share no close relationship.

7.7.2 Galloanserae

Galloanserae include the Galliformes (landfowl) and Anseriformes (waterfowl), two groups with extremely divergent ecologies. Galliformes are primarily ground dwelling, and many species have weak capacity for sustained flight, being instead adapted to rapid bursts of escape flight. Anseriformes are primarily aquatic and many species are capable of remarkable long-distance flight, such as the bar-headed goose, which flies over the Himalayas during migration. *Asteriornis*, the oldest crown bird, provides some insight into the ancestral ecology of Galloanserae. Long, slender hind limb bones suggest it dwelled near the shoreline. The small size and littoral ecology of this species, if general to early galloanserines, may have been key features helping them survive the K-Pg mass extinction (Field et al., 2020).

Although a full treatment of Galloanserae would require several additional chapters, it is worth noting that many of the most remarkable extinct clades of birds belong to this clade. On the Anseriformes side of the tree, the giant flightless Dromornithidae of Australia and Gastornithidae of the Northern Hemisphere were among the largest birds ever to have lived. Dromornithidae survived well into the Pleistocene before they were driven to extinction by humans (Roberts et al., 2001). On the Galliformes side, Sylviornithidae represent another family of giant flightless birds. They survived even closer to modern times, likely being wiped out soon after humans arrived in New Caledonia and Fiji approximately 500 years ago (Hume and Walters, 2012). Most unusual were the Pelagornithidae, marine soaring birds, whose place (or even inclusion) within Galloanserae remains uncertain. These remarkable birds had serried ranks of "pseudoteeth" lining their beaks, which were formed by bone covered by keratin rather than dentine and enamel. Pelagornithid pseudoteeth resemble first-generation crocodilian teeth, which begin as outgrowths of the jaw bones in the earliest developmental stages (Mayr and Rubilar-Rogers, 2010). Thus, pelagornithid pseudoteeth may actually be developmentally homologous to true teeth (Louchart et al., 2018). The largest flying bird ever to have lived was the pelagornithid species *Pelagornis sandersi*, which reached wingspans of ~6.4 m and likely had an albatross-like ecology (Ksepka, 2014).

7.7.3 Neoaves

Neoaves, by far the most diverse of the three major branches of the crown bird tree, includes over 10,000 species. Resolving the relationships of major groups within Neoaves has proven to be one of the most challenging puzzles of avian systematics, but much progress has been made in recent years. Phylogenomic analyses consistently recover the clades (1) Mirandornithes (grebes and flamingos), (2) Columbimorphae (pigeons, sandgrouse, and mesites), and (3) Strisores (nightbirds, swifts, and hummingbirds), but offer conflicting signals over which of these clades occupy the first branch of the neoavian tree (Jarvis et al., 2014; Prum et al., 2015; Reddy et al., 2017). Another early branching clade that is consistently supported is the Otidimorphae (cuckoos, turacos, and bustards). Subsequent branches are occupied by a number of aquatic clades. Strong support exists for a clade uniting the "core waterbirds" (e.g., loons, petrels, penguins, cormorants, pelicans, storks, herons, and tropicbirds), but it remains uncertain whether the Charadriiformes (shorebirds) are also part of this radiation or instead are closely related to the Gruiformes (cranes and rails).

The vast majority of Neoaves belong to the clade Telluraves ("higher land birds"), which contains all birds of prey (hawks, falcons, owls, and seriemas), a diverse array of mostly arboreal coraciimorph birds (mousebirds, courols, rollers, kingfishers, trogons, woodpeckers, and kin), parrots, and the hyperdiverse passerines, which account for more than half of all living bird species. Relationships within Telluraves have become increasingly well resolved, revealing a few interesting patterns. One example is that all four predatory clades occupy branches near the root of Telluraves, which implies the common ancestor of landbirds may have been predatory (Jarvis et al., 2014). Another is that parrots and passerines are sister taxa, which together with fossil evidence suggests passerines were ancestrally zygodactyl (Mayr, 2008).

7.8 The impact of humans on birds

The fossil record provides an ever-improving picture of the evolutionary history of birds, but it is important to remember that avian evolution did not stop when we reached the present day. Indeed, the rise of humans has arguably affected avian evolution as profoundly as the K-Pg mass extinction. Humans have long benefited from sharing the planet with birds, starting with the hunting, followed by domestication of birds for food, and even present-day bird watching which generates billions of dollars in economic activity. Yet, this relationship has rarely been mutually beneficial. Island species were initially the hardest hit types of birds, with more than 500 species, many flightless or with reduced flight capabilities, wiped

out as humans spread throughout the Pacific and Indian Oceans (Hume and Walters, 2012). These included many of the largest birds ever to have lived, such as the elephant bird and moa, thus greatly reducing not only the species diversity but also the morphological and ecological diversity of our remaining avifauna. By measure of raw abundance, the impact of humans is even more profound: domestic chickens now account for three times the biomass of all wild bird species on the planet (Bar-On et al., 2018). To a much less extreme degree, some of the more common wild bird species have also undergone population booms due to human-mediated introduction to new regions and habitat modification. For example, the combined population of Eurasian Starlings, Rock Pigeons, and House Sparrows in the United States rivals that of humans. A paleontologist from 10 million years in the future would infer an extinction event for birds, noting the loss especially of so many larger species, though they might be hard pressed to explain the appearance of a galliform disaster fauna with chickens spreading ubiquitously across the Earth like ferns rapidly recolonizing a posteruption volcanic island. Whether this hypothetical paleontologist ranks the extinction as minor or major will ultimately depend on our own response to overpopulation and attendant deforestation and climate change.

Acknowledgments

The author thanks Jaime Headden for creating the skeletal silhouette artwork, Kate Dzikiewicz for creating the character illustration line art, Mick Ellison, Jingmai O'Connor, and Mariela Fernandez for providing photos, and Daniel Field, Jingmai O'Connor, Steve Brusatte, and Kristin Lamm for helpful feedback.

Chapter 8

Domestication of poultry

Paul B. Siegel[1], Christa F. Honaker[1] and Colin G. Scanes[2]
[1]Department of Animal and Poultry Sciences, Virginia Tech, Blacksburg, VA, United States; [2]Center of Excellence for Poultry Science, University of Arkansas, Fayetteville, AR, United States

8.1 Introduction

Birds, from a range of species, were domesticated for numerous reasons including sport, communication, ceremony, and food. The focus here will be on domesticated birds or "poultry", namely chickens, ducks, geese, guinea fowl, Japanese quail, ostriches, pigeons, and turkeys. Chickens, ducks, and turkeys have been much studied and are important sources of food for their domesticators, namely humans. Crawford (1990) and Appleby et al. (2004) provide brief overviews for other domesticated birds, including pigeons, quail, and ratites. Domestication of chickens commenced during the Neolithic period (Stevens, 1991) about midway during the First Agricultural Revolution (see Table 8.1). Domestication of ducks commenced at least several centuries BCE (McKinney, 1969), while in more recent times, turkeys were domesticated in the Americas.

8.2 Domestication

Domestication is dependent on human intervention and actions, be they intentional (e.g., artificial incubation of eggs) or indirect (e.g., environmental changes). Thus, modifications of the process may be abrupt or gradual. Domestication is considered as directed evolution with humans deciding which individuals are chosen to produce the next generation. Changes in the phenotypes reflect shifts in genotypes as they interact with internal and external environments, including multiple physiological processes. The effects may be short-term or generational because of mate choice and sexual reproduction.

Domestication of plants and animals is a continuing process that may be viewed historically in a time and geographical context (Diamond, 1999; Zeder, 2015). Table 8.1 summarizes the domestication of birds. The Neolithic Revolution was a major turning point in the development of human society with many plants and animals domesticated. Domestication is arguably considered as one of the great innovations in human history. Adapting the Merriam-Webster definition of domestication, domestication of birds is the adaptation of an avian species "*from a wild or natural state (as by selective breeding) to life in close association with humans.*" Zeder (2015) defined domestication as "*a sustained multigenerational, mutualistic relationship in which one organism assumes a significant degree of influence over the reproduction and care of another organism in order to secure a more predictable supply of a resource of interest, and through which the partner organism gains advantage over individuals that remain outside this relationship, thereby benefitting and often increasing the fitness of both the domesticator and the target domesticate.*" Domestication involves changes whereby the breeding and care of animals are directly or indirectly controlled by humans and is more than simply taming (Darwin, 1868). In comparison to plants, the domestication of poultry is very recent in terms of human history (see Table 8.1). To put it into perspective, Craig and Crawford (1981) wrote, "*a crude calculation suggests that man has lived alongside domesticated animals for only about one-half of 1% as long as he has been a toolmaker.*"

In recent centuries, knowledge and technologies in the life sciences (e.g., rediscovery of Mendelism, DNA, and genomics) have and continue to have major impacts on the paths taken to direct residual and "new" genetic variation via intercrosses, which in turn influence physiological and behavioral mechanisms and phenotypes. Such techniques address the evolutionary process of domestication and selection. Rubin et al. (2010) used whole genome sequencing to trace the origin of the domestic fowl. Corso et al. (2017) reported that while the domestic turkey came in plumage colors controlled by at least five genetic loci, only the bronze has been precisely identified. Deng et al. (2019) used genome-wide association studies to detect novel loci in Pekin ducks. Another example of the use of genomic approaches has been study of the development of a "new" genetic breed of chicken, the White Plymouth Rock; this being a breed that was a large contributor to today's meat-

type broiler chickens. Using current genetic tools, Guo et al. (2019), via genomic analysis, revealed not only genome-wide contributions from the foundation breeds (Dominique [sire] and both Black Cochin or Black Java [dams] together with contributions from Brahma, Langshan, and Black Minorca breeds), but also differences in contributions to each of 29 chromosome pairs of the White Plymouth Rock.

Although unaware of Mendel, Darwin (1868) wrote of the importance of variation in domestication. The same thinking may be seen in the writings of Fritz Muller (West, 2003, 2016). Certain behaviors that facilitated the domestication of poultry that were important at one point in time (e.g., escape behaviors) may be redundant today when animals are kept in confinement. Also, the behavioral and physiological processes involved may not be all or none, but modified by the degree of stimuli, response thresholds, point in the life cycle, heritability, and epigenetics. Conditioning may influence both the behavior and response of an animal, an example being nest locations and adaptation responses between the first and subsequent ovipositions (Beuving, 1980). A recent and quite different example is the "henny feathering" phenotype in the Seabright chicken (Li et al., 2019). Although the presence of female-like plumage on males is known to be caused by a dominant mutation, the mechanisms involved have been elusive. Today we know that, physiologically, the phenotype was caused by ectopic expression of *CYP19A1* encoding aromatase in the skin, thus precluding development of male-specific plumage, but not sexual behavior.

8.2.1 Chickens

Today, the domestic chicken (*Gallus gallus domesticus*), which originated during the First Agricultural Revolution from the junglefowl of Southeast Asia, is found throughout the world (Robinson et al., 2014, Fig. 8.1). Charles Darwin (1868) considered that chickens were domesticated exclusively from red junglefowl (*Gallus gallus*). In contrast, Hutt (1949) proposed that modern chickens were derived from four species of junglefowl, specifically, red junglefowl native to Indochina, gray junglefowl (*Gallus sonneratii*) native to the Indian subcontinent, Ceylon or Sri Lanka junglefowl (*Gallus lafayetti*) native to Sri Lanka, and green junglefowl (*Gallus varius*) native to Java. Genomic studies have demonstrated that the chickens are derived from the red junglefowl in a monophyletic manner (Fumihito et al., 1994, 1996). There is also evidence that there has been introgression of genes from other species. For instance, if the trait of yellow legs due to carotenes in the skin and a mutation depressing expression of beta-carotene dioxygenase 2 is considered. This appears to have been introgressed from gray junglefowl (Eriksson et al., 2008). There is also evidence of introgression from *Gallus lafayetti* based on mitochondrial DNA (Nishibori et al., 2005). Conversely, there have been intrusion of chicken genes into the green junglefowl (Sawai et al., 2010). Within diverse environments, chickens have adapted to conditions ranging from that of scavengers to highly intensive production systems that focus on intense and persistent year-round egg production and rapid growth. In the case of the latter, although the individuals are marketed prior to sexual maturity, their parents must be capable of reproduction (Siegel, 2014).

Do the differences between the junglefowl and today's commercial egg or meat-type chickens go beyond plumage color (although not all egg-type commercial chickens have white plumage), and, respectively, numbers of eggs laid or body size? It is noteworthy that among domestic farm animals, the chicken has increased in size while that of mammals has decreased (Diamond, 1999). Sutherland et al. (2018) reported body weights of <100 g for Red junglefowl at 35 days of age. The commercial chicken industry, developed with breeding programs in the post-World War II period, focused on either egg or meat production. This resulted in dramatic increases in body size of meat-type chickens. Body weights at 35 days, typically 1400 g in 1985 were, in 2010, slightly in excess of 2400 g (Siegel, 2014), and have since increased at 40 to 50 g per year (also see Table 8.2). For commercial egg laying stocks, the neuroendocrine cascade for the onset and persistency of egg production is well documented (Scanes et al., 1992). Also needed for the onset of egg production are minimum age, body weight, and body composition, which may be stock specific (Zelenka et al., 1987). This knowledge has allowed the development of breeding and husbandry programs so that stocks routinely peak at greater than 95% and maintain intensity and persistency of egg production for extended periods (Preisinger, 2017; Fernyhough et al., 2020).

Plumage colors for breeds of chickens are summarized in The American Standard of Perfection (American Poultry Association, 1947). Because white plumage color is inherited as recessive white (*cc*) or as dominant white (*II*) (Hutt, 1949), it masks the phenotypic expression of genes responsible for other colors, although feathers of chickens that are *Ii* may have some colored spots. Thus, the changes are in conformation, not structure. Male junglefowl have "showy" plumage while the females are drab, which provides camouflage to reduce predation during incubating eggs and chick rearing. Both junglefowl and domestic chickens are ground nesters. The colorful plumage of junglefowl males may be viewed as a compromise between sexual selection (female choice) and predation. The introduction of *cc* and *II* in commercial flocks facilitated processing (no dark pin feathers) for marketing.

Behaviors that favored domestication of poultry are intertwined with physiological mechanisms at any point in the life history of the individual. Examples include the

FIGURE 8.1 Junglefowl and domestic chicken examples, as represented by female and male (top) Red Junglefowl, (middle) White Leghorn egg-type chickens selected for antibody production, and (bottom) White Plymouth Rock meat-type chickens selected for high body weight. *Photos courtesy of (top) Dez-Ann Sutherland and Jingyi Li and (middle and bottom) Christa Honaker.].*

neuroendocrine behavioral aspects of reproduction and responses to acute and chronic stressors (the general adaptation syndrome). Although the adaptability of the chicken is a function of its behavioral and physiological makeup, Price (1984) pointed-out that the influence of domestication has been mostly quantitative rather than qualitative. Over the years, stimuli may have been altered as have the thresholds of responses to stimuli. Whole genome sequencing has provided a schematic tree on the domestication of the chicken and its breeding history with experimental and commercial populations as examples (Rubin et al., 2010).

Scavenging domestic chickens capitalize on those behaviors and the underlying physiological mechanisms that facilitated their domestication. Although under intensive husbandry, as the physiological processes remain, some of

the behaviors that facilitated domestication of the chicken have become redundant. Hale (1969) and Price (1984) summarized and discussed traits that initially favored domestication of the chicken. Chickens were not a migratory species, thus while they may exhibit escape behaviors, flight was not an issue. Other traits that favored domestication included a social structure that allowed grouping of males and females. In addition, within sexes, in small groups, the social structure was stable (Guhl, 1953), inferring a capacity for recognition and memory. Other behaviors considered included promiscuity, incubation behavior, precocial young, omnivorous dietary habits, and adaptation to a range of environments.

Although at oviposition the embryo has proceeded to a multicellular stage and the second of the three primary "germ layers" have usually begun to appear (Romanoff, 1960), the embryo essentially develops outside the body of the dam. Upon hatching, the chick transitions over a brief period from cold to warm blooded, thus providing opportunity for an interface between hen and human intervention. In the natural state, parental care is by the hen, however, males will express maternal behavior under certain conditions (Kovach, 1967). The intervention by humans in the domestication process accelerated during the transition from the Agricultural to the Scientific Revolution. This was further enhanced during the 20th century with the rediscovery of Mendelism, recognition of B and T cell immunity, advances in nutrition, and their interface with the dynamics and relationships among physiological systems. For example, although the development of the force-draft incubator made incubation behavior irrelevant, it took generations of selection to modify neuroendocrine thresholds to preclude broody behavior. The implementation of group rearing of precocial chicks also removed the need for

maternal behavior. Although artificial incubation can be traced to at least the Ch'in period of 246–207 BCE (Landauer, 1951), its development became suddenly abrupt via a technological breakthrough. Namely, large scale forced-air incubation did not become routine until the 20th century with the discovery of electricity. This led to the control of brooding and selection for the onset and persistence of egg production by manipulation of the photoperiod and genetics (Siegel, 2014).

The evolutionary tree of the domestic chicken has branches where, over time, behavioral and physiological characteristics may have or had different relevance. That we may no longer observe chickens exhibiting certain behaviors does not imply that they no longer exist. Rather, the normal cascading of physiological processes may have been disrupted and thus altered thresholds for responses. An example is polygenic trait broodiness (Saeki, 1957). This may be because it is rarely expressed in populations bred for high egg production and rapid growth. Pedigrees for scavengers are seldom known, and the sizes of pedigree populations for show and fancier stocks are too small for the necessary statistical reliability. Yet, we know that broodiness is a threshold trait with at least two components (i.e., initiate incubation and to persist throughout the period). These behavioral and physiological dynamics are well documented, as are those involved with posthatching relationships.

Overall, the domestic chicken may be viewed in numerous forms with a multitude of uses, from the Neolithic period to the present day. Yet, much of the standing genetic variation from the junglefowl remains. Namely, the physiological processes involved and morphological structures, while altered, remain fundamentally the same, and this holds true not only for chickens but also other domestic species as well.

8.2.2 Turkeys

The turkey (*Meleagris gallopavo*) has a rich history in the United States beginning with the settlements at Jamestown in 1607 and Plymouth Rock in 1620 and with it being the "center of the table" for the Thanksgiving holiday. The turkeys of lore from Virginia and Massachusetts were wild, not the domestic turkeys that Hernán Cortés observed a century earlier in the conquered Aztec empire (Schorger, 1966). His classic, "The Wild Turkey: Its History and Domestication," is generally considered the primary source for what has been written on the early history of the domestication of the turkey. About 25 years later, Buss (1990) provided history and insights on the metabolism, neuroendocrinology, and muscle physiology in the development of the "broad breasted" domestic turkey that is common in America, Europe, and the Middle East. His history of the "broad breasted" turkey compliments and is not independent of the behaviors described by Hale et al. (1969).

The turkey was already domesticated when Cortés arrived in the Yucatan Peninsula in Central America before conquering the Aztec Empire in 1519 (see Table 8.1). There is evidence from Mayan archaeological sites dating to 300 BCE–100 CE of the presence of domesticated turkeys (Thornton et al., 2012). These were genetically distinct from local turkeys suggesting trading of domestic turkeys (Thornton et al., 2012). The turkey, unlike the chicken and duck, has unique head and neck appendages that lack feathers (Scanes et al., 1992). These anatomical features (Fig. 8.2) are consistent with initial domestications in hot, dry climates. A lack of feathers is beneficial to aid in dissipation of heat and thermoregulation.

This domesticated turkey was taken to Europe and returned to the Americas several times, resulting in a series of domestications with introgressions from wild turkeys (Schorger, 1966). Schorger (1966) also writes that there is evidence of turkey domestication in Arizona and New Mexico during Pueblo I (700–900 CE) and perhaps two centuries earlier (500–700 CE), as well as later in Pueblo II and III (900–1100 CE) (Schorger, 1966, Table 8.1).

Fundamental to acceleration of the process of turkey domestication during the 20th, and now into the 21st, century was further understanding of the physiological-behavioral interface described for the chicken. Commercial turkey breeds are more closely related to three of the heritage breeds, the Blue Slate, Bourbon Red, and Narragansett, than to either Royal Palm or Spanish Black breeds (Kamara et al., 2007), and the turkey genome exhibits markedly lower diversity than the chicken (Aslam et al., 2012).

Human interventions on reproduction in the domestication of the turkey involved primarily neuroendocrine relationships associated with onset and persistence of egg

FIGURE 8.2 A Bourbon Red tom turkey. *Photo courtesy of Audrey McElroy.*

and sperm production, incubation, and maternal behaviors. The high heritability and intense selection for growth and breast meat yield resulted in considerable changes in motor ability as well as sexual dimorphism in body weights of males and females. Although the adult female to male body weight ratio may have remained constant at approximately two-thirds, a dimorphism in body weight per se of 6 and 9 kg to 12 and 18 kg has been considerable. Thus, unlike the chicken and duck, artificial insemination (Bakst and Dymond, 2013) has become routine in commercial turkey production. This dimorphism requires sex separate breeding flocks of domestic high meat yielding turkey populations for the procedure to be successful. The photoperiod response is not only important for the onset and persistency of egg and sperm production but also remains unchanged. While on the topic of reproduction, we would be remiss in not pointing out that a considerable literature exists on parthenogenesis in the turkey (e.g., Olsen and Marsden, 1968). This phenomenon was recently reviewed for several avian species (Ramachandran and McDaniel, 2018).

8.2.3 Ducks

The mallard, or mallard duck (*Anas platyrhynchos*), and the Muscovy (*Cairina moschata*) are the progenitors of domestic ducks (McKinney, 1969, 1975; Dohner, 2001). The literature is unclear as to when and where ducks were first domesticated. When viewed in the context of traits that favored domestication (Hale, 1969), the aspects of flight and migration were probably major factors in multiple initial domestications, especially for the mallard. Most domestic ducks trace back to mallards, whose early domestication occurred during the Iron Age in Southeast Asia and China (Crawford, 1990; Zhou et al., 2018, Table 8.1). Chinese breeds of domestic ducks are predominantly derived from mallard ducks, with some contribution from the spot-billed duck (*Anas zonorhyncha*) (Qu et al., 2009; Li et al., 2010). Domesticated ducks moved on to Europe, being farmed by the Romans in about 50 BCE (Cherry and Morris, 2008). In contrast, the domesticated Muscovy was present in present-day Latin America when the Europeans first arrived during the 15th century (Table 8.1).

There are numerous distinguishing characteristics between mallard and Muscovy ducks, and their routes to domestication differed in time and source. The incubation periods are 28 and 35 days for mallards and Muscovy, respectively. Although they will mate naturally, the incubation period of about 32 days is intermediate. The resulting progeny are sterile (Dohner, 2001), with those between a Muscovy male and mallard female called "mules," while those from the reciprocal cross are called "hennies."

Mallards are wildly distributed in the Northern hemisphere including Eurasia, North America, and North Africa and exhibit migration (e.g., Yamaguchi et al., 2008; van Toor et al., 2013; Bengtsson et al., 2014). Up until commercial production with confinement husbandry (Cherry and Morris, 2008), matings frequently occurred between wild and domestic ducks, resulting in introgression of genes from their wild ancestors. This may have facilitated the development of ducks that are highly recognized for meat characteristics such as the Pekin or prolific egg production such as the Khaki Campbell (American Poultry Association, 1947; Qu et al., 2009). Although there are numerous genes associated with plumage color, among duck populations, the white feathers and down relevant in the processing of meat-type ducks are *cc* (recessive white), which is an epistatic genotype for color, thus masking plumage color expression. While major loci, such as recessive white, may have remained a constant and precluded expression of other genes, we must recognize that most physiological traits are quantitatively inherited with inter- and intralocus interactions. Human intervention may have had a considerable effect in the formation of breeds developed from mallards and Muscovy, but branching may have been considerable with the two species. For example, within the Chinese breeds, the Pekin haplotypes are distinctly different from those of other domestic breeds originating from the wild mallard (Qu et al., 2009).

As with the chicken, human intervention has replaced, via artificial incubation, the need for incubation and parental behaviors, altering thresholds and cascades necessary for development and physiological processes. An example was provided by Lockner and Youngren (1976) in their detailed description of the neuromuscular development and sound production in mallards. Their experiments on the structural development and physiological interface of sound production in ducks are classics. Although highly domesticated from dual sources and locations, a duck is still a duck. The female "quacks," while the male remains relatively silent.

8.2.4 Geese

European and Chinese domestic geese originated from independent domestication events, respectively, in the eastern Mediterranean region/"Fertile Crescent" and in East Asia (Shi et al., 2006; Heikkinen et al., 2015, Table 8.1). European breeds of domestic geese are derived from the Greylag goose (*Anser anser*) (Heikkinen et al., 2015). In contrast, almost all Chinese breeds originated from the swan goose (*Anser cygnoides*). Of 26 breeds of Chinese domestic geese, the maternal lines of 25 are the swan goose while one (the Yili goose) was derived from the Greylag goose (Li et al., 2011).

8.2.5 Other domesticated birds

For details of the domestication of other birds, see Table 8.1. Pigeons were domesticated from rock pigeons (*Columba livia*) between 1000 and 3000 BCE, probably in the Eastern Mediterranean region (discussed Darwin, 1868; Stringham et al., 2012, Table 8.1). The breeds fall into categories such as tumblers and rollers, fan-tails, owls, pouters and croppers, and mane pigeons, with their genetics having been characterized (Stringham et al., 2012).

Farmed ostriches (*Struthio camelus*) were developed in the second part of the 19th century from a cross between two subspecies of ostriches, respectively, the South African (*S. c. australis*) and North African (*S. c. camelus*) ostriches (reviewed: Spinu et al., 1999). While they have been subjected to considerable selection (reviewed: Spinu et al., 1999), it not clear whether they should be considered as domesticated or tamed; with 300,000 tame ostriches (*Struthio camelus*) being farmed in the Cape province of South Africa in the first decade of the 20th century (Duerden, 1906, Table 8.1).

The guinea fowl was domesticated from the helmeted guinea fowl (*Numida meleagris*) about 2000 years BP in North Africa in present-day Mali and Sudan as a food resource (Vignal et al., 2019, Table 8.1). Japanese quail (*Coturnix japanica*) were domesticated in about 1000 CE in China and later in Japan (Chang et al., 2005, Table 8.1).

8.3 Conclusions

Table 8.2 summarizes multiple factors influencing domesticated birds and consequently their physiological and anatomical phenotypes. The corollary to this is that there are effects on wild birds that are directly or indirectly anthropogenic in nature. This includes the following: (1). invasive and introduced species, (2). feral birds, and (3). introgressions from domesticated birds to wild species.

It may be questioned whether we should consider that a chicken is still anatomically, behavioral and physiologically, a chicken, be it a junglefowl, fighting cock, broiler, layer, etc. In an evolutionary context, this may be considered minor because matings between individuals of each of these groups can produce fertile progeny (e.g., Sutherland et al., 2018; Godinez et al., 2019). Differences in body size may preclude natural matings between wild birds and commercial poultry (chickens: Blohowiak et al., 1980; turkeys: Bakst and Dymond, 2013), however, they produce fertile progeny via artificial insemination. There are, however, caveats as recently discussed by Bennett et al. (2018). The caveats may vary because populations of chickens, ducks, and turkeys may vary in their degree of domestication. There are populations of chickens, for example, bred for sport, feathers, meat, or egg production. The same may be the case for ducks and turkeys. Thus, one cannot generalize without consideration of the process in reverse (i.e., feralization). Namely, what is the capacity of the domestic bird to survive and reproduce in nature? This will depend on several factors and is not independent of the weakest link in the biological process for adaptation to the environment into which it has been released. For the chicken, perhaps the example most intensively studied is that of McBride et al. (1969) for the feral fowl.

There are genotypic and phenotypic effects of domestication, introgressions, and selection (Zeder, 2015). For instance, marked differences in brain anatomy have been reported between red junglefowl and modern chickens (Kawabe et al., 2017). Similarly, brain size is reduced in red junglefowl selected for tameness (Agnvall et al., 2017). Selective breeding led to the development of White Leghorn chickens exhibiting persistent egg production due to the absence of incubation behavior; this being due to shifts in prolactin physiology (Hutt, 1949; Zhou et al., 2008; Basheer et al., 2015).

Examination of chicken bones from archaeological sites and comparison with modern commercial chickens and red junglefowl indicates four important aspects of the development of today's commercial chickens. There was little difference between maximal breadth of tibiotarsus between red junglefowl and either ancient or more recent chickens (Bennett et al., 2018). In contrast, there was a marked increase in maximal breadth in modern meat-type chickens (Bennett et al., 2018). Another major shift is the diet with chickens prior 1900 being omnivorous while today's commercial chickens are almost exclusively granivorous (Bennett et al., 2018).

It is important to recognize that the scientific consensus changes with new information, and every study should not be viewed as necessarily conclusive. It was supposed that a mutation of the thyrotropin receptor (TSHR) (residue 558 is arginine in chickens and glycine in red junglefowl) (Grottesi et al., 2020) was linked to the domestication of chickens about 8000 years ago (Rubin et al., 2010). It was argued, as it permits year-round production of eggs (Rubin et al., 2010). However, based on examination of DNA extracted from ancient chicken specimens from archaeological sites (280 BCE−1800 CE) in Europe, it was concluded that the mutated TSHR gene was only fixed in poultry populations in the last 500 years (Girdland et al., 2014). Among the physiological consequences of the mutation are shifts in hypothalamic TSHR expression and reduced plasma concentrations of thyroxine but not triiodothyronine (Karlsson et al., 2016). What is not clear is to what extent the arginine 558 form is found in the exotic breeds or village/indigenous chickens.

Another change with domestication and selection is plumage. Although colored plumage has an advantage in the wild regarding predator-prey, current commercial meat poultry predominantly have white plumage for processing

purposes. It is the result of the recessive genotype (*cc*), which precludes expression of plumage color (Somes, 1984). Our sense is that *c* was a "spot" mutation and, unlike albinism, the expression was essentially limited to preclusion of plumage color expression. Initially, humans were interested in white plumage as a "sport" that could be easily introgressed into their population because the phenotype was recessive. During pre-Mendelian periods, matings of like to like allowed for simply inherited traits to form "new" strains.

It has been hypothesized that decreased fear of humans was important to domestication. In red junglefowl selected for either high or low fear, there were shifts in brain gene expression (Bélteky et al., 2016). There were, however, no differences in baseline and stressed bird circulating concentrations of the stress hormone, corticosterone, between red junglefowl selected for either low or high fear of humans (Agnvall et al., 2015).

In conclusion, the initial domestication of different species of birds, including chickens, ducks, and turkeys, occurred during different time periods (Table 8.1), and this should be viewed as a continuing process. Thus, the involvement of humans in the process may be considered as directed evolution. Although today, domesticated and wild birds are distinguished by phenotypic characteristics, their basic anatomy and physiology have much in common. It is also noted that there are effects on wild birds that are both anthropogenic and avian in nature. This includes the following: (1). invasive and introduced species, (2). feral birds and (3). introgressions from domesticated birds to wild species together with obviously (4). habitat loss.

nVI Nucleus nervi abducentis
NVI Nervus abducens
nVII Nucleus nervi facialis
nXIIts Nucleus nervi hypoglossi, pars tracheosyringealis
Ov Nucleus ovoidalis
PE Nucleus pontis externus
PrV Nucleus sensorius principalis nervi trigemini
RPcvm Ventromedial part of the parvocellular reticular formation
Rt Nucleus rotundus
SCi Intermediate part of the core nucleus of the preisthmic region (Puelles et al., 1994)
SI Primary somatosensory cortex
SII Secondary somatosensory cortex
sP Nucleus subprincipalis
SS Synsacral segment
SSp Nucleus supraspinalis
St Striatum
Uva Nucleus uvaeformis
VB Ventrobasal complex

9.1 Introduction

Once thought to be a meager sensory system (Ariens Kappers et al., 1936), the avian somatosensory system has in more recent times been shown to be every bit as detailed and complicated in its anatomical and functional organization as in mammals (reviews in Necker, 2000a,b; Wild, 2015). Necker (2000a) provided a concise overview of the system's basic organization, from the types, distribution, and physiology of mechanoreceptors and other sensory receptors found in avian skin, to the synaptic and functional connectivity of the somatosensory pathways ascending throughout the neuraxis (Fig. 9.1). He divided the avian somatosensory system into two parts, spinal and trigeminal, noting that the former innervates the body surface and extremities, minus the head, and the latter mainly the beak. However, with regard to ascending systems, "spinal" usually implies an origin in the spinal cord itself, rather than in the periphery, and "trigeminal" excludes other primary afferent projections from the head, such as the tongue,

Sturkie's Avian Physiology. https://doi.org/10.1016/B978-0-12-819770-7.00018-9

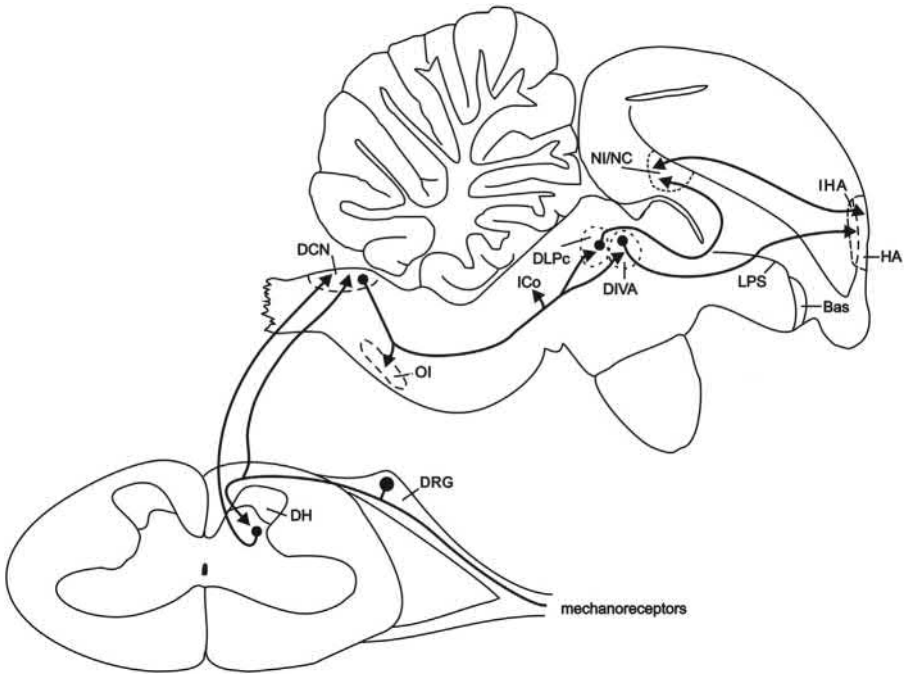

FIGURE 9.1 **Schematic parasagittal view of the brain of a pigeon showing the main somatosensory pathways from the body (minus the head).** *Filled circles* denote cell bodies, *arrows* denote terminations. Note that there are substantial deviations from this plan in some other species (see text and Figs. 9.3 and 9.5). *Adapted from Necker (2000a).*

which is not innervated by the trigeminal nerve in birds, but which plays a major somatosensorimotor role in feeding. In the present chapter, therefore, as in the previous (Wild, 2015), we make a preferred division of somatosensory origins into, on the one hand, those from the body (including feathered or unfeathered integument of the neck, thorax, abdomen, pelvis, wings, lower limb, and reproductive organs), and, on the other, those from the head (beak and mouth, tongue, head skin, and cornea). At a stretch, somatosensory input may also be provided by joint and muscle receptors, and in birds by receptors in the air sacs and syrinx (Kubke et al., 2004; Suthers et al., 2002).

9.2 Body somatosensory primary afferent projections in different species

9.2.1 Spinal cord

Our knowledge of primary afferent projections to the bird's spinal cord is based on a variety of techniques, such as tracing degenerating fibers following dorsal rhizotomy (van den Akker, 1970; Leonard and Cohen, 1975a), injecting tracer into dorsal root ganglia or applying it to the cut ends of dorsal roots (Necker, 2001), injecting tracer into feather follicles, whole wing or leg nerves (Wild, 1985; Necker and Schermuly, 1985; Schulte and Necker, 1994; Ohmori and Necker, 1995), applying tracer to cutaneous nerves and skin (Woodbury and Scott, 1991), and injecting ankle joint receptors (Gentle et al., 1995) or muscles (Wild, 1985) in pigeons and chickens. Neurophysiological analyses of pigeon dorsal horn responses have been provided by Necker (1985a,b; 1990) for pigeons and by Woodbury (1992) for chickens.

Although the different techniques provide different patterns of projections to the cord and brainstem, it is clear that primary afferent fibers enter and terminate in the cord differently depending on their diameter, as in mammals. Necker (2001) found that at the entry level of C5, for instance, large-diameter fibers entered the dorsal horn from its medial aspect, between laminae IV and V. These fibers continued into the ventral horn, where they terminated densely, and some continued laterally to terminate in the marginal nuclei. Fine-diameter fibers entered the dorsal horn laterally and terminated in various parts of the horn at the level of entry, whereas other fine fibers extended as far as C1 rostrally and at least as far as C8 caudally. Intermediate diameter fibers entered the dorsal horn from dorsal and medial positions to terminate, from Cl to C8, in lamina IV and medial lamina V. Some fibers crossed in the dorsal commissure to terminate in similar areas on the contralateral side.

That the primary afferent projections are somatotopically organized is indicated by the fact that the follicles or primary flight feathers and their coverts of the wing are represented in lamina I and medial lamina II, whereas the

follicles of secondary flight feathers and their coverts are represented at the lateral edge of the dorsal horn (Wild, 1985; Necker, 1990). Terminal fields of chicken ankle afferents are found in laminae I–III and VI, with a few terminals in deeper laminae (Gentle et al., 1995), which is similar to the projections from the cutaneous nerves of the leg in chicks (Woodbury and Scott, 1991). It should be remembered, however, that in birds as well as in mammals, different types of tracer tend to produce labeling in different laminae, with wheat germ agglutinin tending to produce labeling in laminae I and II, and cholera toxin B (CTB)-chain producing labeling predominantly in lamina III and IV (Robertson and Grant, 1985).

Primary afferent terminations in the dorsal horn can extend over several segments and are not necessarily heaviest at the level of entry of the dorsal root fibers. Gentle et al. (1995), for instance, found that although ankle joint afferents entered the cord predominantly over synsacral level SS5-7, terminations were split such that there was a small field in SS7 and 8 and a larger field in SS3 and 4. Split terminal fields were also found for whole nerve inputs (Woodbury and Scott, 1991). Terminations of wing nerve fibers extend well beyond the rostrocaudal extent of incoming rootlets, although the density of terminations declines with increasing distance from the entry zone (Leonard and Cohen, 1975a; Wild, 1985). These terminations are likely collaterals of fibers ascending or descending to more distant levels. In the case of wing nerve afferents, at least, fibers ascending in the dorsal column to the medulla provide collaterals to the dorsal horn of most, if not all, of the dozen or so cervical segments (Wild, unpublished observations in pigeons). In the greenfinch wing, nerve afferent terminations in the cervical cord are concentrated in medial lamina V (Wild, 1997), as are primary afferent fibers in budgerigars (Wild et al., 1997). Neurons at similar locations and in the nucleus of Bischoff in the upper cervical spinal cord of pigeons can be retrogradely labeled from injections of tracer into either a dorsal thalamic somatosensory nucleus (DIVA; see below) or a multimodal thalamic nucleus (DLP; see below) (Wild, 1989), which could suggest the presence of a spinothalamic projection from medial lamina V of upper cervical spinal cord segments. These findings should be contrasted with those of Schneider and Necker (1989), who found that DIVA injections retrogradely labeled very few cells in the brachial spinal cord intermediate region, but many cells at lumbar levels, suggesting a spinothalamic projection mediating lower limb somatosensory input, but the virtual absence of one from the wing.

Apart from the limbs and neck, there is little information about input from other parts of the body. Recent interest in the neural control of avian reproductive behavior, however, has involved making injections of fluorescent tracers (e.g., CTB) into the cloaca of quail and canary, a procedure that has revealed a major terminal field in the medial part of the dorsal horn throughout several sacral segments (Fig. 9.2), roughly co-extensive with the rostrocaudal distribution of retrogradely labeled cloacal motoneurons (see Wild and Balthazart, 2013; Wild, 2015). Although the supraspinal and reflex connectivity of neurons in this medial part of the sacral dorsal horn has not been determined, the data could suggest an important somatosensory role of the input from principal structures involved in reproductive behavior and voiding.

9.2.2 Brainstem

Primary afferent projections from the body to the brainstem were first visualized in pigeons by van den Akker (1970) using degeneration techniques following dorsal rhizotomies, and later using the transganglionic horseradish peroxidase (HRP) technique by Wild (1985). Neck primary afferents were also visualized in pigeons by Necker (2001), and limb primary afferents have been visualized in pigeons, chickens, greenfinches, and barn owls (Schulte and Necker, 1994; Necker and Schermuly, 1985; Gentle et al., 1995; Wild et al., 1997; Wild et al., 2001).

At caudal levels of the dorsal column nuclei (DCN, i.e., gracile, cuneate, and external cuneate nuclei) in pigeons, leg afferent terminations in the gracile nucleus lie medial to those of the wing in the cuneate nucleus, but more rostrally there is substantial overlap of leg and wing inputs throughout the DCN, although wing inputs extend further laterally around the periphery of the medulla than leg inputs. A picture of the representation of the wings can be gained by imagining them spread out and extending over the dorsal and dorsolateral periphery of the medulla. Only in the barn owl have terminations from the wing and leg been seen to be confined to clearly separate gracile and cuneate nuclei (Wild et al., 2001). In pigeons, neck primary afferents were found by Necker (2001) to project rostrally and ventrolaterally in the DCN complex, where they terminated in the external cuneate nucleus[1] (CuE), in a nucleus that he compared with the intermediate nucleus of Cajal, as well as in another nucleus he thought comparable to nucleus *x* located lateral to the nucleus of the descending trigeminal tract (nTTD) and ventral to the descending vestibular nucleus, well rostral to the obex. As in mammals, primary afferent projections to the DCN are supplemented by a dorsal column postsynaptic system (Fig. 9.1), which in pigeons takes its origin from lamina IV of the brachial spinal cord, where mechanosensitive neurons have been located (Necker, 1985a,b, 1991).

1. The avian external cuneate nucleus is not the equivalent of the same named nucleus in mammals because its inputs are not confined to upper limb proprioceptors and, at least in pigeons, it does not project to the cerebellum (Wild, 1985; Reinke and Necker, 1996).

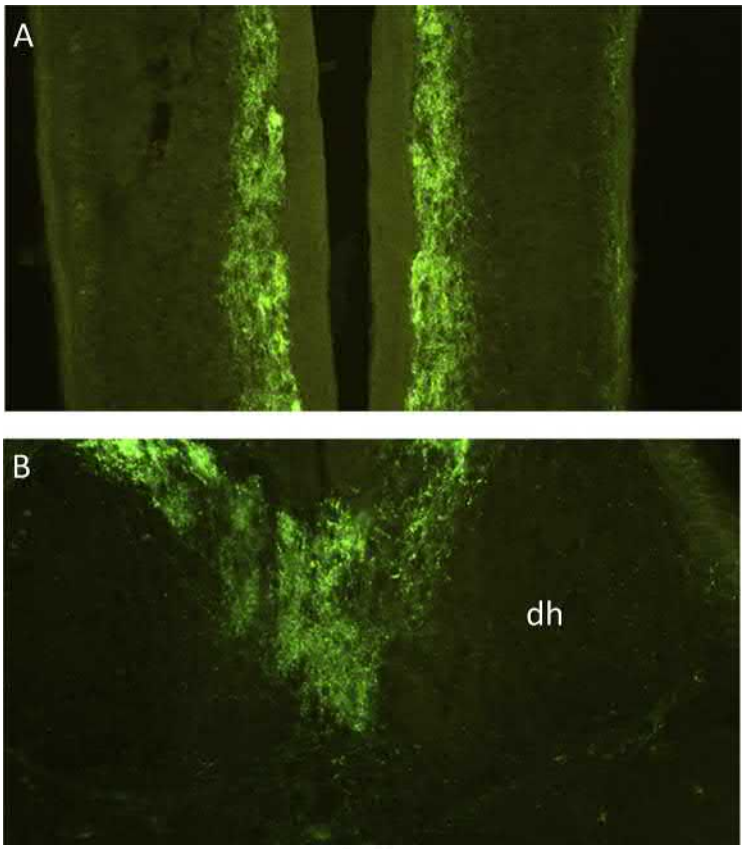

FIGURE 9.2 Cloacal afferent terminations in the sacral spinal cord. (A) Horizontal section, (B) transverse section (dorsal is up). These terminations, which were visualised following subcutaneous injection of green flourescent CTB (CTB-488) into the cloaca of male canaries, were localised to the medial aspect of each dorsal horn.

In pigeons, finches and barn owls primary afferent projections extend ipsilaterally throughout the medulla and into the pons, where they terminate sparsely in proximity to PrV (Wild, 1985, 1997). In the Australian budgerigar (*Melopsittacus undulatus*) (Wild et al., 1997) and possibly other psittaciforms (Wild, 1981), primary afferents from both wing and leg also reach pontine levels, where they terminate densely and topographically in nucleus subprincipalis (sP), immediately subjacent to PrV (Fig. 9.3). One implication of these findings in the budgerigar is that here at pontine levels there is a striking instance of a complete, somatotopic representation of the whole body, with the beak and tongue and possibly some other parts of the head being represented massively in PrV (see below) and, ventral to PrV, a smaller representation of the rest of the body in sP (Fig. 9.3).

9.3 Ascending projections of the dorsal column nuclei

As in mammals (Berkley et al., 1986), the DCN in birds project predominantly contralaterally to several more rostral nuclei via a medial lemniscus, en route to their final targets in the thalamus (Fig. 9.1, Wild, 1989, 1997). The inferior olive (0I) in the caudal brainstem is the first target, which then projects to the cerebellum via the inferior cerebellar peduncle. Because in pigeons, at least, the DCN do not project directly to the cerebellum, the route to the cerebellum via the OI may be one way that somatosensory inputs serve sensorimotor control.

Another significant target of the DCN is the midbrain, where there are terminations not only in intercollicular regions surrounding the auditory nucleus mesencephalicus lateralis, pars dorsalis (MLd) but also within it (Karten, 1967; Leibler, 1975; Wild, 1989, 1995, 1997). Units recorded electrophysiologically in the region between the dorsal border of MLd and the tectal ventricle respond to both somatosensory and visual stimuli (Ballam, 1982). The region ventral to more caudomedial regions of MLd forms a distinct nucleus called the intermediate part of the core nucleus of the preisthmic region (SCi; Puelles et al., 1994). Its neurons are exquisitely sensitive to tactile stimuli applied to feathers and body surface and respond with large-amplitude action potentials (Wild, 1995). Its ascending projections require further definition, but the location of terminations around the ventral periphery of the

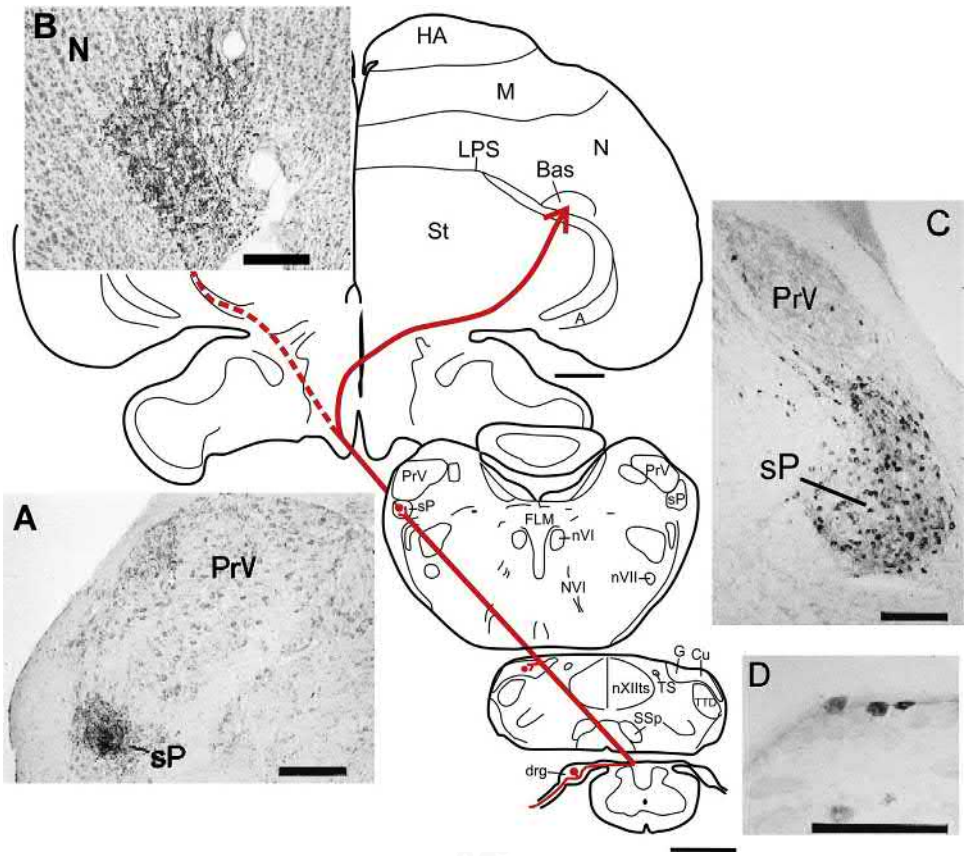

FIGURE 9.3 **Somatosensory pathway in the budgerigar (parakeet).** Primary afferent fibers project to and terminate in the ipsilateral nucleus subprincipalis (sP), cell bodies of which project their axons to the body regions of Bas, predominantly contralaterally (*solid lines*). Scale bars for schematics: 1 mm. (AJ Terminal field in sP fo1lowing an injection of horseradish peroxidase-conjugated cholera toxin B (CTB)-chain in the ipsilateral radial nerve. The terminal field of sciatic fibers (not shown) is located ventrolateral to that of the wing. (B) Terminal field (note its precise borders) in the body part of Bas following an injection of biotinylated dextran amine (BDA) in the contralateral sP. (C) Retrogradely labeled cells in sP following an injection of CTB in the contralateral body part of Bas. (D) Retrogradely labeled cells in a dorsal root ganglion of a spinal segment from the brachial enlargement, following an injection of BDA in the ipsilateral sP. Note that the gracile (G) and Cuneate (C) nuclei of the dorsal columns also project to sP. Scale bars = 200 μm for photomicrographs. *Adapted from Wild et al. (1997).*

thalamic auditory nucleus ovoidalis (Ov), Ov being the main target of MLd projections (Karten, 1967), closely mirrors the location of SCi with respect to MLd (Wild and Williams, 2000). In pigeons and finches, it appears that the DCN also project directly to MLd, where diffuse terminations overlap the much denser terminations of projections from brainstem auditory nuclei (Wild, 1989, 1995, 1997). Speculations concerning the functions of the somatosensory projection to MLd can be found in Wild (1995). In the barn owl, there is a similar but more restricted DCN projection to rostrodorsal parts of MLd (known in barn owls as the central nucleus of the inferior colliculus; Wild et al., 2008). These findings represent but one of the several instances in the avian brain of somatosensory and auditory proximity or overlap.

At caudal thalamic levels, the DCN project upon the medial spiriform nucleus, which then projects to the cerebellum (Karten and Finger, 1976; Wild, 1992). Next, the DCN target a nucleus called dorsolateral posterior thalami (DLP), the caudal part of which in pigeons (DLPc) has been considered comparable with nucleus uvaeformis (Uva) in finches (Wild, 1987, 1994; Funke, 1989a). DLPc and Uva tend to be multimodal (Korzeniewski, 1987; Korzeniewski and Güntürkün, 1990; Wild, 1994), and in this respect are perhaps similar to the posterior group of thalamic nuclei of mammals (Gamlin and Cohen, 1986). Both beak and body responses have been found in DLP in pigeons (Korzeniewski, 1987), but beak responses are likely to arise from the nTTD (Korzeniewski and Güntürkün, 1990) rather than from the DCN (see also Wild, 1989; Faunes and Wild, 2017a). Rostral to DLP, the DCN target the nucleus DIVA, which lies immediately dorsal and lateral to the auditory nucleus Ov and the visual nucleus rotundus (Wild, 1989, 1997; Faunes and Wild, 2017a). Unlike DLP, DIVA is specifically somatosensory; although it contains a representation of most body parts (including toes, but not the beak), it is weakly somatotopically organized (Schneider and Necker, 1996). DIVA is probably

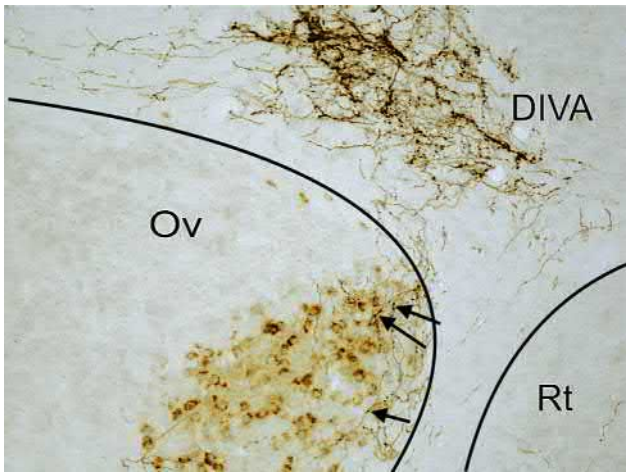

FIGURE 9.4 Dorsal column nuclei projections to nucleus ovoidalis and DIVA. Labeled fibers and varicosities (black, e.g., at *arrows*) in the lateral part of nucleus ovoidalis (Ov) and the overlying dorsal thalamic somatosensory nucleus DIVA in the zebra finch, following an iontophoretic injection of BDA in the dorsal column nucleus (section midline is to the left). Neurons in the lateral part of Ov (brown) were retrogradely labeled by an injection of cholera toxin B-chain in the lateral part of Field L, the primary thalamorecipient auditory field in the telencephalon. Rt: nucleus rotundus. *Wild, unpublished observations.*

homologous to part of the ventrobasal complex (VB) of mammals. In zebra finches, there is a small but distinct projection from the DCN to a lateral part of Ov, as fibers pass to the overlying DIVA (Fig. 9.4). This is yet another instance in the avian brain of somatosensory and auditory proximity or overlap.

Unlike the case for mammals (Berkley et al., 1986), there is some evidence in finches, at least, that single DCN neurons project to more than one more rostral nucleus (e.g., intercollicular nucleus and DIVA) via branched axons (Wild, 1997).

To complete this section, again in the curious case of the budgerigar, the DCN project ipsilaterally to sP in the pons (Wild et al., 1997), as do primary afferents from the wings and legs (Figs. 9.3 and 9.5). Whether the DCN also project to the thalamus in this species is not known. Another variation on the DCN projections occurs in the barn owl, in which there is a projection from both gracile and cuneate nuclei to a large nucleus at the lateral edge of the pons called pontis externus (PE) (Wild et al., 2001). Such a nucleus, which in the barn owl does not receive primary afferent projections directly from the body surface, has thus far not been described for any other species. PE may, however, be the functional equivalent of sP in budgerigar because, like sP, it provides a major body somatosensory and topographically organized input to nucleus basorostralis pallii (Bas) (see below). The various ascending somatosensory pathways are depicted for four species in Fig. 9.5.

9.4 Telencephalic projections of thalamic nuclei receiving somatosensory input

The ascending projections of DLP/Uva and DIVA are quite separate. In pigeons, DLP projects to the intermediate and caudal parts of the nidopallium (NI/NC: Gamlin and Cohen, 1986; Funke, 1989a; Wild, 1987). The terminal field of more rostral parts of DLP (DLPr) lies medially adjacent to the visual entopallium, whereas the terminal field of DLPc lies more caudally, closer to the thalamorecipient auditory field L, and is predominantly somatosensory (Wild, 1987; Funke, 1989b). In finches, which are songbirds, the equivalent region of the nidopallium to which Uva projects is called nucleus interface (NIf), which is usually regarded as belonging to the song system (Nottebohm et al., 1982). It is possible, however, that following a sufficiently fine-grained electophysiological and anatomical analysis, this region of the nidopallium may be subdivided into visual, somatosensory, and auditory components (Wild, unpublished observations), with the auditory component in songbirds then providing the predominant input to HVC of the song control system (Nottebohm et al., 1982; Wild, 1994; Vates, 1996; Lewandowski et al., 2013).

In both pigeons and finches, the ascending projections of DIVA are specifically to the interstitial hyperstristum accessorium (IHA) of the rostral, somatosensory Wulst (Wild, 1987, 1997; Funke, 1989a). In finches, the input to IHA is distinctly and regularly patchy, but a somatotopic organization has not been examined. In pigeons, there is a very weak somatotopic organization of this region (Funke, 1989b).

It has been suggested that the somatosensory area in the rostral Wulst of birds may be equivalent to SI in mammals, whereas the more caudal somatosensory area in NI/NC is equivalent to SII (Wild, 1987). The two regions are reciprocally connected (Wild and Williams, 1999). Unlike the somatosensory inputs to SI in mammals, however, the avian classical three-neuron sequence of somatosensory projections from the body surface to the telencephalon via primary afferent projections to the DCN, contralateral DCN projections to the dorsal thalamus, and DIVA projections to the rostral Wulst, mediates a decreasingly specific somatotopic organization as it ascends. In the spinal dorsal horn, the somatotopy is both anatomically and electrophysiologically clear cut (see above; Necker, 1990; Woodbury, 1992); in the caudal parts of the DCN, it is reasonably clear, but much less clear in more rostral parts of the DCN (Wild, 1985). In DIVA, the somatotopy is unimpressive (Schneider and Necker, 1996), as it is in the rostral Wulst (Funke, 1989b). Furthermore, the beak appears not to be represented in DIVA, but the toes and foot joints are (Schneider and Necker, 1996).

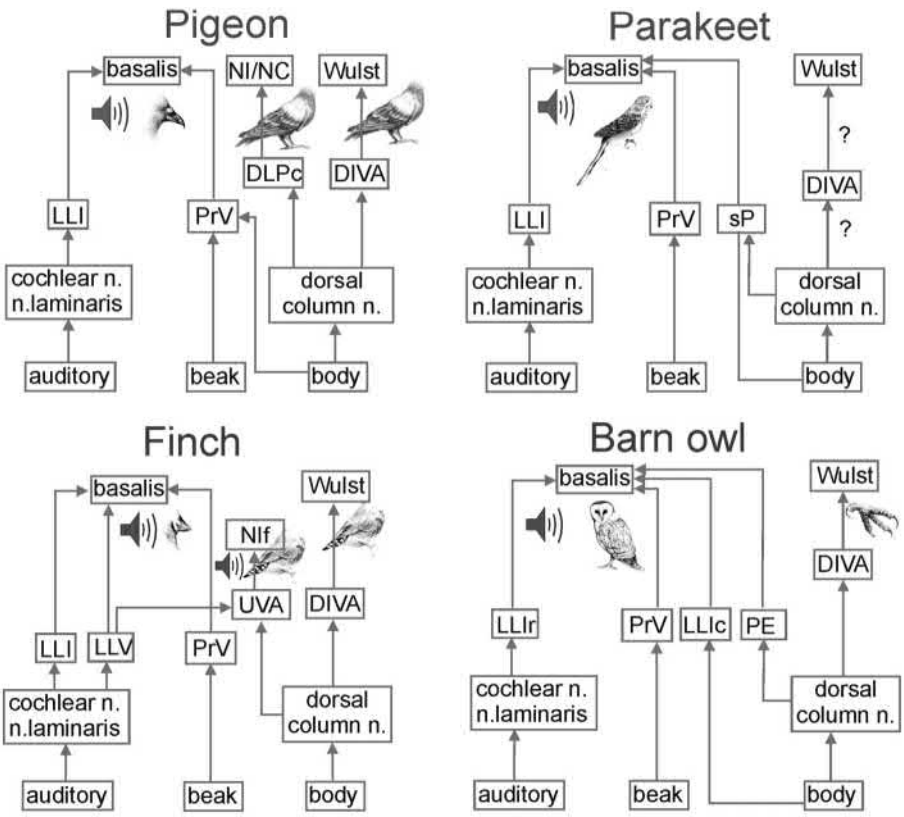

FIGURE 9.5 **Comparative schematic of ascending somatosensory and auditory projections to the telencephalon via thalamic and nonthalamic pathways in four different species.** Note the "beakless" representation of the body in the rostral Wulst of pigeons and finches and the complete body + beak + auditory representation in Bas of parakeets (budgerigars) and barn owls (auditory representations are symbolized by speakers). Note also the auditory projection to nucleus interface of finches, which is relayed via projections of the ventral nucleus of the lateral lemniscus to nucleus uvaeformis (Coleman et al., 2007), and perhaps by projections of ovoidalis to the nucleus interface (not shown; Wild, unpublished observations). *Adapted from Wild et al. (2008).*

At the frontal pole of the brain of the barn owl, rostral to what would be the rostral Wulst of other birds, there is an apparently unique bulge that contains a detailed somatotopic representation of the contra1ateral claw (Manger et al., 2002; Wild et al., 2008, Fig. 9.6). Curiously, a representation of more proximal parts of the lower limb, or of any other body part, was not found in or near this bulge, but the foot and other parts of the body are also represented in what is now called Bas (Reiner et al., 2004, and see below). Apparently, sensory input from the claw is all-important for the predatory barn owl. It would be most interesting to determine the representation of the claw in other predatory avian species that strike and capture their prey in a similar way to barn owls, such as eagles.

9.5 Somatosensory primary afferent projections from the beak, tongue, and syrinx to the trigeminal column

9.5.1 The principal sensory trigeminal nucleus

The bird's beak or bill varies hugely in shape and size between different species (e.g., compare the beaks of pelican, spoonbill, tucan, kiwi, flamingo, duck, cockatoo, wren)—a variation that is generally correlated with the different feeding habits and preferred foods, on the one hand, and on the other with the size and morphological

complexity of the principal sensory trigeminal nucleus (PrV, to which trigeminal beak afferents project) (Stingelin, 1961). As an instance of microevolutionary processes at work, the size and shape of the beaks of Galapagos finches may even vary according to the annual availability of preferred types of food (Weiner, 1995).

In many species, there are specializations of the beak for various feeding strategies or for probing the substrate. For instance, ducks have an elaborate bill tip organ packed with mechanoreceptors (Berkhoudt, 1980), which enable the discrimination of food items through dabbling and sifting. Many shorebirds, such as sandpipers (Scolopacidae), possess Herbst corpuscles densely packed into honeycomb-like cavities in the bill, which enable the detection of food items even remote from the bill (Gerritsen and Meiboom, 1986). This is similar in kiwi, for probing the substrate during their night time foraging (Cunningham et al., 2007; Martin et al., 2007). In many other species, such as parrots and finches, however, the mechanoreceptors are not in the bone but lie more superficially, nearer the bill surface for the detection, manipulation, and guidance of food items within the mouth (Demery et al., 2011; Krulis, 1978). During feeding, these processes are aided by tongue movements, but differently in different species. Again in parrots and finches, the tongue is loaded with mechanoreceptors (Herbst and Grandry corpuscles) that enhance the efficiency of the cracking and husking of seeds in conjunction with the beak (Krulis, 1978; Wild, 1990; Demery et al., 2011). In contrast, in pigeons, the beak functions as a simple grasper, like the combination of forefinger and thumb of humans (Fig. 9.7). Once the food object is grasped, the tongue aids the transport of food objects, such as peas or grain, from the beak tip lo the back of the mouth, and these items are then swallowed whole (Zweers, 1982).

PrV receives topographic projections from the beak by way of ophthalmic (upper beak), maxillary (palate, lower eyelid), and mandibular (lower beak) branches of the trigeminal nerve (Dubbeldam, 1980; Dubbeldam and Karten, 1978; Wild and Zeigler, 1996; Faunes and Wild, 2017b). Depending on the species, PrV may also receive projections from the tongue, but unlike the case for mammals, not by way of the trigeminal nerve. In pigeons, there does not appear to be a representation of the tongue in PrV (Wild, unpublished observations), but in finches, parrots, and ducks, there is a substantial lingual representation in PrV. In ducks, lingual afferents are carried by the glossopharyngeal nerve and terminate in a dorsomedial portion of PrV (Dubbeldam et al., 1979; Dubbeldam, 1980). In finches and parrots, they are carried by the hypoglossal nerve and terminate in a dorsolateral portion of PrV (Wild, 1981, 1990; Faunes and Wild, 2017b). These afferents are unlikely to be trigeminal afferents that hitchhike via other nerves because their cell bodies are not located in the trigeminal ganglion, but in a combined "jugular" ganglion (Dubbeldam et al., 1979; Wild, 1981). The innervation of the orderly arrays of sensory receptors (Herbst and Grandry corpuscles; Berkhoudt, 1980; Gottschaldt, 1985) in the tongue can be visualized by injecting the hypoglossal nerve with CTB-chain (Fig. 9.8) or staining tongue sections with a trichrome stain (Wild, 1990). These receptors have also been visualized with electron microscopy (Toyoshima and Shimamura, 1991), although the source of their innervation was apparently not known to these authors.

The tracheosyringeal nerve, the other major branch of the hypoglossal nerve (CN XII) in birds, also has a sensory component, and this projects upon a lateral aspect of PrV, at least in zebra finches (Bottjer and Arnold, 1982; Faunes et al., 2017). The fibers have been identified as substance P-immunopositive syringeal muscle afferents, a finding that may be of particular interest in the context of the sensory control of vocalization in general and singing in particular, especially in view of the absence of muscle spindles in avian syringeal muscles generally (Faunes et al., 2017)—see nTTD below.

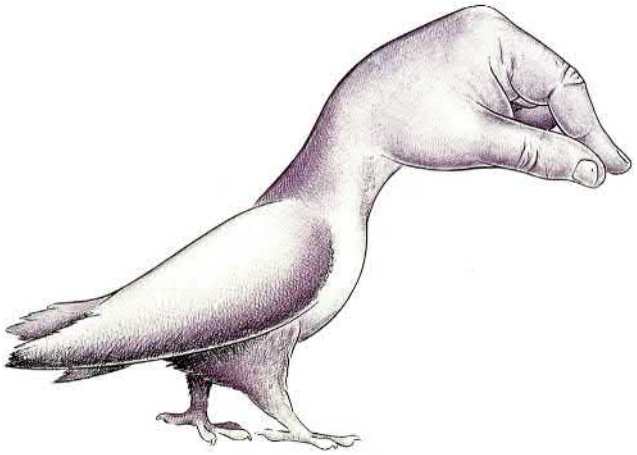

FIGURE 9.7 Drawing of the pigeon body and human hand to illustrate the functional nature of the bird's beak as a combined thumb-and-forefinger grasper and mouth.

9.5.2 Nucleus of the descending trigeminal tract

Because PrV is the predominant origin of trigeminal projections to the telencephalon (Fig. 9.9), the descending component of the trigeminal column (nTTD) has traditionally been studied only sporadically, in ducks and pigeons (Silver and Witkovsky, 1973; Dubbeldam and Karten, 1978; Arends and Dubbeldam, 1984; Arends et al., 1984). More recent and specific analyses of the central projections of trigeminal nerve branches or their innervated peripheral territories have used injections of either HRP-conjugated CTB or unconjugated CTB in pigeons, chickens, and zebra finches (Wild and Zeigler, 1996; Wild and Krutzfeldt, 2012; Faunes and Wild, 2017b). These studies show a fairly consistent pattern of descending

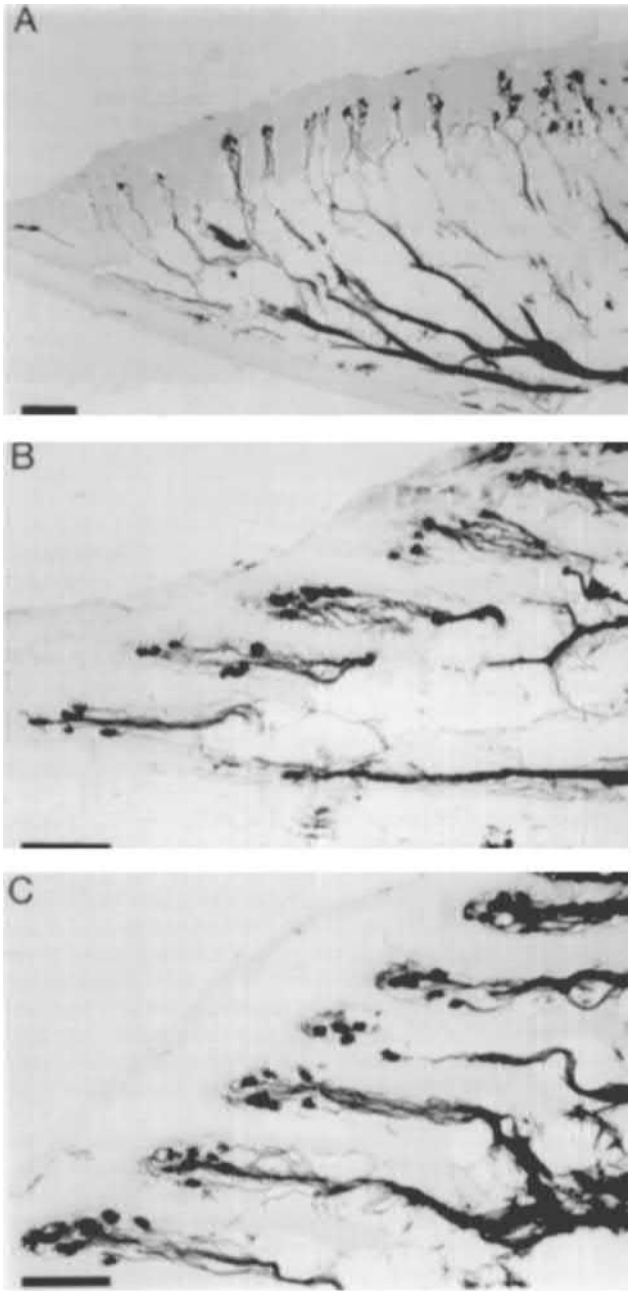

FIGURE 9.8 Photomicrographs of horseradish peroxidase-conjugated cholera toxin B-chain labeled hypoglossal nerve branches innervating the papillae of the tongue in zebra finch (A), a greenfinch (B), and a gold finch (C), anterior to the left. The terminal "blobs" visible at this magnification (bars = 200 μm) are terminal cell receptors at the sides and apices of the bowls of flask-shaped papillae. Note how the papillae of the zebra finch tongue are perpendicular to the surface, whereas those of the other two species lie in the horizontal plane and are hence at approximately 45″ to the surface. *From Wild (1990).*

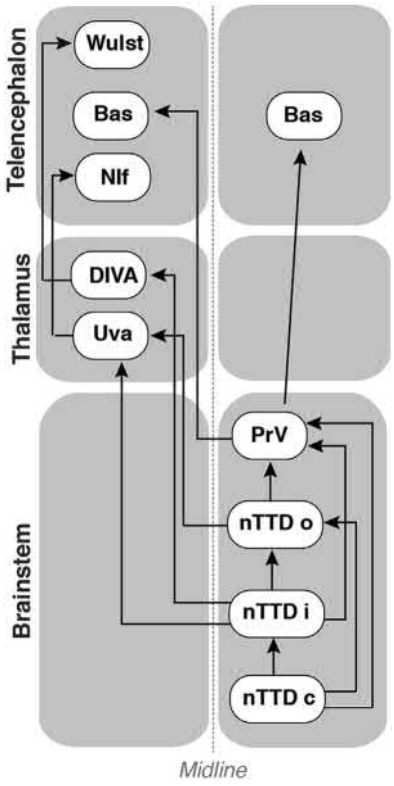

FIGURE 9.9 Schematic depiction of the ascending projections of the sensory trigeminal complex in the zebra finch. *From Faunes and Wild (2017b).*

projections throughout the three subdivisions of the nTTD, there being a roughly inverted representation of mandibular, maxillary, and ophthalmic afferents throughout pars interpolaris and parts of caudalis, but a clear-cut mediolateral representation at upper cervical spinal levels. Corneal afferents terminate specifically in a ventral portion of the ophthalmic representation in pars caudalis and in the laterally adjacent external cuneate nucleus (Wild, 1999), and in the zebra finch, the corneal afferents in nTTD have been shown to be calbindin-like immunopositive (Faunes and Wild, 2017b). Dubbeldam and Karten (1978) also described a lateral descending tract in the pigeon, which is also present in certain snakes possessing infrared detection. It is possible, therefore, that in birds this tract might carry thermosensitive afferents (see Wild and Zeigler, 1996).

As in mammals, mechanosensitive afferents that terminate in nTTD in birds arrive over other nerves in addition to the trigeminal. In the mallard duck, lingual afferents traveling in the glossopharyngeal nerve terminate dorsomedially in nTTD (Dubbeldam et al., 1979). In finches, lingual afferents traveling in the lingual branch of the hypoglossal nerve terminate dorsolaterally in pars interpolaris and pars caudalis of nTTD, but most medially at upper cervical spinal cord levels (Wild, 1990; Faunes and Wild, 2017b). This suggests that although the tongue makes contact with both upper and lower beaks during feeding, in the brainstem, lingual afferents are aligned with mandibular afferents (which innervate the lower beak) rather than with ophthalmic ones (which innervate the upper beak). As in PrV, some substance P-immunopositive

syringeal muscle afferents in finches terminate in a dorsolateral part of the interpolaris portion of nTTD, having arrived there by way of the tracheosyringeal nerve (Faunes et al., 2017). This finding gains further importance in the context of hypothesized feedback from the syrinx during singing (Bottjer and Arnold, 1982, 1984), especially now that a projection from nTTD to nucleus Uva of the songbird song system has been identified (Faunes and Wild, 2017a, Fig. 9.9).

9.6 Nucleus basorostralis

Anatomical knowledge of trigeminal components of the avian somatosensory system has existed for much longer than knowledge of its spinal components, Wallenberg describing a direct projection from PrV to a nucleus in the rostrobasal part of the avian forebrain via the quintofrontal tract as early as 1903. Although considerable anatomical and physiological attention has been directed to Bas in several species in the last 40 years, the nucleus remains enigmatic from both an anatomical and to some extent from a functional point of view. The absence of a thalamic relay in the PrV projection to Bas remains puzzling, at least in comparison with the organization of the somatosensory system in mammals (Cohen and Karten, 1974). Although Bas has been known for decades to play a major function in the sensory control of feeding in pigeons and ducks, it is now known to be more than a forebrain nucleus dedicated solely to the somatosensory representation of the beak (Witkovsky et al., 1973). Dubbeldam and colleagues in the 1980s used the mallard to investigate the functional morphology of Bas in relation to the duck's feeding apparatus and its various mechanoreceptors involved in the different sensory phases of feeding (Berkhoudt, 1980). The projections of PrV subnuclei were traced to Bas (Dubbeldam et al., 1981), and the nucleus was mapped electrophysiologically to reveal a distinct functional topography based on the representations of the glossopharyngeal and trigeminal nerve branches innervating the tongue and beak, respectively (Berkhoudt et al., 1981). Projections of PrV to Bas were also traced in pigeons (Wild et al., 1985) and in zebra finches (Wild and Farabaugh, 1996), but Bas is much smaller in these species than in ducks and does not lend itself so readily to detailed electrophysiological mapping. In budgerigars, as in ducks, however, Bas lies atop the pallial-subpallial border rather that lateral to it, so a complete mapping of the representations of beak and tongue has been performed (Wild et al., 1997, Fig. 9.10). As in ducks, a large lingual representation is present rostrally in Bas, but this is hypoglossal territory rather than glossopharyngeal. Behind is an even larger representation of the beak, followed by a smaller one of the head. On the lateral aspect of the head representation is an indentation that includes a representation of the cochlea and possibly of the semicircular canals; these representations seemingly mirroring the position on the lateral aspect of the skull of the cochlear and vestibular apparatus at the medial end of an external auditory meatus. Progressively more caudal to the representation of the head are representations of the wings, body, and legs and feet. These body inputs are relayed predominantly by the contralateral nucleus sP, ventral to PrV, which supplies the inputs from beak and tongue. Thus, in the budgerigar, there is a complete representation of the body in Bas, much as there is at pontine levels (see above).

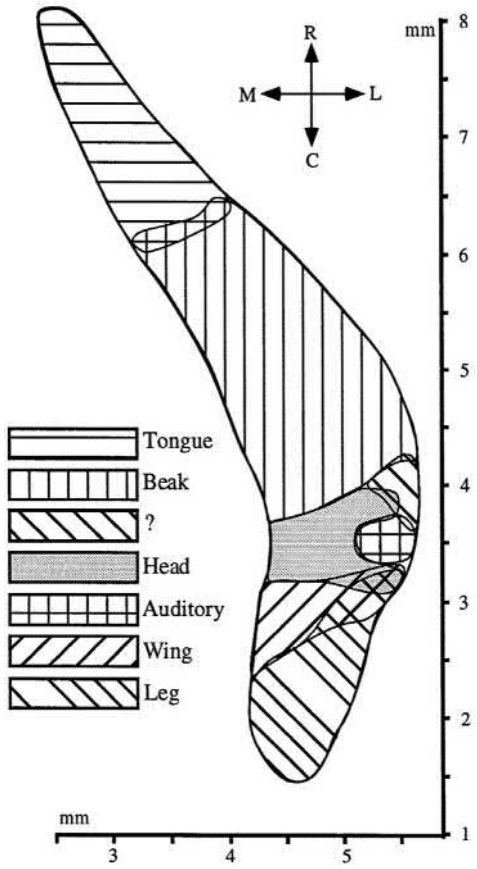

FIGURE 9.10 A two-dimensional map of Bas on the right side of the brain of the budgerigar (parakeet). The map is based primarily on recordings of evoked multiple-unit activity in Bas. The area rostral to the auditory area possibly receives inputs from a vestibular nucleus. *From Wild et al. (1997).*

The auditory representation in Bas of all species thus far examined reflects its input from the intermediate nucleus of the lateral lemniscus (LLI, which lies close to PrV), a projection first defined in pigeons (Arends and Zeigler, 1986) and later in zebra finches (Wild and Farabaugh, 1996). In these last two species, however, complete body representations have not been found in Bas, although in finches, as in parrots, there is a large lingual (hypoglossal) representation rostrally in the nucleus.

The largest Bas thus far encountered is that of the barn owl, in which there also appears to be a complete body representation, including a tonotopically organized auditory component (Wild et al., 2001). Injections of tracers in Bas retrogradely label neurons in the massive PE nucleus that forms a bulge on the lateral aspect of the pons and lies ventrolateral to the equally large anterior and posterior divisions of the dorsal nucleus of the lateral lemniscus (LLda and LLDp). In turn, injections in PE retrogradely label neurons in the DCN, thereby completing a three-neuron sequence of somatosensory projections from the body periphery, but one that is quite different from the classical sequence in mammals that projects via the thalamus. Medially adjacent to PE is a smaller LLI that presumably provides most of the auditory input to Bas, although Bas seems also to receive a small auditory projection from LLDa.

9.7 The meeting of the spinal and trigeminal systems

In his chapter on the spinal cord, Necker (2000b) briefly mentioned a difference between pigeons and chickens in the laminar organization of the dorsal horn, a difference that has received further examination (Wild et al., 2010). In pigeons, the dorsal horn laminae are arranged in mammalian fashion, with lamina II lying dorsal to lamina III; however, in chickens the latter lies medial, not ventral, to the former (cf. Brinkman and Martin, 1974; Leonard and Cohen, 1975b). In fact, as Woodbury (1998) showed, the majority of bird species resemble chickens, rather than pigeons, in the bifid, side-by-side arrangement of laminae II and III. Nevertheless, the functional organization of these laminae in chickens and their kin is not dissimilar to that in pigeons and their kin, in that smaller diameter and unmyelinated primary afferents terminate in lamina I and II, whereas larger diameter, myelinated primary afferents terminate in lamina III (Woodbury and Scott, 1991; Wild, 1985).

Many years ago, Woodbury asked a related, interesting question about the organization of the trigeminal dorsal horn: since this was generally considered to be a direct continuation of the spinal dorsal horn, and to have a similar organization, did this organization reflect the organization present at spinal levels in species in which II and III were side by side rather than arranged in mammalian-type laminar fashion? In other words, was the trigeminal dorsal horn also split in chickens, etc., with a side-by-side arrangement of superficial and deeper laminae? This question has been answered, and the findings compared with those in pigeons (Wild and Zeigler, 1996; Wild et al., 2010). It was found that the trigeminal dorsal horn in chickens was organized in a laminar fashion, as it is in pigeons, and remained laminar down to about the level of C3. Thereafter, however, lamina III gradually, over a couple of segments, shifted medially, until from C5 caudally laminae II and III came to lie side by side. It was also shown that, although the three branches or the trigeminal nerve in the chicken terminated throughout the dorsal horn in a similar fashion to that in pigeons—with ophthalmic afferents laterally, mandibular afferents medially and maxillary afferents in between—they did not extend further caudally than about C3, in contrast to C6 or C7 in pigeons. Thus, it appears that trigeminal primary afferents in the chicken do not terminate at cervical spinal levels that have a side-by-side arrangement of dorsal horn laminae. These findings suggest a discontinuity of spinal and trigeminal dorsal horn organization, the reason for which remains obscure. What is clear, however, is that Woodbury's (1998) hypothesis of a side-by-side arrangement of laminae II and III defining a novel clade of birds is not supported, for when an appropriate phylogenetic analysis is performed, a reversion to the mammalian type of arrangement of dorsal horn lamina is seen to have occurred several times in avian evolution (Wild et al., 2010).

9.8 The somatosensorimotor system in birds

In mammals, somatosensory inputs to the cortex initiate somatomotor responses that reach brainstem and spinal targets via corticobulbar and corticospinal components of the pyramidal tract. Such a tract in birds originating in the rostral part of the Wulst was proposed by Zecha (1962) and shown with contemporary tracing techniques in pigeons and zebra finches by Wild and Williams (2000). The pyramidal tract equivalent originates in the hyperpallium apicale (HA) of the rostral Wulst, implying rather direct connections between somatosensory inputs to IHA and somatomotor outputs from HA. The tract and its terminations are far from meager. As in mammals, the red nucleus is a prime target, which then projects to all levels of the spinal cord (Wild et al., 1979). Further caudally, the tract terminates profusely throughout wide regions of the brainstem reticular formation and secondary sensory nuclei, such as the external cuneate nucleus, but does not proceed further caudally than upper cervical levels.

An interesting but little-known somatosensorimotor link in the brainstem reflects control of the lower eyelid, which relaxes during sleep to cover the eye, in contrast to the descent of the upper lid in mammals. During waking hours, the lower eyelid appears to be under tonic control to keep the eye open, until a corneal stimulus initiates a defensive reaction. These actions are mediated via corneal afferent input to the ophthalmic part of nTTD and projections of nTTD to the dorsal motor nucleus of the trigeminal motor complex that innervates the two muscles of the lower eyelid (Wild and Williams, 1999).

In contrast to motor output from rostral HA via the pyramidal tract, outputs of Bas exit the telencephalon from the arcopallium at the caudal pole of the brain. They reach the arcopallium indirectly via an overlying part of the frontal nidopallium and the caudolateral part of the nidopallium caudolaterale (Wild et al., 1985; Dubbeldam and Visser, 1987). In finches, beak and auditory components of Bas were shown to follow this route independently (Wild and Farabaugh, 1996). The descending projections of different major parts of the arcopallium were originally described by Zeier and Karten (1971) in pigeons and shown to include secondary sensory nuclei in the brainstem. This was specifically confirmed using contemporary tracing techniques in zebra finches, in which Bas-recipient components of the lateral arcopallium were shown to target the nTTD (Wild and Farabaugh, 1996) and the ventromedial part of the parvocellular reticular formation (RPcvm), which is a major nexus of premotor projections to the jaw and other upper vocal tract motor nuclei (Wild and Krutzfeldt, 2012).

9.9 Somatosensory projections to the cerebellum

In the pigeon cerebellum, there are two somatosensory areas, one rostrally (lobules I–VI) and another caudally (lobule IX) (Necker, 2000a; see also Whitlock, 1952). Somatosensory projections to these regions are relayed from the spinal cord (Necker, 1992, 2000a; Okado et al., 1987). Spinal inputs to the anterior cerebellum arise predominantly from neurons in Clarke's column and hence are proprioceptive. Spinal inputs to the posterior cerebellum arise primarily from cervical lamina IV neurons, which are mechanosensitive (Necker, 1992). Another source of putative mechanosensitive spinocerebellar fibers is the paragriseal cells, which in the lumbosacral spinal cord are contacted by the axons of neurons in the contralateral accessory lobes of Lachi (marginal nuclei) (Necker, 1997). These lobes comprise a sensory component of a lumbosacral specialization involved in a sense of equilibrium (Necker, 1999; Necker et al., 2000; Rosenberg and Necker, 2000).

9.10 Magnetoreception and the trigeminal system

The link between magnetoreception and the trigeminal system in birds is historically highly controversial (Mouritsen, 2015, 2018; Wild, 2015). In European robins experimentally induced rapid changes in magnetic field intensity, horizontal direction, and inclination were shown to lead to neuronal activation in parts of the nTTD and in a ventral crescent of the principal nucleus (PrV; Heyers et al., 2010). Such activation was significantly reduced by section of the ophthalmic nerve (V1), which innervates the upper beak where magnetoreceptors have been thought to lie (see Treiber et al., 2012 for negative evidence from pigeon beak analysis). It is never the less interesting that in another migrant songbird (the Eurasian blackcap, Kobylkov et al., 2020) has shown that some neurons in a similar ventral crescent of PrV can be retrogradely labeled from a region of the nidopallium close to, but separate from, Bas, to which the main, dorsal part of PrV projects (Wild and Zeigler, 1996; Wild and Farabaugh, 1996); and some of these labeled neurons were also shown to be neuronally activated by experimentally induced magnetic field changes. Widely distributed projections from the frontal nidopallium could ensure appropriate connections with other parts of the brain involved in the computation of parameters underlying long-distance migration.

9.11 Summary and conclusions

It is hoped that this chapter will lead to the realization and appreciation of considerable diversity in the organization of the somatosensory system in birds. Even within the few species so far examined, there seem to be major deviations from the commonly accepted mammalian-type sequence of somatosensory projections throughout the brain. Of course, within mammals also, there are huge differences in the species-specific representation of the integument and of parts of the head-representations that, as in birds, reflect the functional importance of the body part in the everyday behavior of the animal. However, these distorted representations in mammals are the end stations of a common three-neuron sequence of somatosensory projections from the periphery to the cortex, via the DCN and the thalamus. In contrast, in some species of birds, even the DCN are not an obligatory relay in the sequence of ascending projections from the periphery. Furthermore, in parrots, at least, there appears to be a complete representation of the body and head at pontine levels-a phenomenon not encountered in mammals, or probably in many other species of birds. Another striking and equally puzzling feature of the somatosensory projections in birds is the complete or partial separation of the representations of the beak and body in Bas or in the rostral Wulst. The great majority of beak inputs are relayed via PrV to Bas. In barn owls and budgerigars, the representation of the beak in Bas is but one part, albeit a major part, of a complete representation of the whole body. In ducks, pigeons, and finches, a representation of the rest of the body is apparently absent in Bas (or has not yet been found), except for that of the cochlea.

In pigeons, the somatosensory, rostral part of the Wulst comprises a weakly somatotopic representation of the body minus the beak, with a second nonsomatotopic body representation further caudally in NI/NC of the nidopallium

(Wild, 1987; Funke, 1989a). Whether there is a somatosensory representation of the body in the rostral Wulst of ducks and parrots remains to be determined. In barn owls, the claw—and only the claw—is represented in what may be a specialization of the rostral Wulst. In the dunlin (Pettigrew and Frost, 1985), the finding of a tactile fovea in the rostral part of the telencephalon, representing the specialized probing beak tips, is intriguing, but whether the recording electrodes were in Bas or a body representation in another part of the telencephalon is not clear.

In the final analysis, we should remind ourselves—obvious though it may be—that one of the main functions of the body somatosensory system, at least for most birds, is to enable flight. Once underrated as a somatosensory system (Ariens Kappers et al., 1936), its complex organization can now be appreciated with the help of the tools of modern neuroanatomy and electrophysiology; and with the help of cameras fixed to flying birds (jdp.co.uk/programmes/earthflight), we can also marvel at the feedback from feathers this system must provide to guide the birds through their aerial worlds (Bilo and Bilo, 1983; Necker, 1985c).

Chapter 10

Avian vision

Graham R. Martin
School of Biosciences, University of Birmingham, Birmingham, United Kingdom

10.1 Introduction

The primary reliance of birds on vision is readily and frequently asserted. Casual observations of birds completing their everyday behaviors is sufficient to convince most observers that birds are using vision to control their key behaviors. This assertion is supported by evidence that in most bird species relatively large portions of their brains are devoted to the analysis of information from vision (Reiner et al., 2005). Also, the so-called intelligent behaviors of birds seem to be based primarily upon visual information (Emery, 2006). Thus, gaining information from vision and using it to guide sophisticated behaviors, seems to be the essential function of the brains of most birds.

Only in a handful of extant bird species does vision appear not to be the primary sense. The prime examples of "nonvisual" birds are the five species of flightless Kiwi (Apterygidae), whose vision seems to have regressed as they evolved in the absence of mammalian predators (Martin et al., 2007b). Even blind individual Kiwi have been recorded living healthy lives in the wild (Moore et al., 2017), presumably guided exclusively by olfaction, touch, and hearing. In some bird species, these senses play a complementary role to vision. This is found among some of the petrels (Procellariidae), shorebirds (Scolopacidae), and owls (Strigidae), in which olfaction, touch, and hearing play a key role in finding food items (Martin, 2017a). However, in these birds, vision is probably the primary guide for locomotion.

The importance of vision in birds was encapsulated in the phrase "a bird is a wing guided by an eye." Coined almost 80 years ago by Rochon-Duvigneaud in his influential survey of the eyes and vision of vertebrates (Rochon-Duvigneaud, 1943), this phrase captured the essence of birds from a sensory ecology perspective. Rochon-Duvigneaud's inspiration sprang from the idea that the dominant feature of bird biology is flight, and that the key features of birds can be explained by considering them as "flying machines" (King and King, 1980). This provided a unified framework for thinking about birds as vertebrates in which low body mass is combined with muscles, respiratory, and digestive systems capable of generating high power output. If adaptations to facilitate flight could be considered dominant in shaping core aspects of bird biology, it was a small step to assume that the control of flight would also make particular demands on the information that birds gather from their environment, hence birds could be succinctly summed up as "wings guided by eyes."

It now seems, however, that this assumption may have been misplaced. As more has been learned about the sensory ecology of birds, it seems that controlling flight may not be the prime driver of their vision (Martin, 2017b). The key driver of bird senses is now best regarded as stemming from the demands of foraging, that is the detection, acquisition, screening, and ingestion of food items, with vision being driven primarily by the demands of detection and acquisition. The second key driver that has shaped bird vision is the detection of predators. However, the visual tasks of foraging and predator detection can make antagonist demands for information, and these demands can be seen played out in the eyes of most birds (Martin, 2014). The informational demands for controlling flight can perhaps best be considered as met within the requirements set by the primary sensory challenges of foraging and predator detection.

It is now argued that it is more appropriate to regard a bird as "a bill guided by an eye" (Martin, 2017b). This is because the bill is the prime tool with which a bird interacts intimately with its environment. In the majority of species, survival depends upon bringing the bill unfailingly to "the right place at the right time." For some species, particularly some of the birds of prey, it might be better to suggest that they are primarily "feet guided by an eye." This is because it is the feet that do the crucial act of prey acquisition and so have to be positioned accurately in space and time,

Sturkie's Avian Physiology. https://doi.org/10.1016/B978-0-12-819770-7.00023-2

although even these birds also need to place their bills accurately when manipulating items.

This change in the short-hand way of describing birds is important because it changes how we might think about birds in an everyday sense. It indicates that the main task of a bird, day-in-day-out is getting its bill (or feet) to the right-place at the right-time, over-and-over again. The informational control of these tasks is subject to constant selective pressure. In foraging, getting the right information to control the bill is as important as having a bill of the right shape. It is argued that bill shape is likely to be under constant selective pressure (Grant and Grant, 2014) and so it seems likely that controlling the bill is also subject to similar levels of selection. There is no value in having a tool that cannot be effectively controlled. Making a sensory-based error when flying may be important, but it is not as important as being unable to explore the environment at close range and use the bill to acquire food.

10.2 What vision does?

The essence of vision is simple; it is the determination of the direction from which light has traveled to reach the observer (Land and Nilsson, 2012). All aspects of vision are elaborations of this basic ability.

The light sensitive patches found on the surfaces of early animals could record only the presence of light. What marked the evolution of those patches into eyes 500 million years ago was the ability to determine where light was coming from (Nilsson, 2009; Nilsson and Pelger, 1994). Once this basic ability had evolved there followed rapid selection for eyes with ever more accurate spatial resolution (Nilsson and Pelger, 1994; Parker, 2003).This was coupled with the evolution of the ability to detect light over an increasingly wider range of intensities, eventually resulting in eyes that could function from bright sunlight to dim moonlight. Spatial resolution was further enhanced through the evolution of color vision, the ability to differentiate between light of different wavelengths.

Vision in some modern birds is arguably at the pinnacle of eye performance. In some bird species, spatial resolution is close to the very limits of what is theoretically possible for a vertebrate eye, dictated by the physical properties of light (Land and Nilsson, 2012). The highest known spatial resolution of any animal has been recorded in eagles and vultures (Fischer, 1969; Reymond, 1985). In these birds, resolution reaches close to the limits set by the physical properties of light.

Color vision enables many birds to differentiate between lights of very similar wavelengths, perhaps giving some species the highest levels of spectral resolution among vertebrates (Wright, 1972, 1979). However, even with high-spectral resolution, the ability to resolve spatial detail using colored light is below that of spatial resolution involving achromatic patterns (Potier et al., 2018).

Many birds, perhaps the majority of species, achieve spectral resolution across a broad light spectrum, from ultraviolet to far red (Cuthill et al., 2000). However, it should be noted that contrary to popular belief, birds are not exceptional in this, the same broad spectral range of vision is found in many mammals (Douglas and Geffery, 2014) and invertebrates (Cronin, 2008). Furthermore, vision in the ultraviolet region of the spectrum is not a property of vision in all birds. The majority of nonpasserine species cannot be considered as truly ultraviolet sensitive in that they do not have a photoreceptor that is maximally sensitive in that region (Odeen and Hastad, 2013), and in some birds (notably diurnal birds of prey), ultraviolet light is filtered out by the lens and cornea and does not reach the retina (Lind et al., 2013, 2014).

The vision of birds can also function within the full range of naturally occurring light levels, a range of 100 million-fold. This allows birds to use visual information in both bright daylight and in low-light level environments, for example, in nocturnal forests and deep water habitats (Martin, 2017a).

Another remarkable performance of the vision of most bird eyes it that they can extract spatial information simultaneously across a wide sector of space about the bird. Most bird eyes have an extensive visual field and because there are always two eyes in the skull, the total visual field is typically very extensive. In some species, eye placement and visual fields combine to give complete panoramic vision without blind areas above and behind the head (Martin, 2014). Such total panoramic vision is, however, not unique to birds; it is also found in some mammals, most notably in the Lagomorpha, rabbits, and hares (Hughes, 1977).

10.3 Variations in avian vision

While examples of outstanding visual performance are fascinating, general descriptions of visual performance must be couched with uncertainty. Qualifications of "most" or "some" when describing the visual performance of bird species are essential. It is not possible to talk about "avian vision" in a unified way; there is much variation between species (Martin, 2017a). Differences in visual performance apply especially with respect to resolution (acuity), visual fields, and absolute sensitivity. For example, an owl's eye may be approximately 100 times more sensitive than that of a dove, and a falcon may have visual acuity four times greater than that of the dove it is pursuing. Some ducks can see all around their heads, while vultures have extensive blind areas above and behind their heads. Clearly, such differences in vision need both functional and mechanistic explanations.

The ability of eyes to extract accurate and precise information from the world is not without cost. Eyes, and the processing of information by the visual system, are metabolically expensive (Laughlin, 2001), and the eyes of no one species can do everything (Land and Nilsson, 2012). Like all evolved structures, there are compromises and trade-offs, and these may be dictated by both physics and biology. For example, it is well understood that the nature of light itself means that adaptations of eye structures that can achieve high resolution run counter to adaptations that enhance high sensitivity (Land and Nilsson, 2012).

It is these metabolic and physical limitations that have led to the specializations of eyes across species. Much of the fascination of avian vision lies in understanding these specializations. They are perhaps best understood as the result of natural selection for eyes that can extract information which is finely tuned to the sensory challenges presented by the execution of particular tasks in particular environments. Regarding the evolution of eyes as being "task-led" (Nilsson, 2009) has provided a valuable explanatory framework with which to account for the diversity of bird eyes found today (Martin, 2017a). Metabolic considerations can provide a basis for explaining the apparently suboptimal and near loss of vision in some bird species, such as Kiwi, Apterygidae (Martin et al., 2007b).

10.4 Variations in eyes

All bird eyes are based upon the same basic anatomy and physiology. Variations in visual performance between species are derived from relatively simple differences in structure. These include differences in absolute eye size, differences in optical performance, and differences in the relative numbers and distributions of photoreceptors types across the retina. These differences can be large but even subtle variations are functionally significant, and they can all be interpreted as specializations for the extraction of particular information related to the conduct of particular tasks, in particular, light environments.

Just what those tasks are requires detailed understanding of the behavior and ecology of particular species. Although these are well studied in some species, knowledge is still partial or nonexistent for many species. Some interspecies variations in vision can be attributed to trade-offs between visual information and information provided by other senses. These can include hearing, touch, and taste. Understanding how they are used in the conduct of specific tasks in particular environments may be necessary to develop a full understanding of a species' visual capacities. Such trade-offs between vision and other sources of information have been well demonstrated in examples of underwater foraging in cormorants (Phalacrocoracidae) and penguins (Spheniscidae) (Martin, 1999; White et al., 2007), and in the nocturnal foraging behavior of a range of species including owls (Strigidae, Tytonidae), shorebirds (Charadriidae, Scolopacidae), kiwi (Apterygidae), and oilbirds (Steatornithidae) (Martin et al., 2004; Martin, 2017a).

10.5 Bird eyes: function, structure, and variations

Precise and accurate spatial resolution is achieved in vertebrate eyes through two anatomically linked but functionally separate systems. The *optical system* receives light and creates an image of the world. This image is projected onto a surface, the retina, which is the *image analysis system*. It is here that analysis of the image begins, and information is extracted and sent to the brain for further processing (Fig. 10.1). High resolution requires the production of an image which is a spatially accurate representation of the world. The image must be distortion free and sharply focused, but the physical nature of light and optics place fundamental limits on image properties, an image can never be an exact representation of the physical world (Land and Nilsson, 2012).

Although the two main functional systems of an eye are physically linked, they are subject to independent evolution. Even if the eyes of two different species have similar optical systems, they may analyze their images in different ways. Similarly, eyes which have the same overall dimensions can have different optical systems which present different images for analysis by their retinas. It seems unlikely that the eyes of any two species are exactly the same. This means that birds of two different species sitting side-by-side will extract different visual information from the environment which they share. Indeed it is subtle variations between eyes of individuals, not just species, which provides the raw material that drives the evolution of vision (Nilsson and Pelger, 1994).

The visual information extracted from the environment by different species can also differ markedly because eyes never occur singly, they are always paired. Although bird eyes are arranged symmetrically in the skull with respect to its median sagittal plane, their positions can differ markedly between species. These differences in eye positions can result in significant differences in the visual fields of birds (Martin, 2014). These are the regions of space about the head from which visual information can be retrieved at any one instant. It includes the degree to which there is overlap between the fields of each eye, the binocular field. Differences in visual field configurations have important implications for what information is made available at any one instant and therefore how vision can influence a bird's behavior.

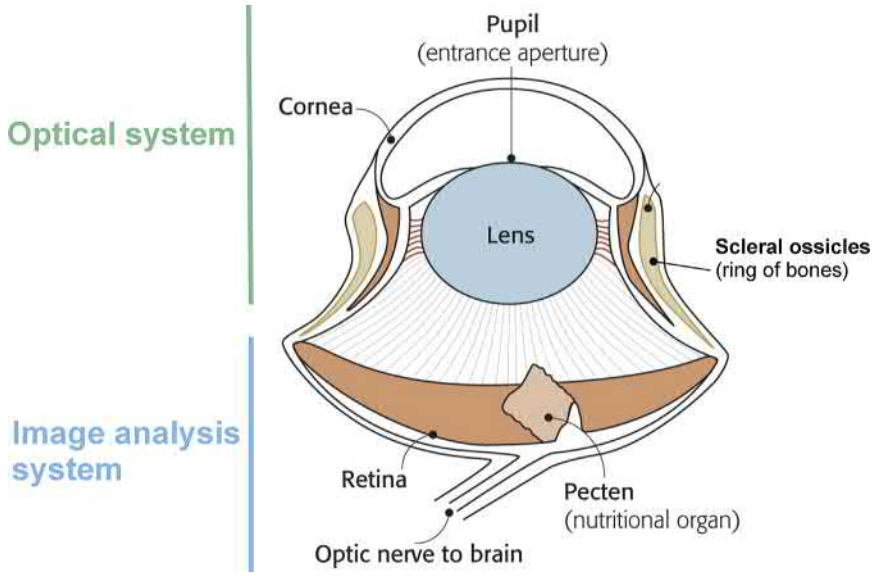

FIGURE 10.1 The two main functional systems of a bird's eye illustrated by a sectional diagram of the eye of an owl. The optical system has two components: cornea and the lens. These produce a focused image projected onto the retina which is where the first stage of image analysis begins, and from where information is sent via the optic nerve to the brain. In different eyes, the lens and cornea can have different optical properties depending upon their shape and size. These produce images with different properties (size, brightness, contrast) in different eyes. The image analysis system in different species exhibit large variations in the way photoreceptors and ganglion cells are arrayed across the retina, influencing markedly the way that images in different eyes are analyzed. *Drawing by Nigel Hawtin (Nigelhawtin.com) based upon an original drawing by the author.*

10.5.1 The optical system

The properties of the optical system of an eye can affect four key parameters of the image: brightness (how much light is captured to make the image), size (the area over which the image is spread), angular size of the image (how wide a field of view is captured in the image), and quality (the precision with which light from a point in the world is brought to a focus in the image). Variation in each one of these parameters can alter the information that an eye can extract from its environment.

The optical system has two main elements: cornea and lens (Fig. 10.1). The cornea, the curved surface at the front of the eye essentially functions to provide a boundary between media of two different refractive index; air and the fluid-filled chamber of the eye. The radius of curvature of the cornea is the key to its image-forming properties. A more highly curved surface produces a smaller image than a more shallowly curved one. The lens, suspended in the fluids that fill the two chambers of the eye, derives its primary optical function by virtue of its two convex surfaces. The overall refractive index of the lens is greater than that of the surrounding fluids, enabling it to bend light that passes into and out of it. The lens surfaces can vary in their curvature, and in whether curvatures are uniform or become flatter or more curved toward the equator of the lens. The refractive index of the lens is not uniform, but rather it varies with position within the lens. Combined, the properties of the cornea and lens determine the size of the image, how far behind the lens it is focused (the focal length of the eye), its quality (how sharply it is focused), over how much of the image best focus is maintained, and how much of the scene is contained in the image (the field of view).

In vertebrate eyes, the lens also has a role in adjusting the focus of the image so that objects at different distances from the eye can be brought into sharp focus, that is, the eye can "accommodate." In larger eyes with wider pupils, accommodation becomes increasingly important compared with small eyes. In mammals and reptiles, accommodation is achieved primarily by deformation of the lens surface curvatures, while in fish the lens is moved but not deformed (Land and Nilsson, 2012). In birds, the curvatures of both the cornea and lens surfaces can be altered during accommodation (Glasser et al., 1994; Schaeffel and Howland, 1987).

10.5.1.1 Variation in the optical systems of bird eyes

The relative amount of focusing contributed by the lens and the cornea in forming the image upon the retina can differ quite significantly in different eyes. This is clearly seen when comparing the optical systems of eyes of the same overall size. A good example is provided by comparison of the eyes of Rock Doves *Columba livia* and Manx Shearwaters *Puffinus puffinus* (Fig. 10.2). Although these eyes have the same axial lengths ($\approx$12 mm), the curvature of

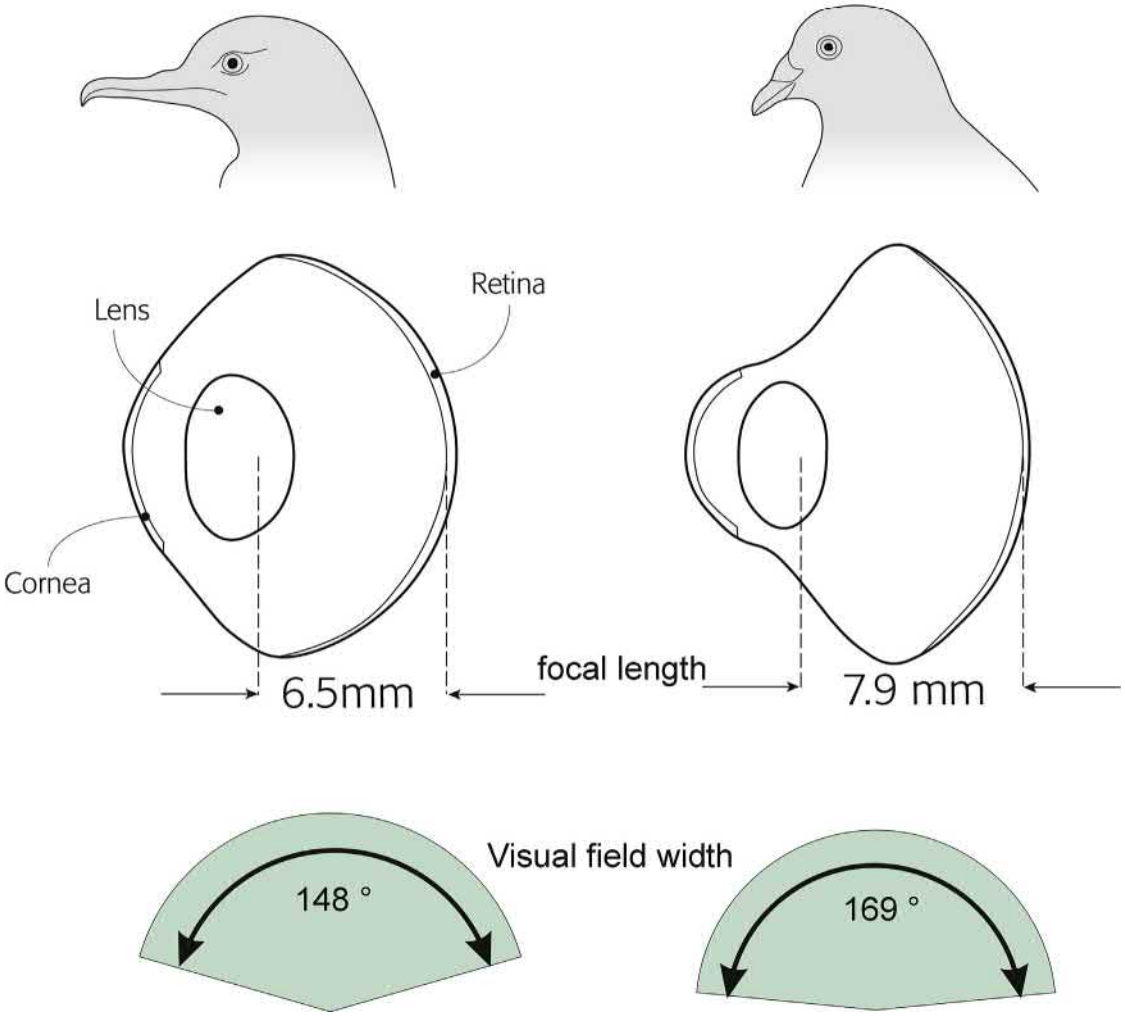

FIGURE 10.2 **Diagrams of sections through the eyes of Manx Shearwaters and Rock Doves.** The eyes of these birds are of the same overall size (both in length and diameter), but their corneas and lenses have quite different characteristics. The result of these differences is that the images produced by them have quite different properties. The image is smaller in Shearwaters (indicated by a shorter focal length) and brighter. Also, the visual field of a Shearwater's eye is significantly narrower than in a Dove. *Original diagram by the author from* Bird Senses *(2020).*

their corneas, and the curvatures of their lens surfaces, differ. Although these are relatively small differences, they result in important differences in the image properties in these two eyes. In shearwaters, the shorter focal length of the optical system results in a smaller but brighter image compared with doves (Martin and Brooke, 1991). These differences can be interpreted by reference to the frequent night-time activities of shearwaters whereas doves usually go to roost at twilight. The narrower visual field width of Shearwater eyes (Fig. 10.2) is a consequence of the shorter focal length of their optics and reduces the space around the head from which shearwaters can gain information, compared with doves.

Vertebrate eyes can also vary greatly in size. This is captured in Fig. 10.3 which compares the overall size and basic optical parameters of the eyes of Common Starlings *Sturnus vulgaris*, Tawny Owls *Strix aluco*, and Common Ostriches *Struthio camelus*. As in any optical system, absolute size inevitably determines the size of the image that it produces, and a larger sized image of a given scene can contain more detailed spatial information than a smaller image. Furthermore, a large entrance pupil determines the upper limit on the quality of the image, with respect to how sharp the focus of the image can be. This is driven by the wave nature of light and to achieve the sharpest focus requires an absolutely large entrance aperture (Land, 1981; Shlaer, 1972). However, absolute size also determines the maximum amount of light that can be gathered and hence the brightness of the image, and this is especially important when viewing small discrete sources of light in a scene (Land, 1981). A consequence of this is that eyes which have evolved for high sensitivity rather than high resolution

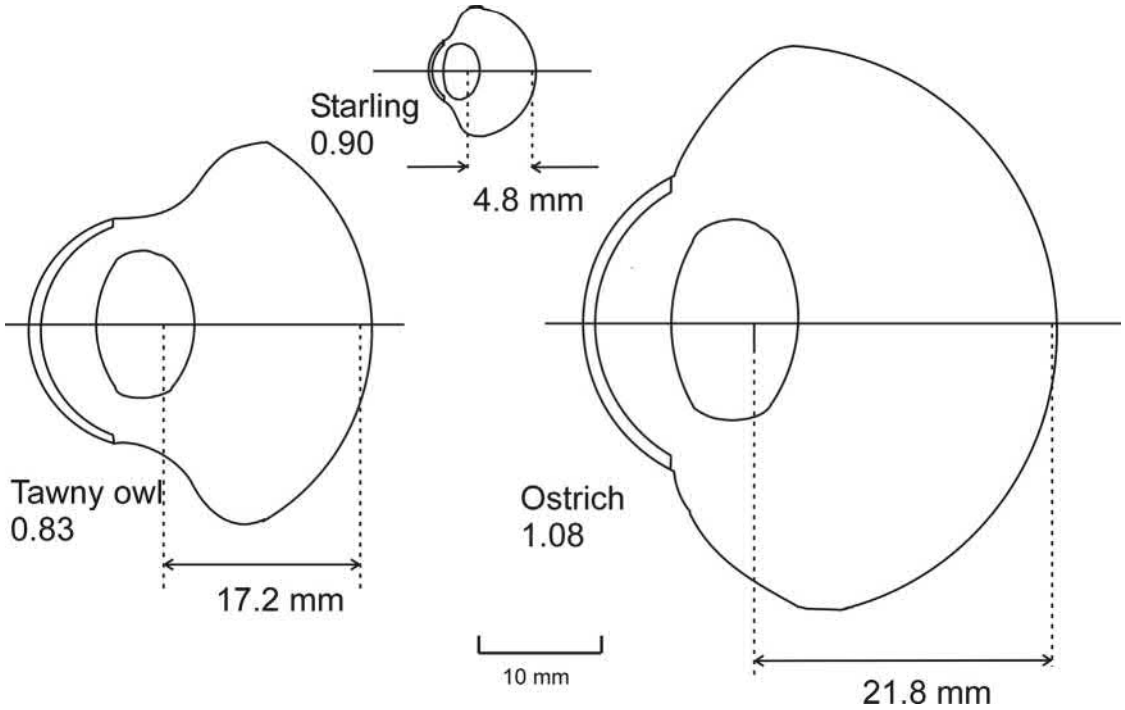

FIGURE 10.3 Sectional diagrams of schematic models of the eyes and optics of Tawny Owls, Common Starlings, and Ostriches. These diagrams are to scale and show the large size variation found in the eyes of birds. Also indicated are the focal lengths of these eyes and the ratio of the power of the lens to the power of the cornea. The longer the focal length, the larger the image of the same object when viewed by each eye. The ratio of lens to corneal power is another key descriptor of the optics of vertebrate eyes. *Original diagram by the author from* Bird Senses *(2020).*

also have absolutely large eyes, as is the case in some owl species (Fig. 10.3).

Large eye size, however, does not guarantee high resolution. That also requires that the image analysis system is matched to the task of extracting fine details that the image may contain (see section below). The Ostrich eye is an important example of this (Fig. 10.3). Despite it being probably the largest eye of any terrestrial vertebrate, its spatial resolution is not the highest. In fact, maximum acuity of Ostriches is estimated to be similar to that found in birds with much small eyes, including Indian Peafowl *Phasianus colchicus*, Rock Doves, and Silver Eyes *Zosterops lateralis* (Boire et al., 2001; Coimbra et al., 2015; Hodos et al., 1976). Thus, the functional significance of the Ostrich eye's large size may lie in the enhancement of sensitivity rather than resolution, which is correlated with ostriches' vulnerability to large mammalian predators at night.

10.5.2 Vision under water

Many bird species habitually forage under water. However, when an eye is immersed, its cornea loses it optical function because it no longer separates two surfaces of different refractive index. It is reasonable to assume that the eyes of amphibious species should operate effectively in both air and underwater, although evidence for this is limited. There is evidence that both Great Cormorants *Phalacrocorax carbo* and Australasian Gannets *Morus serrator* are equally focused in both air and water (Katzir and Howland, 2003; Machovsky-Capuska et al., 2012). However, it has been shown that underwater the eyes of Great Cormorants have very low acuity, the lowest recorded in any bird under daytime light levels (White et al., 2007).

Two possible mechanisms of how the optical effects of immersion might be mitigated in amphibious birds have been proposed (Fig. 10.4). The first mechanism is suggested by the observation that some penguins have corneas that are relatively flat and hence of low refractive power (Sivak and Millodot, 1977). This means that the loss of focusing power upon immersion is not large, and the lost power can be compensated for by a more spherical lens whose power is increased upon immersion. There is evidence that this type of mechanism does occur in some penguin species (Howland and Sivak, 1984; Martin and Young, 1984).

The second mechanism is proposed to occur in species whose eyes have a more typically curved cornea. It is suggested that loss of their higher refractive power upon immersion is compensated by the eye having a mechanism that combines a highly malleable lens with a rigid iris. Upon immersion, it is suggested that the lens is pushed up

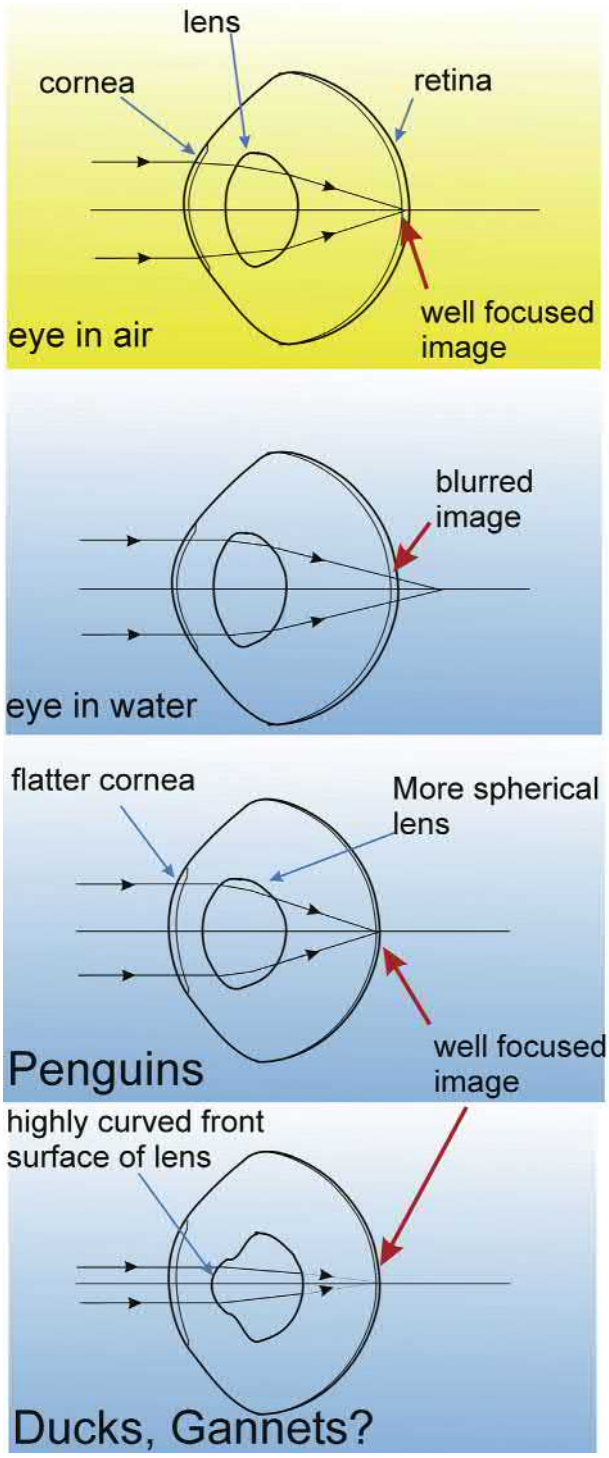

FIGURE 10.4 The problems of immersion and how it might be overcome in birds. An eye that is well focused in air loses the power of the cornea upon immersion. An image instead of being well focused on the retina is in effect focused behind the eye and the image appears blurred. Two possible mechanisms may have evolved to overcome this problem in amphibious birds. In some amphibious species, the cornea is relatively flat and therefore its loss upon immersion is less of a problem. The extra power needed to focus the image on the retina when the eye is immersed can be achieved by a more spherical lens whose power needs to change little. This type of mechanism may be a feature of the eyes of penguins and albatrosses. An alternative mechanism employs a malleable lens which upon immersion is pushed against a stiffened iris and the lens' front surface bulges through the pupil to make a highly curved, and hence powerful, lens. There is some evidence that this may occur in some ducks, gannets, and cormorants. However, the bulging lens may be an artifact of the investigation procedure which has over driven the muscles of the eye that control lens position and the iris. *Original diagram by the author from* Bird Senses *(2020).*

against the iris. The front surface of the lens bulges through the pupil to make a highly curved surface and hence a powerful lens (Fig. 10.4). It is suggested that this mechanism occurs in some diving ducks (Anatidae), and in gannets and cormorants (Sulidae) (Cronin, 2012; Hess, 1909; Levy and Sivak, 1980). However, the mechanism has not been optically modeled, and the evidence is not compelling. The bulging lens seen in the experimental work with ducks may be an artifact of the investigative procedure which used drugs applied to the eye. These may have over-driven the muscles that control lens position, pupil size, and iris rigidity.

As well as effects on focus, the loss of corneal refractive power upon immersion has two other important effects. First, the effective diameter of the pupil decreases. This is because it is no longer magnified by the cornea. This reduction in effective pupil size results in a decrease in the brightness of the image. In Humboldt Penguins, the decrease in image brightness has been shown to be nearly threefold (Martin and Young, 1984). Second, abolishing the magnifying power of the cornea also moves the margins of the field of view toward the axis of the eye. The effect is that a smaller section of the world is projected onto the retina, and so the total visual field shrinks. These changes are also not trivial, for example, in Humboldt Penguins, the visual field width of an eye may shrink in width by more than 30 degrees which is sufficient to abolish binocularity in all but a small section of the frontal visual field (Martin and Young, 1984). Such changes are significant for understanding the extent of the environment that an amphibious bird can see upon immersion. Certainly, measures of a bird's visual field in air cannot be applied directly to understanding its behavior underwater.

10.5.3 The image analysis system

10.5.3.1 Photoreceptors and visual pigments

Image analysis in vertebrate eyes begins with the detection of light by the photoreceptors of the retina. These are the familiar rods and cones which are found in all vertebrate eyes. Each photoreceptor signals the absorption of light photons by the photopigment molecules in their outer segment. These signals are collated by ganglion cells, which in turn send a signal along the optic nerve to the

brain where they are integrated with signals from the many millions of photoreceptors which are distributed across the retina. While differences between species in the type of photoreceptors is very limited, the number of photoreceptors and the way they are distributed across retinas, differ significantly. The result is that even if identical mages were present in the eyes of two species, the information that is extracted from them is likely to be significantly different.

The rods of bird retinas are of similar structure, and contain a similar photopigment, to those found in the retinas of other vertebrate taxa. The cones, however, differ from those of other vertebrates in respect of both their structure and the wavelengths of light to which their photopigments are maximally sensitive (referred to as their λmax). In birds, two types of cones occur, "single" and "double," which refers to the number of outer segments (Fig. 10.5). Double cones are not unique to birds; they are widespread in vertebrates but are absent from mammals (Bowmaker and Loew, 2008; Cronin, 2008; Walls, 1942). Double cones contain the same photopigment in both of their outer segments. Single cones in bird retinas are usually of four types, classified according to the λmax of the photopigment they contain (Cserhati et al., 1989; Hart et al., 2000a). Thus, most avian retinas contain a total of six photoreceptor types: double cones, four types of single cones, and rods (Martin and Osorio, 2008) (Fig. 10.5). By contrast, most mammalian retinas, including humans, have four types of photoreceptors (three single cones, plus rods).

As in other vertebrate retinas, the important functional difference between rods and cones is that rods function primarily at low-light levels (twilight and below), while cones function at higher light levels (twilight and above).

The types of photopigments found in bird photoreceptor outer segments show a high degree of similarity across species. This suggests that these pigment types arose early in the linage leading to modern birds and that their properties have been highly conserved. Birds regarded as distantly related (Hackett et al., 2008; Prum et al., 2015) have been shown to have very similar photoreceptor pigments. For example, the visual pigments found in the eyes of a species of pelagic seabird (Wedge-tailed Shearwaters *Ardenna pacifica*, Procellariiformes) are very similar to those found in a phylogenetically distant species that is terrestrial and lives in open forest habitats (Indian Peafowl *Pavo cristatus*, Galliformes) (Hart, 2002, 2004; Hart and Hunt, 2007). This suggests that visual pigments in birds have general properties that are not tuned to the performance of specific tasks or to differences in the types of habitat that birds exploit. However, what does differ between species is the number and distributions within the retinas of receptors containing the different photopigment types.

The five types of visual pigments of birds are labeled and characterized by their λmax as follows:

RH1: rhodopsin type 1 (λmax 500 nm), found in the rod receptors

RH2: rhodopsin type 2 (λmax 505 nm), found in single cone receptors

SWS2: short wave type 2 (λmax 470 nm), found in single cone receptors

LWS: long wave (λmax 565 nm), found in both single and double cone receptors

SWS1: short wave type 1—This pigment is also found in single cone receptors but occurs in two types that are found in different species. Pigments with λmax at 365 nm are referred to as ultraviolet sensitive (UVS pigment); those in which λmax is at 410 nm are referred to as violet sensitive (VS pigment) (Wilkie et al., 2000).

Cone receptors containing UVS pigment are found in gulls (Laridae, Charadriiformes), ostriches (Struthioniformes), parrots (Psittaciformes), and oscine passerines (but not in Corvidae) (Odeen et al., 2010, 2011; Odeen and Hastad, 2013). It is only these species which have true UV vision. Other species have the VS pigment, their spectral sensitivity extends into the violet-near UV part of the spectrum, but they lack specific UV sensitivity. It is worth noting that human retinas contain a cone pigment (λmax in the 420−440 nm range) which has peak sensitivity close to that of the avian VS pigment.

The spectral sensitivity characteristics of avian cone receptors are complicated by the presence in each cone of an oil droplet (Fig. 10.5). Each droplet sits in the proximal part of the outer segment so that light must pass through it before it reaches the photopigment in the outer segment (Cserhati et al., 1989). Oil droplets are also found in the photoreceptors of reptiles but are absent from most mammal species.

The droplets contain carotenoid pigments that are derived from the bird's diet. These pigments occur at a high density and give the droplets a bright color when observed using a light microscope. They appear as reds, greens, and yellows, but colorless droplets also occur. The pigments in the oil droplets are not photosensitive, they simply absorb and transmit light in different parts of the spectrum and so do not contribute directly to vision. However, because light must travel through the droplets before reaching the outer segment, they serve an important filtering function and sharpen the spectral sensitivity of the LWS, MWS, and SWS cones (Hart and Vorobyev, 2005). The resultant spectral sensitives (photopigment plus oil droplet filtering) of the different receptor types are shown in Fig. 10.5. The peak sensitivities of the four receptor types are spaced approximately equally across the birds' visible spectrum.

Sharpening the spectral sensitivity does not occur in the double cones because their oil droplets are transparent over the wavelengths that the photopigment is sensitive to. However, these droplets do block UV light from reaching

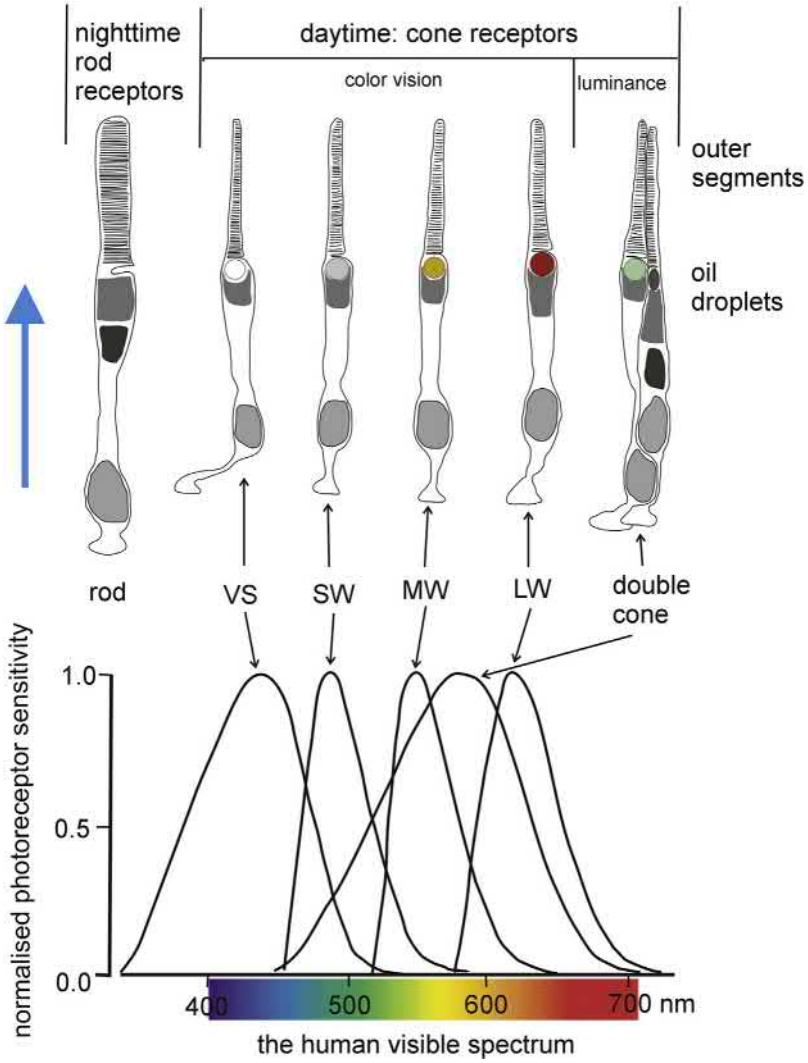

FIGURE 10.5 **The photoreceptors of bird retinas are of few types and are similar in all bird species.** What varies between species are the relative numbers and distributions of the different receptors types across the retinas of different species. In birds, rods are of one type, but the cones are of five different types; four types of single cones and double cones. The different types of single cones are classified by reference to the position in the spectrum of the peak sensitivity of the photopigments that they contain. The top portion of the diagram depicts the types of retinal photoreceptors as they appear when viewed through a light microscope. The outer segments are extremely narrow, generally between 1 and 2 microns in diameter, but they are relatively long. Each outer segment contains many millions of photosensitive pigment molecules. The four types of single cones provide the fundamental mechanism upon which color vision is based. The double cones provide a neural channel that is thought to signal luminance (brightness), and they are not part of the color vision system. Within all cone types there is an oil droplet. The arrow on the left indicates the direction in which light travels from the optics of the eye to the focused image on the retina. This means that the light that makes up the retinal image must pass through the oil droplets before it enters the outer segments. Oil droplets that are colored act as cut-off filters and allow light only above particular wavelengths to pass through to the photopigment molecules. The combination of photopigment types and oil droplet types results in their being four main types of single cone photoreceptors in birds' retinas with each cone type able to absorb light only within a particular part of the spectrum, although there is overlap between them. The lower section of the diagram shows the resultant photoreceptor sensitivities and the labels used to describe them. These are LW (long wave) which absorb light at the orange-red end of the visible spectrum; MW (middle wave), absorbing light in the green-yellow spectral region; SW (short wave) absorbing light in the blue-green spectral region; VS, which absorbs light in the violet-ultraviolet spectral region. *Redrawn from illustration provided by Peter Olsson Lund Vision Group, Sweden, and Daniel Osorio (University of Sussex, UK).*

the photopigment. The oil droplets in the UV/VS cones are also transparent, but they also allow UV light to reach the photopigments.

The key function of the single cone types lies in providing the foundation of color vision; the ability to differentiate between light sources based upon their spectral composition, not just upon their brightness. There is good evidence from behavioral investigations, as well as from retinal physiology that bird color vision should be viewed as based on the four single cone receptor types. It is

therefore referred to as a tetrachromatic system, as opposed to the cone system underlying human color vision, which is based on three cone receptor types, trichromatic vision. A range of investigative techniques (Jones and Osorio, 2004; Osorio et al., 1999) have indicated that double cones are not part of the color vision mechanism and probably constitute a separate channel that signals luminance at daytime light levels.

Because cone photoreceptors do not function at lower twilight and night-time light levels color vision is functional during higher twilight and daytime only. At lower light levels, only the rod receptors are functional and since there is only one type of rod receptor there is no basis for color vision. Furthermore, the photopigments found in rods, the RH1 pigment, have very similar characteristics across all birds and indeed across other animal taxa. The result is that spectral sensitivity at night is likely to be very similar across all bird species, and indeed is similar across most terrestrial vertebrates, with a peak at around 500 nm.

Such similarity in spectral sensitivity is, however, not the case at higher light levels. Under these conditions, spectral sensitivity is determined by the combined functioning of the cone photoreceptors. Although the sensitivity of the cones types does not vary markedly across species, their relative numbers in each retina do vary. Spectral sensitivity functions at high light levels show variations between individual birds and between different measuring techniques and conditions (Wright, 1979). In Rock Doves, maximum sensitivity has been found to lie between 560 and 620 nm in different studies, and all studies also showed an increase in sensitivity (but not a maximum) below 420 nm. Despite this variability, it was possible to model the overall spectral sensitivity of doves by making assumptions as to the relative abundance of cone photoreceptor types found across the whole of the retina (Bowmaker, 1977). This technique has been used to predict spectral sensitivities in other species based upon knowledge of their cone visual pigments and oil droplets characteristics (Hart et al., 1999).

10.5.3.2 Variation in the image analysis systems of bird eyes

Although there is little variation in the suite of photoreceptor types found in the retinas of different bird species, there are known to be very marked differences in the relative abundance of receptor types and in their distributions within the retinas of different species (Hart et al., 1998, 2000a; Hart, 2001, 2004). The result of this is twofold. First, in any eye, the image projected onto the retina is not analyzed in a uniform way across the whole of its area. Second, there can be very marked differences in patterns of analysis between eyes of different species. The result is that an image of the same scene in the eye of one bird species will be subject to different analysis by the eye of another species.

10.5.3.3 Variation in the distribution of receptor types

Variations in the distributions of cone receptor types across the retina can be striking, and it seems likely that they result in differences in spectral sensitivity and probably color vision in different parts of the visual field of a single eye, and there is some evidence to support this (Martin and Muntz, 1978). A striking example of variation in the types of receptors within the retina is found in Rock Doves, in which a large area is dominated by receptors containing red oil droplets (LW-sensitive cones), known as the "red-field" (Galifret, 1968). This area looks downward within the visual field, while receptors containing yellow oil droplets (MW-sensitive cones, the "yellow field") predominate in areas that look laterally and upward. These different areas are obvious even to the naked eye in a trans-illuminated excised retina; there is a very clear boundary between the areas (Fig. 10.6). The visual ecology and function of this striking regional specialization within dove eyes is not understood, although it has been suggested that the yellow field in some way enhances the contrast of objects seen against the blue of the sky (Lythgoe, 1979). Other species show systematic differences in the distribution of cone receptor types (Galifret, 1968), but there is a gradient in the relative abundance of different receptor types across the retina, rather than clearly demarked fields.

10.5.3.4 Variation in the densities of receptor types

Variations in the relative densities of photoreceptors and ganglion cells are also very striking. These differences in the density of cells may be overlaid on patterns of cone receptor types (Fig. 10.6). Very distinct patterns in ganglion cell density have been discerned with light microscopy across a diverse range of species. For example, clear patterns of ganglion cell distribution have been described in doves (Bingelli and Paule, 1969), Ostrich (Boire et al., 2001), waterfowl (Fernandez-Juricic et al., 2011; Lisney et al., 2013a), Procellariiform seabirds (Hayes and Brooke, 1990; Mitkus et al., 2016), penguins (Coimbra et al., 2012), flamingos (Lisney et al., 2020), new world vultures (Lisney et al., 2013b), passerines (Coimbra et al., 2006, 2015), and parrots (Coimbra et al., 2014; Mitkus et al., 2014).

In all of these species, clear patterns of photoreceptor and ganglion cell concentrations occur (Fig. 10.7). These patterns may be roughly circular, with a very high concentration at the center and a gradual decline of cell density away from the center. In some species more than one region of high concentration can occur, while in others high

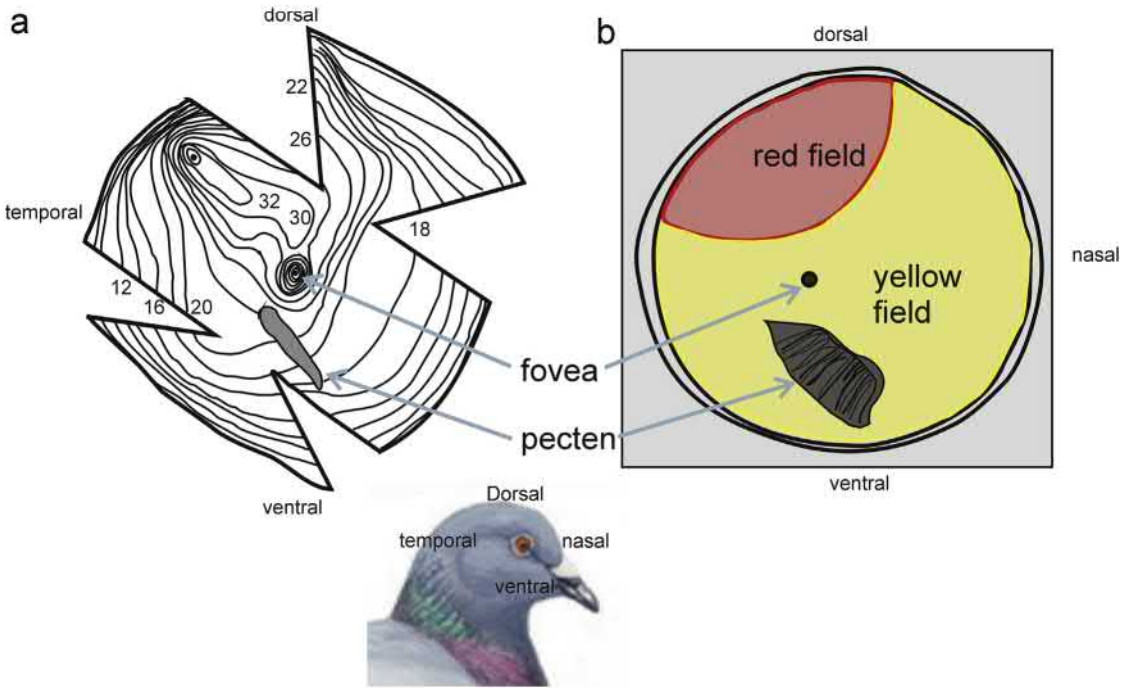

FIGURE 10.6 An indication of the complex way in which image analysis can vary across an individual retina provided by the example of the retina of Rock Doves *Columba livia*. Diagram (A) shows the topography of ganglion cell density in the right eye with the orientation of the retina as in the sketch of the bird. The lines are isodensity contours that join regions in which ganglions cells have the same density (the numbers by contours indicate ganglion cell density as × 1000 per mm^2). A distinct contour pattern is obvious, with low densities of ganglion cells at the periphery in the ventral and nasal sections of the retina (which looks upwards and backwards), and two distinct areas of very high ganglion cell density, one in the central retina (which projects laterally) and another in the temporal-dorsal retina, which looks downwards, possibly in the direction of the bill. The central region of high-cell density is also associated with a fovea. Diagram (B) indicates that the density of photoreceptor types also differs across the retina. The orientation of the retina is the same and so the two diagrams could be overlaid. In the temporal-dorsal retina, there is a region "the red field" in which LW type cones containing red oil droplets (Fig. 10.6) dominate. The rest of the retina is dominated by MW type cones which contain yellow oil droplets. *Diagrams redrawn and modified from originals in (Bingelli and Paule 1969) and (Galifret 1968).*

densities of receptors may occur in a linear band that is typically arranged so that it projects approximately horizontally when the bird's head is held in its usual resting posture. The usual interpretation of these patterns is that areas of high receptor concentration are regions of heightened spatial resolution within the visual field of the eye. These regions may take the form of an elongated band that projects toward the horizon, or they may indicate a direction of elevated resolution projecting in a particular direction.

Areas of the highest cell density may be associated with a fovea. This is a highly localized region in which the outer layers of the retinal cells are displaced to form a small pit or depression in the surface of the retina (Bringmann, 2019) (Fig. 10.8). Displacing the layers of the retina in this way ensures that the highest quality optical image is received directly by the photoreceptors, thus avoiding any image degradation that might be caused by passing through the layers of the retina. A number of hypotheses have been proposed concerning the function of foveas, including image magnification and image fixation mechanisms (Bringmann, 2019; Potier et al., 2020). However, strong evidential support for any of these hypotheses is lacking. Thus, beyond the general observation that displacing the retinal layers enhances spatial resolution by allowing the highest quality image to be received directly at the photoreceptors, it is not clear what the actual form of a fovea does.

It is clear that patterns of photoreceptor and ganglion cell distribution can vary not only between species but also between individuals within a species (Mitkus et al., 2014). Furthermore, differences in cell density and distributions between the eyes of the same individual have also been demonstrated (Hart et al., 2000b), and the shape and size of foveas have been shown to vary between individuals and probably change over an individual's life time (Potier et al., 2020). Such variations provide a very rich substrate for not only interspecific but also interindividual differences in analysis of the retinal image. It is upon such differences that natural selection is likely to be continually acting, resulting in visual capacities which can be considered to have become tuned in different species to informational requirements for the conduct of particular tasks in particular environments.

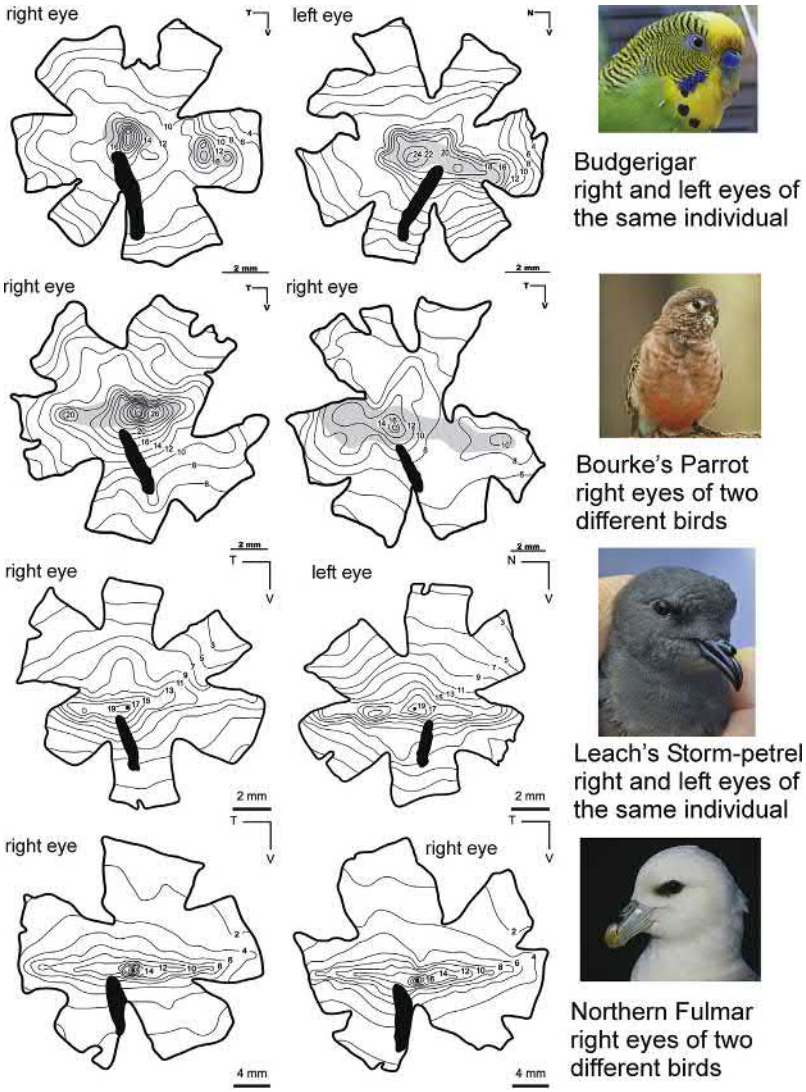

FIGURE 10.7 **Patterns of retinal ganglion cells in birds.** Each diagram shows the contours of equal ganglion cells densities (× 1000 cells mm^{-2}) on a flattened retina, the pecten (indicated by the black shading) creates a blind area in the eye and is a prominent landmark. The two examples from a Budgerigar show the left and right eyes from the same individual. They show a high concentration of ganglion cells in the center of the retina which indicate well demarked regions of high acuity that look out laterally from the eye, approximately in the center of the field of view. There is a second concentration in the retina toward the bill which looks slightly backwards. However, there are also marked differences between the two eyes. In Bourke's Parrots, the two diagrams are for the same eyes from different birds and show marked differences between the individuals. Both have a high concertation of cells in the center of the retina, but in one bird, there is a second concentration which looks forwards while in the other the overall density is much lower and the second area of concentration looks backwards in the field of view. In the two seabird species, clear linear bands of high ganglion cell concentrations are found running across the retina and project laterally toward the direction of the horizon. However, as in the parrots, there are differences between the left and right eyes of the same individual and differences between individuals. *Ganglion cells maps of Budgerigars and Bourke's Parrot are from (Mitkus et al., 2014), Fulmar and Storm-petrel (Mitkus et al., 2015). Photographs, Budgerigar, Michael Cole; Bourke's Parrot, Daniela Parra; Leach's Storm-petrel, Peter R. Flood; Northern Fulmar, Steve Garvie.*

10.6 The visual fields of birds

Differences in optical structure affect not only the size and brightness of the image but also determine the extent of the world that is imaged. This is important, since it determines the extent of a bird's visual world from which it can gain information. In birds, the field of view of a single eye can be as narrow as 124 degrees (owls) and as wide as 180 degrees (ducks and shorebirds) (Martin, 2007).

When the fields of two eyes are combined, variations in the birds' total visual field are considerable (Martin, 2007). Thus, in a horizontal plane, the total width of the visual field in owls is about 200 degrees, while in some shorebirds and ducks, the field provides a total 360 degrees panorama. Associated with these are marked differences in the extent of visual fields above, behind, and below the head. The axes of the two eyes may diverge by a relatively small

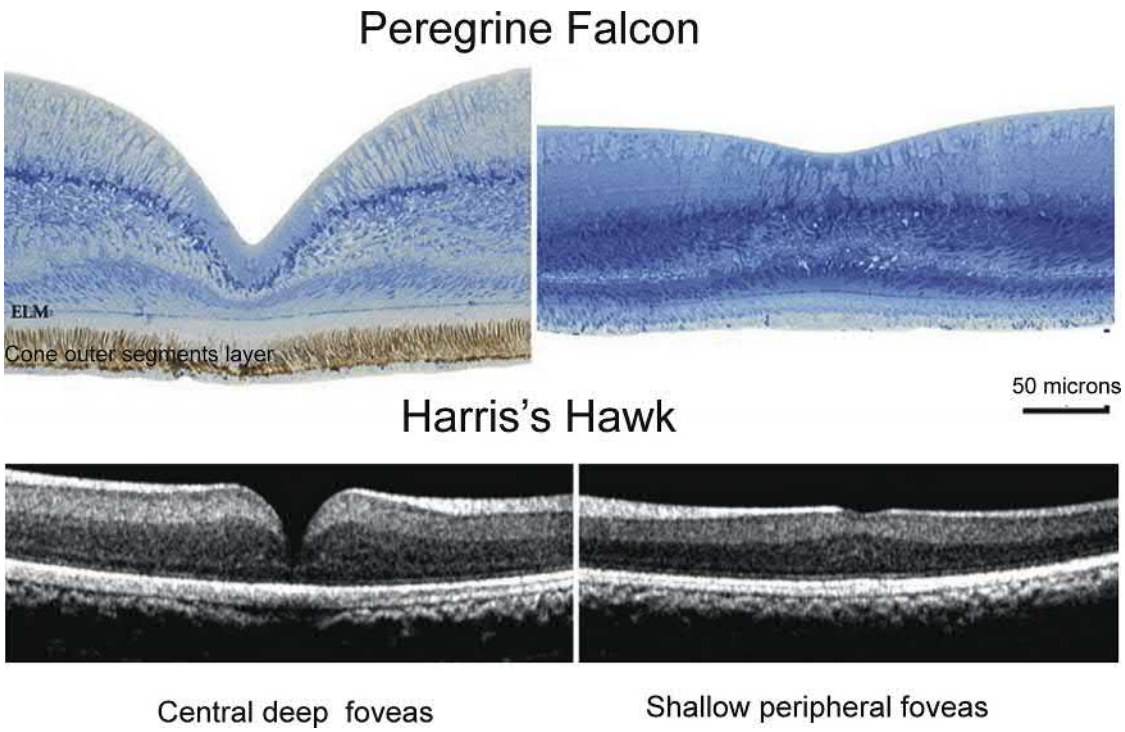

FIGURE 10.8 **Sections through the retinas of a Peregrine Falcon and a Harris's Hawk showing foveas.** In both species, there are two foveas. One is placed more-or-less centrally in the retina and looks out laterally in the bird's field of view. The other is placed toward the periphery of the retina and looks more forwards, although it does not look directly forward. The central foveas are deep and have sharply curved sides, the shallow foveas are more bowl shaped, both are locations where acuity is enhanced compared with the rest of the retina. Note that light making up the image travels from top to bottom in these diagrams and the photoreceptors are in the bottom layers in each illustration. They can be clearly seen in the picture of the Peregrine's deep fovea (top left). *Illustrations courtesy of Mindaugus Mitkus (Peregrine Falcon) and Simon Potier (Harris's Hawk) both University of Lund Vision Group, Sweden.*

amount (e.g., in owls, eyes diverge by about 55 degrees), or they can be almost diametrically opposed (ducks and shorebirds). Thus, the fields of the two eyes have become combined in many ways and so provide a wide range of different total fields of view, as well as markedly different degrees by which the two eyes overlap and provide binocular coverage of part of the total field (Fig. 10.9).

Humans are unusual animals in having two eyes placed on the front of the skull. This results in each eye seeing almost the same sector of space. This arrangement is quite different from that found in birds (Martin, 2007, 2012). In most species, eye position is such that each eye sees something different from what is seen by the other eye. Frontal eye placement in humans leaves us with the subjective experience that the world lies in front of us and that we move into it. For most birds, the world surrounds them, and they flow through it. Birds can extract information from a scene receding behind them while simultaneously gaining information from the world into which they are traveling.

At one extreme are the visual fields of some ducks and some shorebirds, which can see the whole of the hemisphere above and around their head (Martin, 2007, 2014). In fact, the only place from which they cannot retrieve information is the part obscured by their own bodies. The utility of such broad visual coverage for the detection of conspecifics and predators has been demonstrated (Guillemain et al., 2002).

Differences in visual field configuration can occur between closely related species suggesting that visual fields can be finely tuned to subtle differences in the perceptual challenges of different foraging tasks. For example, there are significant differences in the visual fields of different species of ibises in the same family (Threskiornithidae) that depend on whether the birds probe their bills into soft substrata or take items from dry surfaces (Martin and Portugal, 2011). There are differences in the visual fields of closely related ducks which have been accounted for by whether the species feeds by selective grazing or filter feeding (Guillemain et al., 2002), and differences among sandpipers (Scolopacidae) which have been accounted for by whether the species employs tactile cues from the bill rather that visual cues when foraging (Martin and Piersma, 2009; Piersma et al., 1998).

These examples indicate that the vision of different bird species, even within the same family, have been subtly tuned by natural selection primarily to the perceptual

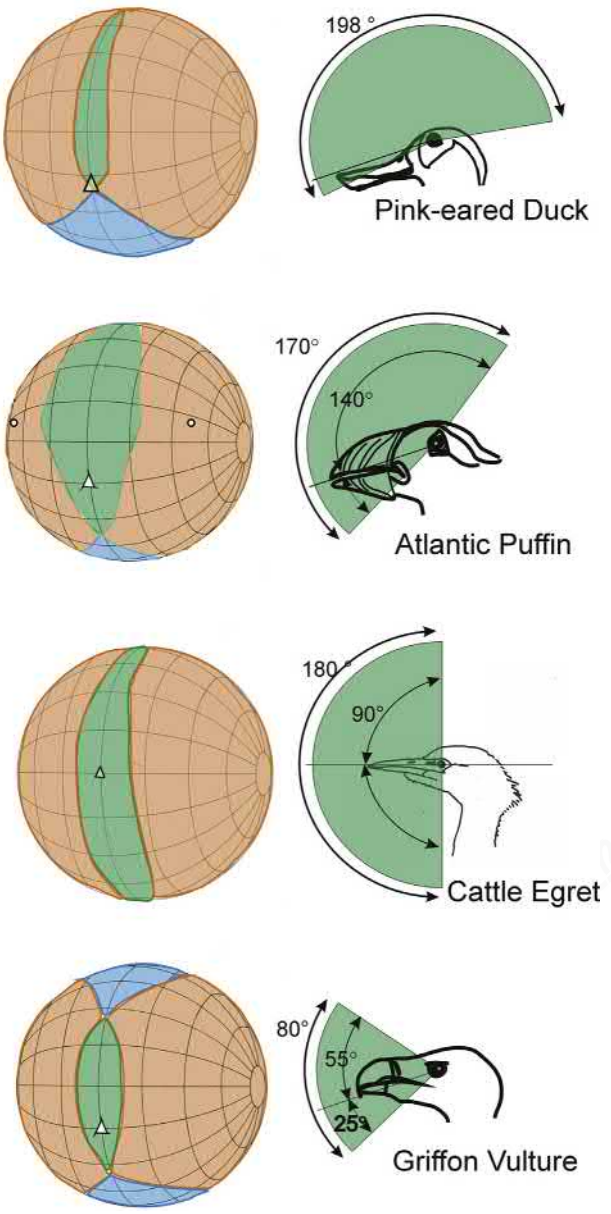

FIGURE 10.9 Diversity in the visual fields of birds. The visual fields of four species are shown with two diagrams for each species. The left hand column shows the visual fields as projected onto the surface of a globe that surrounds the bird's head. This is a perspective view of the head with the bill projecting in the directions indicated by the white triangles. The green sector is the region of binocular overlap, the blue is the blind sector, and the orange sector shows the area covered by each eye alone to the left and right of the head. There are clear differences in the position, width, and vertical extent of the regions of binocular overlap and in the extent of blind regions about the head. The right hand column of diagrams shows the vertical extend of the binocular regions in the median sagittal plane of the head (the plane which divides the head in two vertically). In Pink-eared Ducks *Malacorhynchus membranaceus*, the binocular area extends from the bill through more than 180degrees, hence there is no blind region about the head. In Atlantic Puffins *Fratercula arctica*, the binocular region is broader and oriented upwards but not sufficiently to allow the birds to see fully behind their heads. In Cattle Egrets *Bubulcus ibis*, the binocular region is also long and narrow but is orientated so that the birds can see directly below them in the frontal field and there is a small blind area behind the head. In Griffon Vultures *Gyps fulvus*, the region of binocular overlap is very small in width, and in vertical extent, there is a large blind area above and behind the head. *Drawings by the author based upon originals in (Katzir and Martin, 1994; Martin et al., 2007a, 2012; Martin and Wanless, 2015).*

challenges of particular foraging tasks. It has been argued that such subtle tuning of visual fields should be considered as important as the fine-tuning of bill structures as a means of meeting the physical challenges posed by the exploitation of different foods in these same species (Martin, 2014).

The full range of factors that are considered to play a role in the evolution of visual field configurations in birds have been discussed in some detail (Martin, 2014, 2017b). Data are available on visual field configurations in more than 100 species across a wide range of taxa. It is argued that visual field configurations are driven primarily by two competing informational demands posed by the tasks of foraging and predator detection. The primary demand is for the control of bill position during foraging (or in some predatory species, feet position).

The key requirement, regardless of whether a bird forages by pecking, lunging, or grabbing items with their feet, is the control of direction of travel and the time to contact with a target. As such it is concerned with objects that lie relatively close to the bird, broadly within its frontal field of view. Predator detection requires the detection of objects that are relatively remote from the bird that lie in its lateral or peripheral field of view. Visual field configurations can thus be considered the result of a trade-off between those demands as they occur in different species.

In species with large eyes that have evolved to provide high-acuity vision, a third demand also influences their visual field, avoiding imaging the sun on the retina (Martin and Coetzee, 2004). The image of such a bright light source compromises high-spatial resolution and so these birds, which include eagles, hornbills, bustards, and cranes, have extensive blind regions to the front and above their heads. This can render them vulnerable to collisions when in flight and surveying the land below (Martin and Shaw, 2010).

10.7 Spatial resolution in birds

Spatial resolution in vertebrate eyes is determined by the characteristics of both the image producing and image analyzing mechanisms. To achieve high resolution requires an image that is of high quality, well focused, and large. This requires an optical system which has a long focal length and a large entrance pupil. Pupil size is important since it determines the limit on the quality of the image (Land and Nilsson, 2012). Image size is important since it determines the number of photoreceptors/ganglion cells

over which the image is spread, and hence are available to analyze the image.

The "best" estimate of an animal's spatial resolution is gained by interrogating it, using behavioral training psychophysical techniques. These can be used to determine the limits of visual performance under a range of ambient conditions (Lind et al., 2012; Potier et al., 2016; Reymond, 1985; White et al., 2007). Such investigations are difficult and laborious but they can be substituted using data based upon eye anatomy. This provides an estimate of maximum spatial resolution of an eye but only at high light levels. It requires knowledge of the spatial separation of photoreceptors and/or ganglion cells at their maximum density within the retina. This can be combined with a measure or estimate of the focal length of the eye's optics. The result is an estimate of the maximum resolution of an eye for high contrast stimulus patterns, at high light levels. This anatomical technique has been used to estimate acuity for more than 25 bird species, and behavioral data have been gathered on an equal number of species. Some examples of acuity using behavioral and anatomical techniques are given in Table 10.1. A more comprehensive table of acuity in over 50 species from 25 avian families can be found in (Martin, 2017a).

Crucially, there have been some detailed studies which show that anatomically estimated acuity correlates well with acuity determined at daytime light levels using behavioral psychophysical tests. This was first demonstrated in eagles and falcons (Reymond, 1985, 1987). It should be noted, however, that the anatomical technique

TABLE 10.1 Spatial resolution in a sample of bird species and in young humans.

Order	Family	Species	Spatial resolution cycles/degree	Acuity minutes of arc	Method	Source
Accipitriformes	Accipitridae	Wedge-tailed eagle *Aquila audax*	142	0.2	Anatomy and behavior	Reymond (1985)
Accipitriformes	Accipitridae	Indian vulture *Gyps indicus*	135	0.2	Behavior	Fischer (1969)

Columbiformes	Columbidae	Rock dove *Columba livia*	18	1.7	Behavior	Hodos et al. (1976)
Anseriformes	Anatidae	Canada goose *Branta canadensis*	9.6	3.1	Anatomy	Fernandez-Juricic et al. (2011)
Galliformes	Phasianidae	Red jungle fowl *Gallus gallus*	8.3	3.6	Anatomy	Ehrlich (1981)
Strigiformes	Strigidae	Great horned owl *Bubo virginianus*	7.5	4	Behavior	Fite (1973)
Passeriformes	Passeridae	House sparrow *Passer domesticus*	4.8	6.3	Anatomy	Dolan and Fernandez-Juricic (2010)
Passeriformes	Fringillidae	House finch *Haemorhous mexicanus*	4.7	6.4	Anatomy	Dolan and Fernandez-Juricic (2010)
Suliformes	Phalacrocoracidae	Great cormorant *Phalacrocorax carbo* (underwater)	3.3	9.1	Behavior	White et al. (2007)
		Human	72	0.4	Behavior	Land and Nilsson (2012)

Resolution is shown as both cycles per degree and minutes of arc. The two measures are interchangeable. Older studies tended to use acuity, while more recent studies prefer to express resolution in cycles per degree. All behavioral measures were made at high daytime light levels and indicate the best performance (finest spatial detail that can be resolved)

cannot provide estimates of spatial resolution at lower levels of illumination, when spatial resolution inevitably decreases (Land and Nilsson, 2012). Such decreases in acuity with decreasing light levels have been confirmed using behavioral techniques in a number of bird species including chickens *Gallus gallus* (Gover et al., 2009), doves *Columba livia* (Blough, 1971), wedge-tailed eagles (Reymond, 1985), great horned owls *Bubo virginianus* (Fite, 1973), and barn owls *Tyto alba* (Orlowski et al., 2012).

Table 10.1 illustrates that maximum spatial resolution across bird species can vary over a range of at least 30-fold. The acuity of an eagle is eight times higher than that of a dove, and 18 times that of a chicken. Another way to compare these acuities is that an eagle should be able to detect a given object 8 times further away than a dove, and 18 times further away than a chicken.

It is worth noting that the low acuity of Great Cormorants underwater (Table 10.1) is close to the highest acuity measured underwater in humans without face masks (Gislen et al., 2003), found in children from the Moken people (West coast of Thailand). These children forage underwater guided by vision and although their underwater acuity is high compared to that of Europeans, it is considerably lower than their own acuity in air. Furthermore, the similarity between the underwater acuity of cormorants and this human population indicates that high acuity is not a requirement for successful underwater foraging. In both humans and cormorants, it seems that the relatively poor acuity when immersed is complemented by the employment of specific foraging techniques aimed at particular quarry (White et al., 2007).

As shown in Table 10.1, acuity provides a useful metric with which to compare vision across species. It is also useful to estimate the distances at which high-contrast stimuli can be detected. For example, it is possible to use acuity values to estimate the maximum distance at which typical prey or a carcass could be detected by a foraging predator or scavenger. Acuity data have also been used in a similar way to determine the likely maximum distance at which an obstacle could be detected by a bird. This can also be used to estimate the optimum size and positioning of a pattern designed to function as a warning to a bird that an obstacle, such as a power line, lies ahead (Martin, 2011).

Extrapolations from acuity data to field situations also make it clear that the most conspicuous stimuli are likely to be high contrast (black and white) patterns, rather than colored patterns. Although particular colors may have salience for particular species in the mediation of specific behaviors (Endler et al., 2005, 2014), acuity for colored patterns has been shown to be significantly lower than for black and white patterns. This has been demonstrated recently in Budgerigars *Melopsittacus undulatus* (Lind and Kelber, 2011) and in Harris's Hawks *Parabuteo unicinctus* (Potier et al., 2018). Given the phylogenetic distance between these species and their marked differences in ecology, lower acuity for chromatic stimuli is likely to be a feature of the vision of all bird species, probably a feature of all visual systems. It is well established in humans (Mullen, 1985).

10.8 Contrast sensitivity

Although it is possible to manufacture high-contrast stimuli to act as warnings for birds, natural stimuli are rarely of high contrast. Most avian real-world tasks require the detection of stimuli that of low contrast. The ability to detect stimuli of low contrast is summarized by the determination of a contrast sensitivity function (Ghim and Hodos, 2006). This determines the minimum amount of contrast that can be detected for stripes of different widths when they are presented as gratings of different spatial frequencies. High-contrast gratings of the kind used to determine maximum acuity are one extreme of the contrast sensitivity function. To detect very fine gratings, high contrast is essential, but coarser gratings can be detected at relatively low contrast (Fig. 10.10). A full contrast sensitivity function indicates how wide stripe patterns must be for the smallest difference in contrast to be visible across a range of grating frequencies.

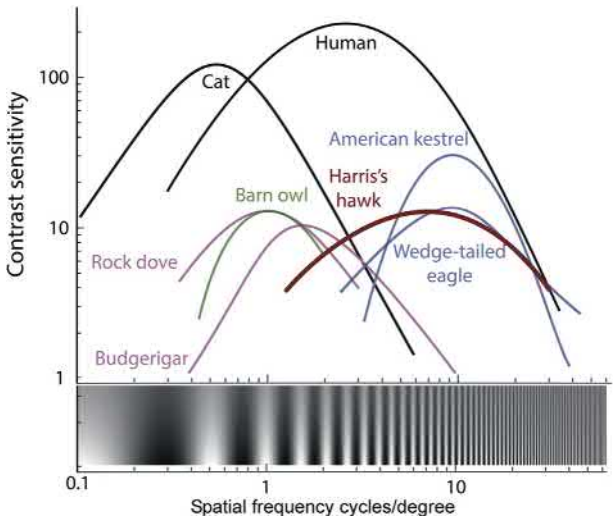

FIGURE 10.10 Contrast sensitivity functions of birds and mammals. At each grating frequency (as indicated across the lower part of the diagram), the contrast of the pattern is varied and the minimum contrast that the bird can detect at that frequency is determined. For each species, there is a range of spatial frequencies in which sensitivity to contrast is high. However, sensitivity drops off rapidly at both higher and lower spatial frequencies. Bird species differ markedly in their sensitivity to contrast, and all birds are much less sensitive to contrast than humans and cats. This means that scenes must have higher degrees of contrast for birds to be able to detect detail within them compared with mammals. *Redrawn from an original figure by Simon Potier of the University of Lund Vision Group.*

Although contrast sensitivity functions are not available for many bird species, they indicate that birds have lower contrast sensitivity compared with mammals, including humans. That is, at a given stripe width, contrast has to be higher in birds than in mammals before it can be detected (Harmening et al., 2007, 2009; Hodos et al., 2002; Lind et al., 2012; Lind and Kelber, 2011).

In all vertebrate species tested to date, contrast sensitivity declines as stripe widths either increase or decrease away from the widths where contrast sensitivity is highest (Fig. 10.10). Thus, there is a middle range of stripe widths where small amounts of contrast differences are relatively easily detected. Most importantly, these studies demonstrate that when stimuli are of low contrast, the optimal size at which they are most likely to be detected is relatively large, much broader than the stripes that are detectable at high contrast. This emphasizes that measures of maximum acuity (of the kind shown in Table 10.1) may have limited application for understanding what spatial information a bird is able to retrieve from within its natural environment.

An illustration of the importance of this is provided by an attempt to use information on how the resolution of Great Cormorants is affected by target contrast. This modeled a "cormorant's eye view" to simulate how a typical prey item would appear at different distances and with different degrees of contrast (Fig. 10.11). The model showed that only at less than 1 m can a fish, of the size typically taken by Great Cormorants, be seen in any detail. Beyond this distance, a prey fish will appear as no more than a faint blur. However, cormorants are able to use this information to forage efficiently by employing specialized foraging behaviors (White et al., 2007).

10.9 Closing remarks

As outlined in the introduction, vision is fundamentally about spatial information, about where light is coming from in the world that surrounds the observer. The remarkable accuracy and precision of vision in birds is built upon finely tuned optics and image analysis mechanisms. Vision in birds is, however, far from uniform. Natural selection has built upon the inherent flexibility of the vertebrate eye's optical system, the flexibility in the way retinal receptors can be arranged, and the flexibility with which eyes can be placed in the skull to give each species a different suite of visual information. There is not one "bird's eye view" but many.

Well-founded comparisons between the vision of different bird species are, however, limited. Only for those species for which there is detailed information on physiology and anatomy of the eyes, or the visual capacities of the whole animal, can reliable comparisons be made. These are but a handful of species compared with the more than 10,000 bird species that exist today.

Even among this handful of species there is wide diversity in the information that their vision provides. Each species appears to have a unique suite of information that guides them in the execution of different tasks in different light environments; from pecking to lunging at food items, from bright sunlight to woodlands at night, from the open skies to below water. It should also be remembered that visual information is complemented by equally diverse sources of information from other senses, and that information provided by vision and other senses are usually used in complementary ways to guide behavior (Martin,

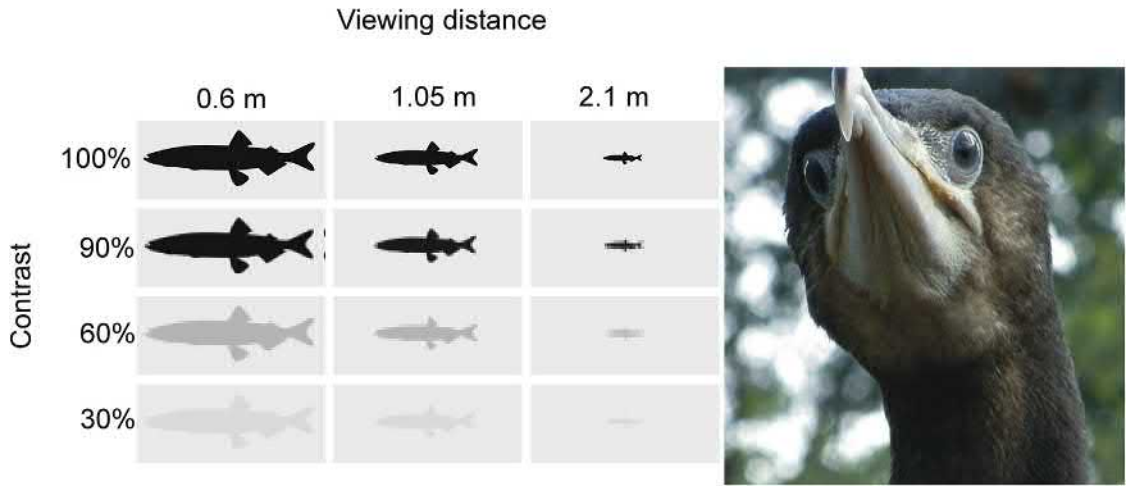

FIGURE 10.11 A simulation of how a fish model might appear to a cormorant at different viewing distance and at different degrees of contrast with the background. The model fish is based upon a 10 cm long Capelin, a species commonly taken by Great Cormorants. The acuity of the cormorant is based upon behavioral measures and assumes the highest acuity of this species underwater. The water is clear, and the light level is 10 lux, which is at the lower end of the daylight range. The simulation shows that apart from the high contrast fish viewed at close range, all target fish will appear quite indistinct. This gives rise to the idea that cormorants will frequently be lunging at an escaping blur when foraging, especially when water is turbid, rather than lunging at a distinct fish shape. *Redrawn from White et al. (2007).*

2017a, 2020). The result of this diversity in sensory information is that while different bird species can share the same environment, they live in different worlds.

Clearly, understanding both the fundamental mechanisms of the eye and visual system, and how these have been elaborated in each species, is vital for understanding the very essence and diversity of birds. While the foundations of our knowledge of avian vision can be considered secure, much remains to be done. Filling in the comparative details, elucidating general principles that explain the diversity of avian vision, and building knowledge of the information that birds extract from the world; these are all fundamental tasks in ornithology.

11.1 Introduction: what do birds hear?

Birds are very vocal. They communicate by a multitude of vocalisations, ranging from simple calls and cries to extremely varied songs, often also beautiful to our ears. Unlike simple calls and like human speech, birdsong must be learned and can serve to recognize other birds individually. Even beyond communication, the sense of hearing has special meaning to many birds. Owls that hunt hidden prey or at night rely on their keen sense of hearing. Some birds use echolocation to find their way in dark caves. However, some myths about the hearing of birds also abound. Perhaps the most notorious is the assertion that they hear ultrasound, that is, frequencies too high for humans to hear. Bird scare devices based on broadcasting ultrasound might scare a lot of mammals but they are inaudible to birds. Although some birds' songs may contain ultrasonic components (e.g., Pytte et al., 2004), they do not hear those themselves. Avian hearing typically remains restricted to below 10 kHz (Fig. 11.1), somewhat lower than human hearing. As a rule of thumb, small birds hear better at high frequencies than larger birds and vice versa (Dooling et al., 2000; Gleich and Langemann, 2011). Some birds, most notably owls, are exquisitely sensitive and able to hear fainter sounds than we can (Fig. 11.1).

In many standard behavioral auditory tests, such as frequency or intensity discrimination, birds do just as well as a typical mammal, including humans (Dooling et al., 2000; Moss and Carr, 2013). On some measures of temporal resolution, especially tasks that require the perception of fast fluctuating fine-structure, birds often outperform mammals (Dooling et al., 2000). Localizing sounds is more of a problem for birds because of their generally small head size which, in combination with their restricted upper hearing range, offers only small interaural cues (Klump, 2000; Köppl, 2009). As a rule, birds can localize sounds in azimuth as well as any mammal of comparable size (Moss and Carr, 2013). However, they cannot localize in elevation. The only exception to this are several owl species, which show extraordinary localization performance and prominent specializations associated with that (Klump, 2000). In more naturalistic auditory tasks, birds have been shown to group complex sounds into perceptual categories and patterns, much like humans do with, e.g., speech syllables (Dooling et al., 2000). Birds also form "auditory objects," that is, they group concurrent sounds in a complex scene into perceptual objects, e.g., different individual birds singing or tonal patterns forming galloping rhythms (Dooling et al., 2000; Moss and Carr, 2013).

Obviously, the auditory world of birds is rich, and hearing plays an important part in their lives. This chapter will summarize the sensory aspects of hearing in birds. How do birds' ears work, and how is sound processed in the brain? It should be pointed out that, although not the focus of this chapter, much of what is discussed below also applies to crocodilians that, together with birds (and a lot of extinct forms), are classified as archosaurs (Carroll, 1988;

Sturkie's Avian Physiology. https://doi.org/10.1016/B978-0-12-819770-7.00029-3

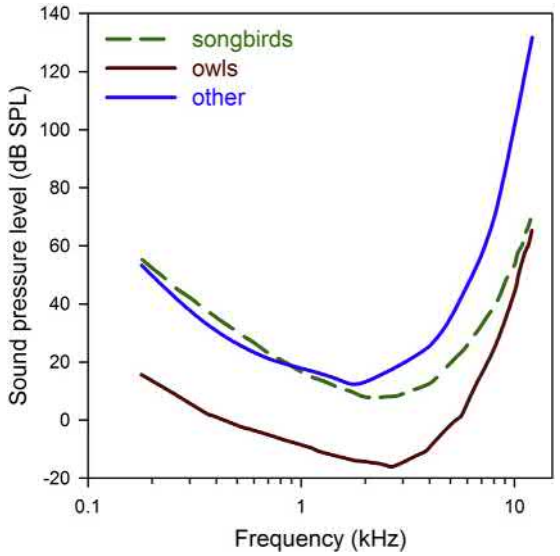

FIGURE 11.1 Median behavioral audiograms for three groups of birds. Note that owls hear sounds below 0 dB SPL, i.e., below the best human thresholds. *Modified Figure 7.1 from Dooling et al. (2000), with kind permission from Springer Science + Business Media B.V.*

Nesbitt, 2011). Like birds, crocodilians are quite vocal, and their auditory system is very similar (Vergne et al., 2009; Young et al., 2013).

11.2 Outer and middle ear

11.2.1 No specialized outer ear structures except in owls

Birds, like all nonmammals, do not have external ears or pinnae. This is easily explained by their generally small body (and consequently head) size in combination with a range of hearing limited to frequencies below about 10 kHz. The mammalian pinna is a sound reflection and filtering device that provides cues about the direction of a sound source relative to the head (Pickles, 2008). For this to be effective, sound wavelength, as a rule of thumb, must be smaller than head diameter, a condition which is generally not met in birds within their limits of hearing. Some very specialized owls, however, exploit similar principles, by bearing asymmetrical outer ears consisting of a facial ruff, skin flaps, and/or even asymmetrical bony ear canals (Norberg, 2002). Effectively, one of the outer ears is pointing slightly upwards, and the other downwards, which differentially reflects frequencies above 4 kHz or so (Keller et al., 1998). If the inputs from both ears are compared, this conveys a sensitivity for sound source elevation (see Section 11.4.2). Remarkably, such asymmetrical outer ears arose several times independently, in different owl genera, as an adaptation to hunting by auditory cues (Norberg, 2002).

11.2.2 The single-ossicle middle ear

Middle ears arose independently in a number of land vertebrate lineages during the Triassic period (Clack and Allin, 2004). In all nonmammalian lineages, the middle ear consists of a simple, piston-like device. It is for the most part homologous with the mammalian stapes (Manley and Sienknecht, 2013). The middle ear of birds consists of an elongate, mostly bony columella that bears a footplate on its medial end that abuts the bony inner-ear capsule. At its peripheral end, the columella grades into the mainly cartilaginous extracolumella that, with one of its several projections, makes close contact to the eardrum (Fig. 11.2). The most important part of the extracolumella is the inferior process, which connects the edge of the eardrum to somewhere close to its center. About half way along its length, the extracolumella is connected almost at a right angle to the columella; the flexible cartilage connection permits the columella to move in a piston-like fashion. Eardrum motion causes the inferior process to tilt on its fulcrum (at the edge of the eardrum), which exerts a force on the columella (Fig. 11.3). The force at the columellar footplate greatly exceeds that of the sound arriving at the eardrum since (a) the columella inserts at (roughly) half the length of the extracolumella and (b) the surface area of the eardrum is much larger than that of the footplate (Saunders et al., 2000). By these means, the middle ear acts

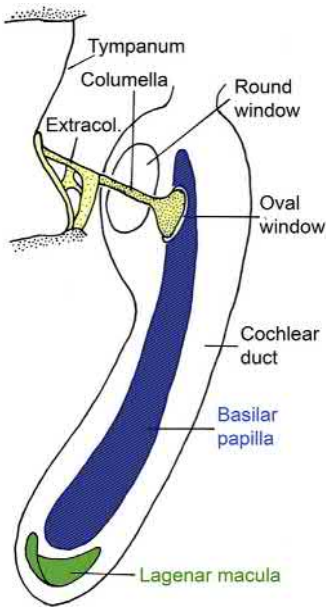

FIGURE 11.2 Schematic drawing of the cochlear duct of a typical bird, and its connection to the eardrum (tympanum) via the columella and extracolumella (yellow) of the middle ear. The dorsal, vestibular part of the inner ear is not shown. Two sensory hair cell organs are located in the cochlear duct: the auditory basilar papilla (blue) and the vestibular lagenar macula (green).

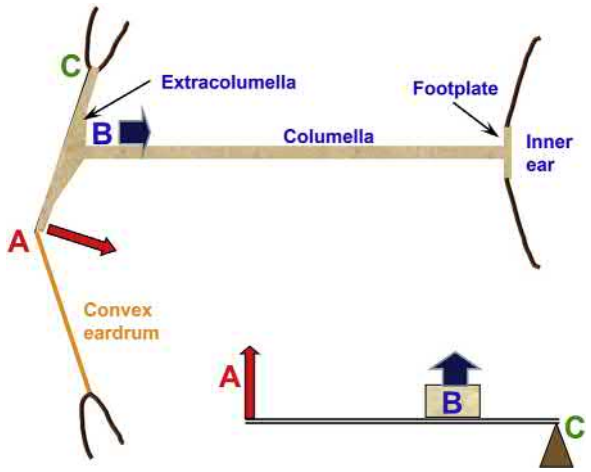

FIGURE 11.3 A schematic diagram of the middle ear of birds and its function. The extracolumella is attached flexibly to the columella, such that movement of the eardrum inwards results in a piston-like movement of the columellar footplate. The illustration at the lower right shows that these structures together build a lever of second order. The arrow length is proportional to the displacement amplitude, the arrow width to the force behind the movement. Thus at point B, the displacement is smaller than at A, but the force proportionately larger. C is the fulcrum, the axis of rotation of the lever.

as an impedance-matching device allowing sound from the low-impedance medium air to very effectively change the pressure in the high-impedance fluids of the inner ear (Fig. 11.3). Without it, the inner ear would be about 40 dB less sensitive (Gummer et al., 1989).

An enigma remains the paratympanic organ, a receptor patch almost exclusively found in birds and crocodiles, situated on the wall of the tympanic cavity (von Bartheld and Gianessi, 2011). It is made up of hair cells that are innervated by the facial nerve. However, its function is unknown. It has been speculated to act as a barometric device.

11.2.3 Internally coupled middle ears

The middle ears of birds are not enclosed in bullae as they are typically in mammals, but are acoustically connected through skull spaces. A prominent part of this connection is formed by wide Eustachian tubes that open into the buccal cavity (Christensen-Dalsgaard, 2011). However, there are very likely multiple routes through the highly trabeculated avian skull that have been difficult to visualize (Larsen et al., 2016). The functional implication of interaural coupling is that the ears function as pressure difference receivers, with sound reaching each eardrum from both sides. Depending on the physical dimensions of the head, the wavelength and the attenuation across the head, significant interactions between the sounds reaching the eardrum from both sides may result in increased directional cues. Although agreed in principle that this helps birds in localizing sound sources, the precise extent to which this happens in different species is still controversial and measurements by different laboratories vary (recent reviews in Christensen-Dalsgaard, 2011; Köppl, 2019; Larsen et al., 2016). Small birds probably experience more of such acoustic cross-talk while larger birds experience less, and limited to lower frequencies. Indeed, in the barn owl, internal coupling of the middle ears appears to play no role in the high-frequency range that the owl uses for prey localization (Calford and Piddington, 1988; Moiseff and Konishi, 1981b).

11.3 Basilar papilla (cochlea)

11.3.1 General morphology and physiology

The inner ear or labyrinth houses both the vestibular organs and the auditory organ, the basilar papilla. The hearing part is commonly referred to as cochlea or cochlear duct, which is correct in the sense that it is homologous to the mammalian cochlea (Manley and Clack, 2004). However, the avian version is not coiled and the term cochlea ("snail") thus not entirely appropriate. The cochlear duct houses the auditory basilar papilla and the vestibular lagenar macula, which forms the apical tip of the labyrinth (Fig. 11.2). This is another salient difference to mammals, which have lost the lagenar macula. In spite of earlier evidence to the contrary, the avian lagenar macula does not respond to sound (Manley et al., 1991) and does not send afferent fibers to the cochlear nuclei (Kaiser and Manley, 1996).

The avian basilar is typically only slightly curved and a few millimeters long; it tapers from being wide near the apical end to narrow at the basal end (Figs. 11.2 and 11.4A) (Gleich and Manley, 2000). It is composed of several thousand sensory hair cells, plus supporting cells surrounding each hair cell in a roughly hexagonal pattern (Fig. 11.4C and D). The epithelium sits on a basilar membrane that is largely suspended over the fluid of scala tympani. At both edges, the structure is anchored to the cartilaginous limbus and at the inner (or neural) edge, a varying proportion of hair cells actually sits atop this solid tissue, not on the basilar membrane (Fig. 11.5). There are two types of hair cells, tall and short (see Section 11.3.2). All hair cells are covered by the tectorial membrane, an acellular, proteinaceous structure (Goodyear and Richardson, 2002). Sound sets the basilar papilla in motion, which ultimately deflects the mechanosensitive bundles of its hair cells through a shear motion between them and the tectorial membrane. However, the precise modes of mechanical excitation in the avian papilla are still unclear. The basilar papilla is tonotopically organized, such that hair cells at apical locations are maximally sensitive to low frequencies, typically down to about 100 Hz, and those at basal locations maximally sensitive

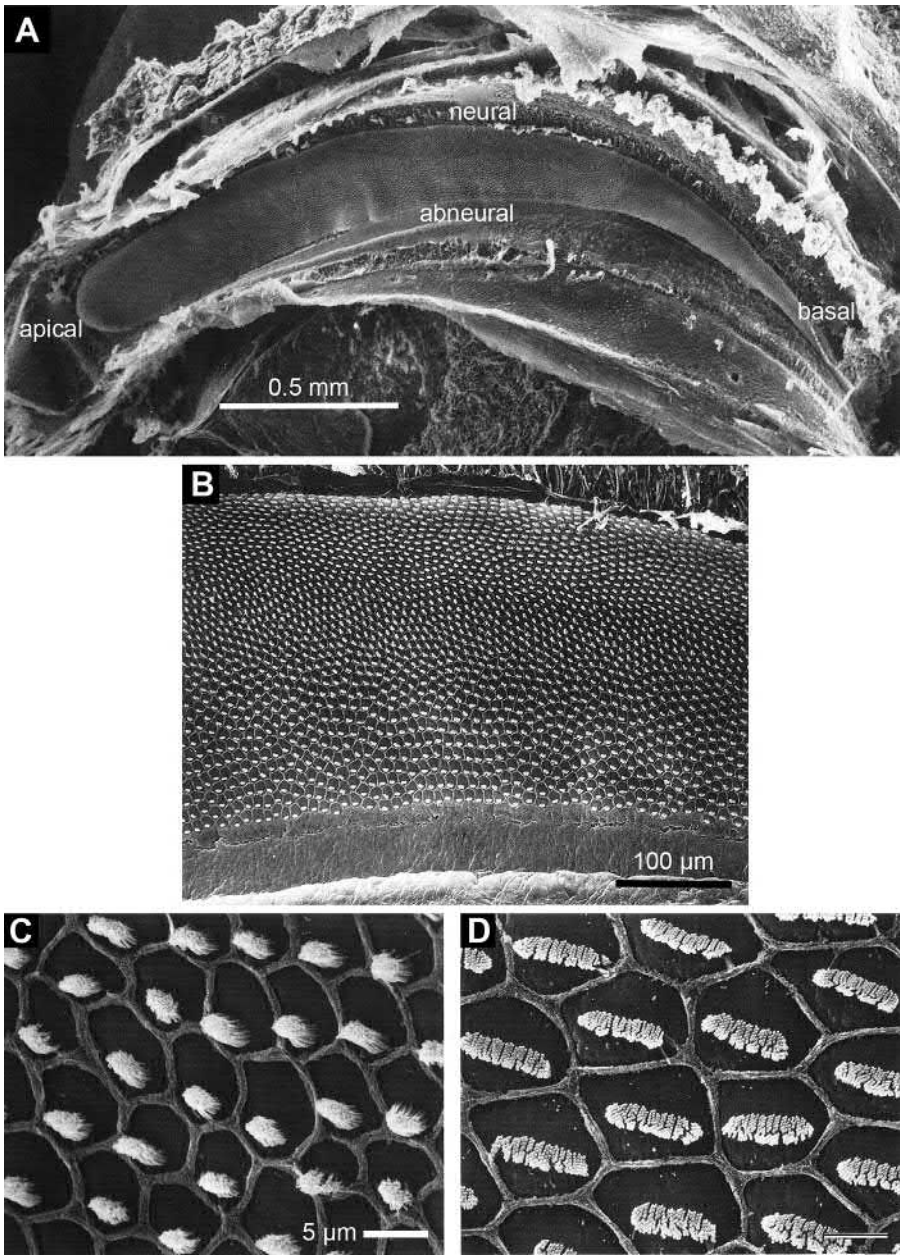

FIGURE 11.4 Surface morphology of the basilar papilla. (A): Low-magnification scanning electron micrograph of the exposed papilla of a chicken, after removal of the overlying tegmentum vasculosum and tectorial membrane. (B): View onto a segment of basilar papilla. Individual hair bundles are identifiable as white structures whose orientation changes across the epithelium. (C, D): High-magnification view onto a small group of hair cells. Note the hexagonal fringe of supporting cells surrounding each hair cell and the mechanosensitive hair bundles composed of tightly packed stereovilli. Note also that hair cells from apical regions (C) have smaller but taller bundles than those from basal regions (D). *Figure 1 from Cotanche et al. (1994), reproduced with kind permission from Springer Science + Business Media.*

to high frequencies, typically 5−8 kHz (Gleich et al., 2004). A traveling wave has been observed at the level of the basilar membrane (Gummer et al., 1987; Xia et al., 2016). However, unlike in the mammalian cochlea, its frequency resolution does not approximate the known selectivity at the neural level. Furthermore, the hair cells conveying the most sensitive responses appear to sit on or at the edge of the solid limbus (Gleich, 1989; Smolders et al., 1995), suggesting that basilar-membrane motion does not directly mediate the hair cells' mechanical stimulation. Hair cells in the avian basilar papilla show a very unique and complex pattern of bundle orientation (Gleich and Manley, 2000, Fig. 11.4B) that has prompted speculation about excitation waves moving obliquely across the tectorial membrane (Tilney et al., 1987), but this remains experimentally untested.

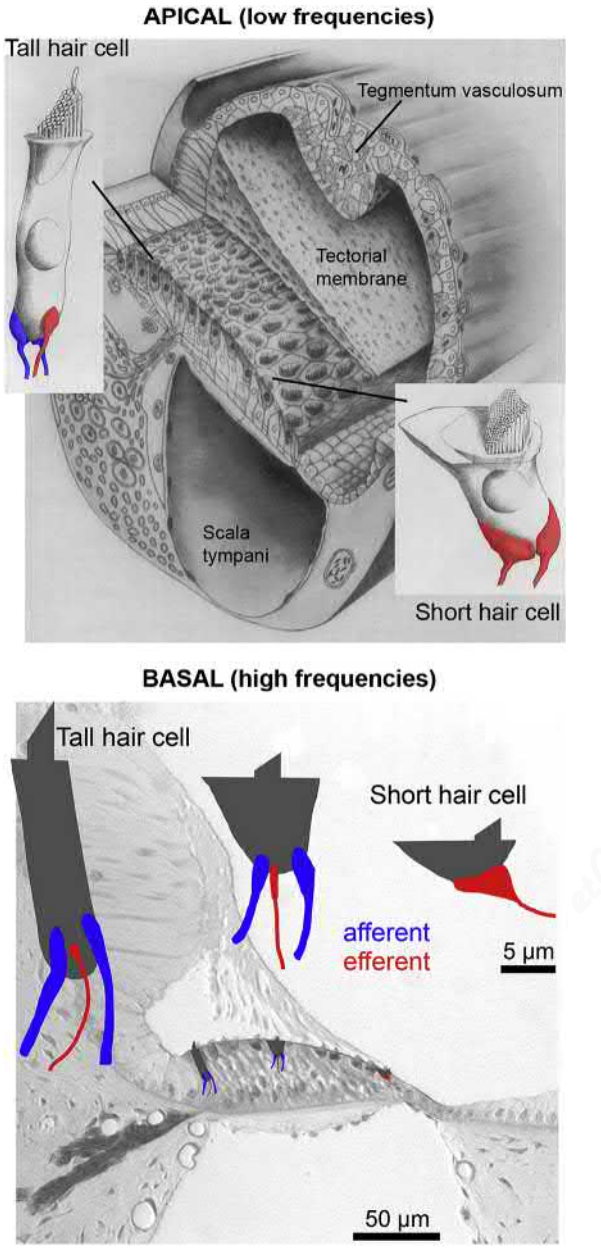

FIGURE 11.5 Overview of basilar papilla morphology and innervation. The top panel shows a three-dimensional (3D) rendering of a typical cross-section through the apical, low-frequency part. The papilla is wide, with many hair cells across, most of which are tall hair cells. Insets are 3D drawings of two representative hair cells, with afferent (blue) and efferent (red) nerve terminals attached. The lower panel shows a light-microscopical cross-section through the basal, high-frequency part, with some hair cells schematically highlighted and also shown enlarged. The lower scale bar applies to the histological image, the upper one to the drawings. The schematic drawings also show the typical innervation pattern, with afferent terminals drawn in blue and efferent terminals in red. *Figure 1 from Takasaka and Smith (1971), reproduced with permission from Academic Press; Figure 7 from Manley and Ladher (2008), reproduced with kind permission from the artist, Johanna Kraus; Figure 1A from Köppl (2011a), reproduced with permission of Elsevier BV.*

Transduction by the hair cells can be assumed to work according to the "gating-spring" principle established in other hair cell systems (Fettiplace and Ricci, 2006). Deflection of the mechanosensitive hair bundle directly modulates the open probability of transduction channels associated with the tip links in the bundle. Opening of the transduction channels leads to the depolarizing influx of cations, chiefly K^+ and Ca^{2+}. The movement of K^+ into the cell is due to the unusual ionic composition and electrical potential in the endolymphatic environment facing the apical surfaces of the hair cells. As is typical for the inner ear of all vertebrates, a high K^+ concentration and low Na^+ concentration, close to intracellular conditions, are maintained in endolymph, together with a slight to moderate, positive potential, the endocochlear potential (reviewed in Köppl et al., 2018). In the cochlear duct of birds, this metabolically demanding task is carried out by the tegmentum vasculosum, the tissue separating scala vestibuli and scala media and thus directly overhanging the basilar papilla (Fig. 11.5). An endocochlear potential of about +15 mV is maintained in avian endolymph (Necker, 1970), much lower than in the mammalian cochlea but higher than in the vestibular parts of the inner ear (Köppl et al., 2018).

Hair bundle morphology varies characteristically along the basilar papilla and thus along the tonotopic gradient. Hair cells at apical locations have relatively tall bundles composed of relatively few stereovilli, while hair cells at basal locations have shorter bundles with many stereovilli (Gleich and Manley, 2000, Fig. 11.4C and D). This morphology is a major determinant of bundle stiffness and, as in all vertebrates, it is believed that this contributes to tune a hair cell's mechanical frequency response. In addition, avian hair cells are electrically tuned to respond preferentially to different frequencies. This is achieved by varying the number and/or kinetics of two principal ion channels in the cell membrane, voltage-gated Ca^{2+} channels and Ca^{2+}-activated K^+ channels (reviewed in Fettiplace, 2020). However, electrical tuning is likely to be less effective or even absent at the highest frequencies (Wu et al., 1995).

One of the most fascinating aspects of hair cell function is the ability for reverse transduction, i.e., the ability to generate mechanical forces and thus to actively amplify low-level stimuli. Active movements of hair bundles have indeed been observed in isolated hair cells in vitro, and it is currently believed that this ability is inherent to the hair cells' transduction mechanism (review in Martin, 2008). In mammalian cochlear outer hair cells, an additional mechanism evolved, conveying somatic motility through the voltage-sensitive protein prestin in the cell membrane (review in Russell, 2013). This appears to dominate amplification in the high-frequency range of several kHz and above in mammals. Hair cells of the avian basilar

papilla have been suggested to represent an intermediate case in which reverse transduction and somatic motility may literally join forces (Beurg et al., 2013). However, this is controversial (Tan et al., 2011; Xia et al., 2016) and much remains to be learned about the precise mechanisms of active amplification in the bird inner ear. Nevertheless, the presence of amplification is undisputed. One of its indirect manifestations is the occurrence of otoacoustic emissions, faint sounds emitted by the inner ear that are believed to be an epiphenomenon of the active processes. Otoacoustic emissions are only measurable under shielded, very quiet laboratory conditions. They may be present spontaneously or can be evoked by a range of stimulation protocols, and have been observed in a wide range of vertebrates, including birds (Bergevin et al., 2015; Engler et al., 2019; Manley and Van Dijk, 2008; Taschenberger and Manley, 1997).

Hair cells are secondary sensory cells, they thus do not form an axon. They are contacted by two basic types of neurones, afferent and efferent to the central nervous system (Fig. 11.5). Afferent neurons have their cells bodies located in a compact ganglion close to the basilar papilla. Their peripheral fibers enter the basilar papilla at its inner or neural edge and contact typically only one hair cell each. The afferent synapses are of the specialized ribbon synapse type, which occurs only in vertebrate hair cells and photoreceptors and in retinal bipolar cells. They are believed to enable high, sustained rates of transmitter release (review in Moser et al., 2020). The central axons of the afferents collectively form the auditory nerve and terminate on the brainstem neurones comprising the cochlear nucleus. A truly unique feature of the avian auditory papilla is that typically 20–25% of the hair cells receive no afferent contacts (see also Section 11.3.2). In contrast, all hair cells receive efferent input from neurons located in the ventral brainstem (review in Köppl, 2011b). The predominant effect of evoked efferent activity on the hair cells is inhibitory. However, very little is known about the behavioral contexts in which efferents are active and, consequently, about their broader role in hearing.

11.3.2 Hair cell types: a remarkable example of evolutionary convergence in birds and mammals

When the ancestors of birds and mammals separated, their common heritage included a dedicated auditory hair cell field, the basilar papilla. This ancestral basilar papilla is likely to have been small, with a uniform hair cell type and sensitive to low frequencies only (Manley and Köppl, 1998). Thus, although the basilar papilla itself is homologous between the groups, its specializations are not. The auditory hair cell types in particular represent remarkable convergent evolutionary developments.

Cross-sections of avian basilar papillae, at first glance, do not show any of the prominent and uniquely mammalian features, such as the tunnel of Corti or the strict arrangement of one row of inner and three rows of outer hair cells. However, looking more closely at the fine structure of the hair cells and especially their innervation, a very salient analogy emerges. Like mammals, birds have two types of hair cells, here called tall and short hair cells. Unlike in mammals, those types are not sharply separated. The extremes are clearly different and well defined, but the two types grade into each other (Gleich and Manley, 2000). Tall hair cells are found on the inner (neural) side of the epithelium and gradually transition into short hair cells toward the outer (abneural) edge (Fig. 11.5). Furthermore, the relative numbers of tall and short hair cells are not fixed in the manner of inner and outer hair cells in mammals, but change along the tonotopic gradient. Basal, high-frequency regions show a predominance of short hair cells and vice versa. Most strikingly, short hair cells receive large efferent terminals but are devoid of afferent innervation (Fischer, 1994a, Fig. 11.5). This may be the only example of a sensory cell entirely losing its primary function. It is even more extreme than the innervation of mammalian outer hair cells, which also receive large efferent terminals but retain a sparse afferent innervation (review in Fettiplace, 2017). Clearly, avian short hair cells are not the principal sensory cells for hearing. The analogy to the mammalian cochlea, in which inner hair cells take most of the classical sensory role and outer hair cells are specialized for mechanical amplification (Dallos, 1996) is palpable. However, much remains to be learned about the assumed amplificatory role of short hair cells, as there is currently little direct evidence for it. Although short hair cells do exhibit bundle motility in vitro, tall hair cells do as well (Beurg et al., 2013), so it remains unclear what the specific role(s) of short hair cells may be.

11.3.3 Hair cell regeneration: birds never lose their hearing

Since human hearing loss often involves damage to and ultimately death of hair cells through noise or ototoxic medication, similar treatments were used on birds in order to find a good preparation to study the underlying phenomena. This led to the remarkable discovery that adult birds are able to regenerate functional hair cells (review in Rubel et al., 2013). It very quickly became apparent that, in contrast to humans, birds did not necessarily suffer permanent hearing loss. Instead, and unexpectedly, hearing thresholds returned to normal or near-normal within a matter of weeks following damage. This discovery initiated an excited search for the underlying cellular and genetic processes. It is now known that after insult and hair cell death, new hair cells are regenerated from the surviving supporting cells, either by rekindled cell division or by

direct transdifferentiation into hair cells (review in Stone and Cotanche, 2007). The regeneration process is extensive and detailed. Specific, local hair cell characteristics such as hair cell shape, bundle shape, and orientation are so well matched to the surviving adjacent areas that it can be difficult to distinguish an undamaged cochlea from a recovered one. In addition, nerve fibers reconnect with the new hair cells, and the overlying tectorial membrane is at least partly replaced (Cotanche, 1999), in total leading to an impressive functional recovery (Ryals et al., 2013; Smolders, 1999). Regeneration reaches its limits, however, if the damage extends over very large areas of the basilar papilla and includes supporting cells (Cotanche, 1999; Smolders, 1999).

Even without severely damaging experience, the avian basilar papilla appears to continuously regenerate hair cells at a low level (Gleich et al., 1997; Ryals and Westbrook, 1990). Thus, there is probably no such thing as age-related hearing loss in birds. Indeed, birds in captivity often reach ages that are multiples of their expected lifetime in the wild, and tests on starlings and barn owls showed that they can still have close-to-normal hearing thresholds at such ripe old ages (Krumm et al., 2017; Langemann et al., 1999). It is not without irony that human breeding of certain races of song birds for their loud songs unknowingly involved these mechanisms. Belgian Waterslager canaries have an inherited high frequency hearing loss and sing a louder and lower-pitched song than normal canaries (Okanoya and Dooling, 1985). In the basilar papilla of those birds, hair cells continuously die at abnormal rates, a process that is incompletely offset by ongoing regeneration of new hair cells (Gleich et al., 1997; Wilkins et al., 2001). Unfortunately, the hope of initiating the same kind of regeneration of hair cells in mammalian cochleae has so far not been fulfilled (Brigande and Heller, 2009; Zheng and Zuo, 2017).

11.3.4 Cochlear specializations: auditory foveae, infrasound hearing

As mentioned above, the basilar papilla is tonotopically organized. Apical regions respond most sensitively to low frequencies, and the characteristic frequency gradually increases toward the basal end. In a typical avian basilar papilla, this tonotopic map is well described by a near-logarithmic function, i.e., each doubling of frequency (equivalent to one octave) corresponds to an approximately equal length of papilla (Fig. 11.6, Gleich et al., 2004). However, there are interesting exceptions to this rule. In analogy to visual foveae, regions of enhanced frequency representation, where some frequencies occupy disproportionally more space along the basilar papilla, have been termed auditory foveae. In birds, the best known example of such an auditory fovea is the barn owl, and a similar case

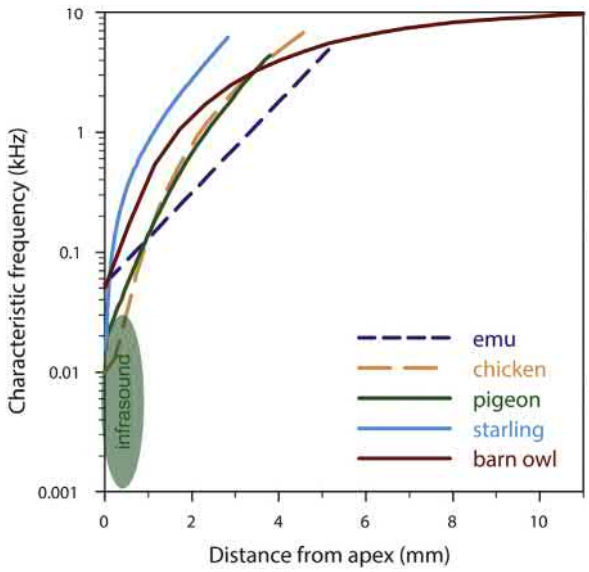

FIGURE 11.6 Tonotopic frequency representation along the avian basilar papilla. The differently colored curves show the mapping functions for several species of birds, as determined from labeling physiologically characterized auditory nerve fibers to reveal their innervation sites in the papilla. Note the exceptional length of the barn owl basilar papilla and the shallow slope of its frequency map over most of its extent, indicating an auditory fovea, i.e., expanded spatial representation of a narrow, high-frequency band. Infrasound sensitivity in the pigeon was found over the most apical mm, but it may not be strictly tonotopic and is therefore represented by the green area. *Data from Chen et al. (1994), Gleich et al. (2004), Köppl et al. (1993), Köppl and Manley (1997), Smolders et al. (1995).*

has been suggested for the kiwi. In the barn owl, the frequencies of the highest octave perceived (5 to 10 kHz) fully occupy the basal half of the basilar papilla (Köppl et al., 1993), as much space as the lower five or six octaves together (Fig. 11.6, red curve). These are the frequencies shown behaviorally to be the most useful for prey localization (Payne, 1971). The anatomical gradients of the owl cochlea, that at least partially determine the frequency response of the hair cells, hardly change along the basal half of the cochlea, concordant with a large expansion of the area processing higher frequencies (Fischer et al., 1988). As a visual fovea is associated with improved acuity, a larger cochlear representation is often assumed to correlate with enhanced frequency resolution. Interestingly, this is not the case in the barn owl (Köppl et al., 1998), suggesting that the role of the fovea instead may be to lay the foundation for massive parallel processing, by increasing the numbers of afferent fibers from this behaviorally important frequency region (Fischer, 1994b; Köppl, 1997b). While there are no physiological data from the ear of the kiwi, studies of hair cell morphology also suggested a foveal expansion of frequency representation in the upper range of kiwi hearing, estimated at 4 to 6 kHz (Corfield et al., 2011).

An equally amazing specialization for extremely low-frequency hearing has been found in pigeons. For some time, it had been known from behavioral experiments that pigeons are sensitive to infrasound, defined as frequencies below those audible to humans, that is < 15 Hz (Kreithen and Quine, 1979). Schermuly and Klinke (1990b) traced the origin of this sensitivity to hair cells located in the extreme apical-abneural regions of the pigeon basilar papilla. The afferent fibers connecting to these hair cells did not respond to normal acoustic frequencies, but showed responses to infrasound at levels comparable to the behavioral thresholds shown previously (Schermuly and Klinke, 1990a). Quite in contrast to the high-frequency foveae discussed above, the infrasound receptive region appears to co-exist, over the most apical 1 mm of the basilar papilla, alongside a conventional logarithmic frequency representation (Fig. 11.6, green) (Smolders et al., 1995). The behavioral significance of infrasound hearing remains unknown. Although it has been suggested that pigeons use it as a navigational cue (Hagstrum, 2000; Kreithen and Quine, 1979), conclusive evidence is lacking. Infrasound sensitivity may be more widespread among birds but remains poorly explored (review in Zeyl et al. 2020). Behavioral sensitivity to infrasound was recently confirmed for chickens (Hill et al., 2014), supporting previous evidence of best response frequencies at least as low as 10 Hz in some neurones in the cochlear nucleus of the chicken (Warchol and Dallos, 1989).

11.3.5 Auditory nerve: what the ear conveys to the brain

All information that the brain receives about the outside acoustic world is encoded in the activity of the auditory nerve fibers. Beginning with Sachs et al. (1974), who recorded single-unit activity in the pigeon auditory nerve, there have been numerous studies on the responses of afferent fibers in various bird species to simple, well-controlled stimuli. Here, I will briefly summarize the encoding of frequency, sound level, and temporal fine structure.

All avian auditory nerve fibers are spontaneously active. Mean spontaneous rates vary between 45 and 90 spikes/s, depending on species, in adult birds (Köppl, 1997a). Unlike in mammals, there is no consistent, strong correlation in birds between spontaneous rate and sensitivity to tonal stimulation, and there is no population of fibers with very low-spontaneous activity (<1 spike/s). Spontaneous activity is irregular, and the interspike interval distribution is typically Poisson-like, modified by the refractory period (Gleich and Manley, 2000; Neubauer et al., 2009). Interestingly, a significant number of fibers show preferred intervals whose period is at or close to their characteristic frequency for tonal stimulation. Although some of this activity for very sensitive fibers may be attributable to inadequate sound shielding during experiments, the bulk of evidence points to this being a genuine phenomenon which reflects spontaneous oscillations of the hair cell membrane potential due to electrical tuning and/or active mechanical amplification processes in the avian cochlea (Gleich and Manley, 2000; Taschenberger and Manley, 1997).

Sound frequency is, of course, collectively coded according to the place principle, where the tonotopic gradient along the basilar papilla is preserved in the projections to the brain. Upon tonal stimulation, each auditory nerve fiber responds most sensitively to one particular frequency, its characteristic frequency. At increasingly lower and higher frequencies, the fiber's sensitivity decreases rapidly, so that its response area forms a narrow, V-shaped frequency tuning curve (Fig. 11.7A). In birds, these curves are very sharply tuned, with higher mean quality factors than mammalian responses at equivalent frequencies, and typically almost symmetrical (Gleich and Manley, 2000). However, the best thresholds of fibers within any narrow range of characteristic frequencies in an individual ear vary in birds more widely than in mammals, by as much as 50 dB (Fig. 11.7B).

Sound level is encoded in the discharge rates of auditory nerve fibers. The dynamic ranges over which individual fibers are able to encode have been studied in depth in response to short tonal stimuli of 50 to 100 ms and vary characteristically. There are: (1) saturating fibers, whose discharge rate rises rapidly above threshold, then also levels off abruptly at a break point, (2) sloping-saturating fibers, whose rate does not show an abrupt saturation but continues to rise more slowly above the break point (Fig. 11.7C), and (3) straight fibers, whose discharge rate slowly rises with a nearly uniform, shallow slope over a broad range of sound levels (Gleich and Manley, 2000; Köppl, 2011a). This shows remarkable parallels to mammals, where the same three types were originally described. However, in contrast to mammals, there are no correlations with other fiber properties in birds. It is believed that in both cases, the discharge behavior of auditory nerve fibers with sound level is shaped by the underlying processes of active amplification, effecting a compressive nonlinearity. However, in birds, the nonlinearity is suggested to develop and vary locally, perhaps at the level of individual hair cells, while in mammals stronger coupling leads to a shared nonlinear response of larger groups of hair cells (Köppl, 2011a). The wide range of thresholds and the different dynamic ranges together ensure that the avian auditory nerve is able to encode a very wide range of sound levels indeed.

Finally, temporal information is encoded by phase locking of auditory nerve fibers, i.e., spikes are discharged preferentially at a specific phase of a sinusoidal or near-sinusoidal stimulus. It is important to point out that a spike need not occur in every cycle of the stimulus

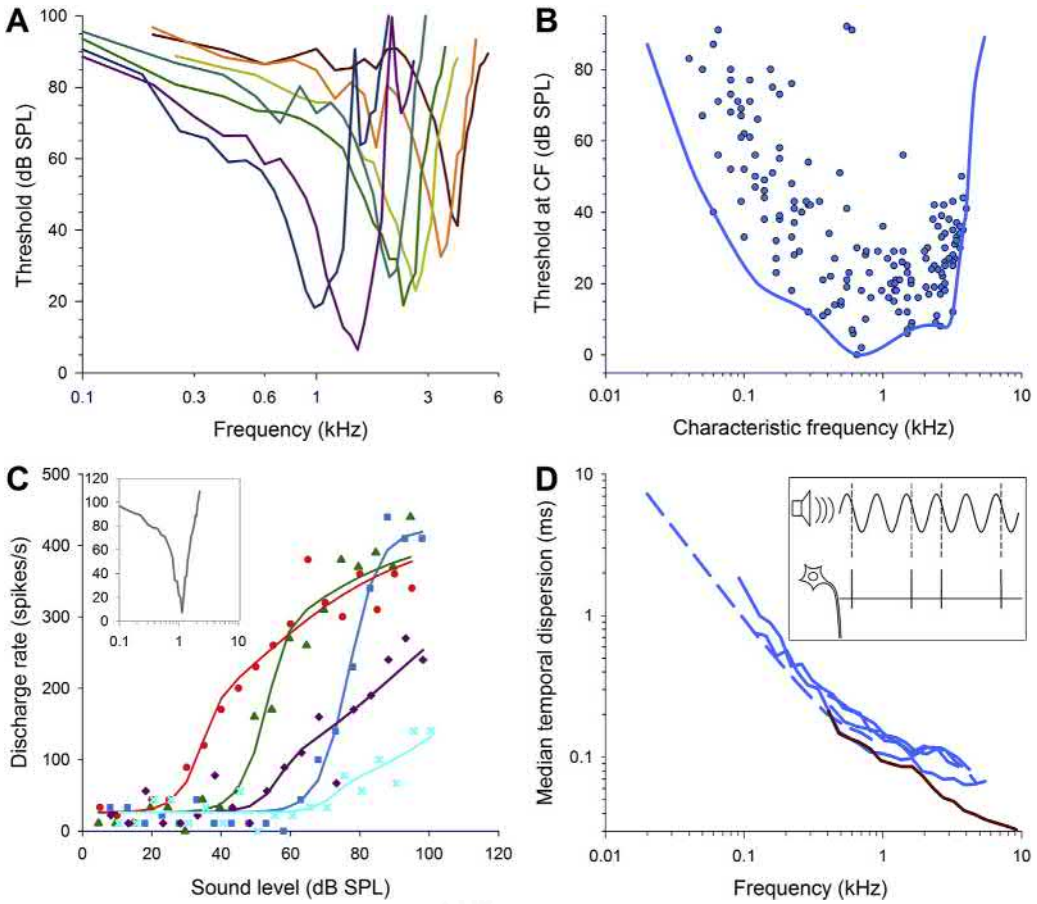

FIGURE 11.7 Salient characteristics of single auditory nerve fiber activity. (A): Examples of frequency tuning curves from the emu (Manley et al., 1997). (B): Distribution of the most sensitive thresholds of a population of fibers from the emu (Manley et al., 1997), as a function of characteristic frequency. Note the large range of thresholds at any one frequency, which is typical and not due to damage. The solid line joins data from the most sensitive fibers, which gives an approximation of the emu's audiogram. (C): Rate-level functions for one particular auditory nerve fiber in the emu, in response to several different frequencies within the fiber's response area shown in the inset. Note the pronounced sloping-saturating behavior at the most sensitive, characteristic frequency (shown in red). (D): The inset illustrates schematically the temporal relationship between a sinusoidal stimulus and phase-locked action potentials. In real auditory nerve fibers, individual spikes vary in their timing around a mean preferred phase. Median values for this temporal jitter or dispersion are shown in the main graph, as a function of frequency, for several bird species: barn owl red (Köppl, 1997c), emu *dashed blue* (Manley et al., 1997), and, all in blue, chicken (Salvi et al., 1992), pigeon (Hill et al., 1989), starling (Gleich and Narins, 1988), redwing blackbird (Sachs et al., 1980). *(C) Data from Yates et al. (2000).*

(Fig. 11.7D inset). Indeed, at frequencies above 300–400 Hz, which is the upper range of sustained discharge rates, many cycles may be skipped but phase locking still persists into the kHz range. Phase locking critically depends on the ability to control spike timing within the temporal window of one stimulus cycle. Thus, the requirement for temporal precision rises with increasing frequency (and shorter cycles), and phase locking invariably fails above a species-specific frequency limit. Avian auditory nerve fibers typically phase lock up to 3–4 kHz (Fig. 11.7D) which compares favorably to other vertebrates, including mammals. A famous exception is the barn owl where phase locking persists to frequencies near 10 kHz, corresponding to a precision of spiking, or temporal jitter, of only 20–30 μs (Fig. 11.7D, red curve) (Köppl, 1997c). Although it remains unknown what cellular mechanisms enable this extraordinary precision, it is clearly an adaptation and prerequisite for the superb sound localization abilities of the barn owl (see Section 11.4.2).

11.4 The auditory brain

11.4.1 Basic organization of auditory pathways

The principal pathways of the avian auditory brain follow a general layout shared by all land vertebrates (Fig. 11.8, Carr et al., 2017; Grothe et al., 2004). The major afferent pathways flow from the cochlear nucleus, either directly or indirectly, through the brainstem areas of the superior olive and lateral lemniscus, to the midbrain inferior colliculus [also termed torus semicircularis, or nucleus mesencephalicus lateralis pars dorsalis (MLd)]. From there,

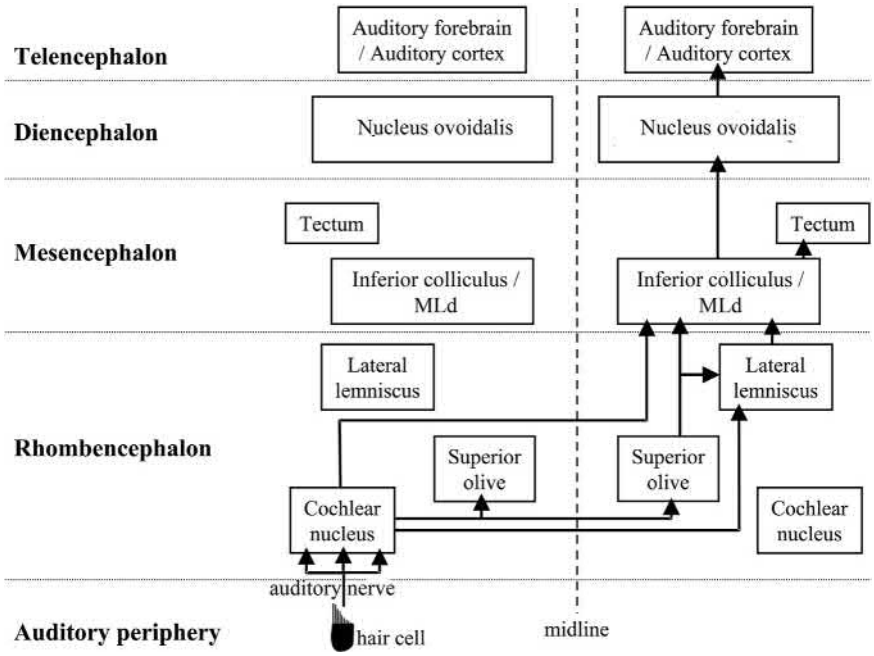

FIGURE 11.8 Principal wiring diagram of the central ascending auditory pathway of birds. Each *box* represents a major center that may contain multiple subareas. *Modified Figure 10.1 from Grothe et al. (2004), with kind permission from Springer Science + Business Media B.V.*

projections go to multimodal layers of the optic tectum (or superior colliculus) and to the auditory thalamus and from the latter on to the auditory forebrain. Beyond this very general pattern, however, the specific nuclei or subdivisions of nuclei can differ substantially between the major vertebrate groups and the evolutionary origin and homology of many auditory areas beyond the broad categories outlined above is quite controversial. In general, differences in the central auditory pathways mirror the major types of basilar papilla specializations and thus are now believed to also be the result of independent evolution (Carr et al., 2017; Grothe et al., 2004). Birds follow an archosaurian pattern that they share with crocodilians; it is also most similar to that of other, more distantly related, "reptiles."

The cochlear nucleus of birds has two major subdivisions, nucleus magnocellularis (NM) and nucleus angularis (NA), both of which receive a shared input by collaterals of each auditory nerve fiber. NM and NA probably form the starting points of several auditory processing streams that specialize in different aspects. NM is the relatively more simple of the two, containing one predominant neuron type that is clearly specialized for preserving or even enhancing the temporal information conveyed through phase locking from the auditory nerve (Carr and Boudreau, 1993; Sullivan and Konishi, 1984). NM is thus the starting point of a "time pathway." The best known function of this time pathway is the extraction of interaural time differences (ITDs) used in sound localization (see Section 11.4.2). NA then appears to be the origin for everything else, although commonly referred to simply as the "intensity pathway," which does not do justice to the complexity already seen at this level. NA contains a range of cell types having distinct anatomical and physiological properties (reviews in Grothe et al., 2004; MacLeod and Carr, 2007). Although cell-specific connection patterns have not yet been investigated, NA neurones collectively have several projection targets in the superior olive and lemniscal nuclei, as well as direct projections to the inferior colliculus. Thus, the potential for different functional processing streams is present. In the barn owl, a specific involvement in deriving interaural level differences (ILDs) for sound localization has been demonstrated (see Section 11.4.2).

While the cochlear nuclei are still strictly monaural, all higher levels show more or less pronounced binaural interaction. A tonotopic organization is, however, retained in the brainstem nuclei. All afferent auditory information then converges again in the midbrain nucleus MLd, which is considered homologous to the mammalian inferior colliculus (Carr and Code, 2000). The definition of MLd subdivisions differs between authors but, in general, a "core and belt"-type organization is recognized and common terms used for those are central and external nucleus, or, abbreviated, ICc and ICx. Brainstem projections terminate in the ICc regions which, in turn, project to ICx. The physiology of the avian auditory midbrain has mostly been studied in the context of sound localization (see Section 11.4.2). In the barn owl, successive processing steps culminate in the formation of a neural map of auditory space in the ICx (review in Konishi, 2003). It is currently

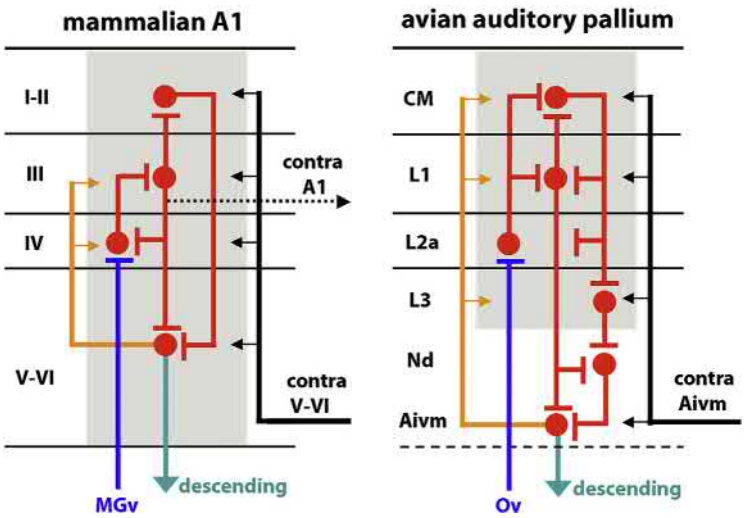

FIGURE 11.9 Suggested analogy in the circuitry between the different layers of mammalian auditory cortex and the principal nuclei of the avian auditory pallium. Thalamic inputs, intrinsic connections, and descending projections are shown in blue, red and turquoise, respectively. *Orange lines* and *arrows* indicate recurrent projections from the deep layers to the more superficial layers. Reentrant projections from the other side of the brain are drawn in black. *Figure 4 from Wang et al. (2010).*

unclear to what extent this generalizes to other birds. In a songbird, the zebra finch, responses of MLd neurones cluster into functional groups that were suggested to represent cues for fundamental acoustic percepts, such as pitch, timbre, and rhythm (Woolley et al., 2009). As a general principle in vertebrates, although a tonotopic representation is maintained in parts of the auditory midbrain, pure tones are often not the most effective stimuli. Instead, selectivity for other, derived sound features, such as location or temporal modulation, begins to predominate.

In parallel to the connections from the ICc to the ICx (and on to the superior colliculus), the ICc also initiates the forebrain ascending auditory pathway, by projecting to the thalamic nucleus ovoidalis (Fig. 11.8, Carr and Code, 2000). The morphology and connections of nucleus ovoidalis are quite well characterized, but its functional role remains unclear and few studies have probed it physiologically (Carr and Code, 2000; Ondracek and Hahnloser, 2013; Proctor and Konishi, 1997). Nucleus ovoidalis projects on to the primary auditory forebrain area in birds. It is important to point out that the nomenclature used in the avian forebrain has seen major revision quite recently, driven by growing evidence that early interpretations of avian forebrain organization had been erroneous and that the classic nomenclature derived from it was seriously misleading (Jarvis et al., 2005). According to the revised nomenclature, the avian auditory forebrain consists of Field L in the caudal nidopallium, the caudal mesopallium (CM), the dorsal nidopallium, and the ventromedial portion of the intermediate arcopallium (Aivm) (Wang et al., 2010). Field L is further divided into subregions with only L2 being the primary, thalamorecipient layer. It has been argued recently that all four avian auditory forebrain areas together form a circuit highly similar in both its columnar and laminar organization to the mammalian auditory cortex (Fig. 11.9, Wang et al., 2010). The physiology of the avian auditory forebrain has been studied most extensively in songbirds (see also Section 11.4.4). Here, a hierarchy of responses is apparent, with a clear tonotopic organization and spectrally defined responses in thalamorecipient neurons, and striking specificities to species-specific vocalisations emerging in higher-order neurons. Also, correlates of perceptual categories of auditory streaming, such as galloping rhythms, have been found in the responses of Field L neurones (Bee and Klump, 2005; Itatani and Klump, 2011). In the barn owl, the forebrain ascending auditory pathway appears to independently generate a second representation of auditory space that resides in the arcopallium. However, the forebrain representation is different in several salient aspects and probably serves different functions to the midbrain topographical map of space (Cohen and Knudsen, 1999; Peña et al., 2019; Vonderschen and Wagner, 2014).

11.4.2 The generation of an auditory space map in the barn owl

Beginning with the classic studies of Roger Payne (1971), who first demonstrated that barn owls use acoustic cues to precisely locate and strike their prey in the dark, many general principles about how the location of sounds in the environment is reconstructed by the brain have been learned from this bird. Unlike vision, the sense of hearing cannot rely on a spatial image of the external world being projected onto the primary receptor surface and relayed to the brain. Sound localization requires central auditory computation, using indirect cues. For birds, these cues are

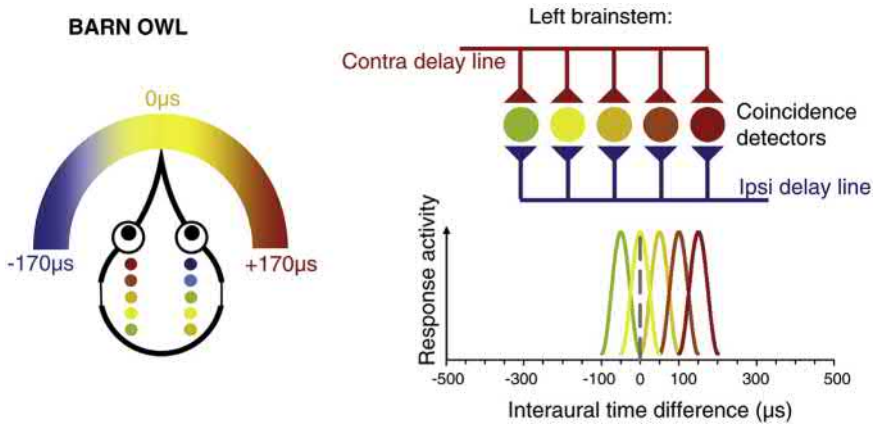

FIGURE 11.10 Schematic illustration of the coding of interaural time differences according to the Jeffress model (1948) and as seen in the barn owl. Each half of the brainstem contains a representation of interaural time differences, corresponding to sound sources mostly in the contralateral acoustic hemifield. This map is created by the basic circuit of delay lines and coincidence detectors illustrated for the left side of the brainstem. Typical responses of barn owl coincidence detector neurones in nucleus laminaris are shown below the circuit diagram, as a function of interaural time difference. Together they cover the interaural time difference range experienced by the owl and form a topographic representation of the auditory azimuth. *Figure 2A from Köppl (2009), reproduced with permission from Cell Press.*

largely binaural in nature, i.e., the inputs from both ears are compared for the minute differences in timing and level that arise from different path lengths of the sound to both ears and from sound shadowing effects of the head and body (Klump, 2000). While for most birds, both ITDs and ILDs are cues for sound source azimuth, the asymmetrical facial ruff of the barn owl (see Section 11.2.1) generates ILDs as a function of sound source elevation. This changes the meaning of ILDs but not necessarily the neural processing steps to derive them. Much of what has been learned from the barn owl is believed to reflect general principles of the neural computation of sound location in birds, if not vertebrates (Aralla et al., 2020; Grothe et al., 2010; Konishi, 2003; Takahashi, 2010). In the barn owl, the binaural comparisons of time and level are carried out in parallel processing streams in brainstem nuclei that are specialized for each task. At the midbrain level, this information is then combined and used to create a "space map," i.e., a two-dimensional (2D) representation of auditory space in azimuth and elevation.

Contrary to intuition, the computation of ITD is not based on a comparison of sound onset at the two ears, but largely relies on ongoing temporal information from neural phase locking in the auditory nerve (see Section 11.3.5). This was shown by clever behavioral experiments with owls wearing headphones that allow for the presentation of stimuli that artificially dissociate onset and ongoing ITDs (Moiseff and Konishi, 1981a). The phase locking of auditory nerve fibers is preserved by the monaural cochlear NM, which then projects to the binaural nucleus laminaris (NL). NL neurones perform arguably one of the most challenging and extreme tasks in the nervous system: they receive the phase-locked inputs from each side and fire selectively if their inputs coincide within a very narrow, submillisecond time window (Funabiki et al., 2011; Kuba, 2007). Of course, such coincidence naturally occurs only when sounds originate directly in front (or back) of the animal. To encode more lateral sound locations, the incoming NM axons contact several NL neurones serially, thus forming functional delay lines that match and compensate for the range of natural acoustic interaural delays (Fig. 11.10). This principle of an array of coincidence detectors, receiving temporal information by delay lines from both sides to create a topographical map of auditory azimuth, was originally formulated by Jeffress (1948). It appears beautifully implemented in the NM-NL circuit of birds in general (Burger and Rubel, 2008; Kubke and Carr, 2006), with the owl displaying a hypertrophied form and achieving the highest temporal resolution (Carr and Boudreau, 1993; Funabiki et al., 2011). The initial topographic map of auditory azimuth is created many times over in NL, separately in each frequency band of the tonotopically organized nucleus (Carr et al., 2015). An important task of subsequent processing steps within the ICc of the midbrain is to converge this information across frequencies and thus remove inherent ambiguities due to the cyclic nature of the phase code underlying it (Konishi, 2003; Singheiser et al., 2012).

The first binaural comparison of sound level occurs in the posterior part of the ventral nucleus of the lateral lemniscus (LLDp, formerly also called VLVp). Here, excitatory inputs from the contralateral ear (coming in via the cochlear nucleus angularis, NA) compete with inhibitory inputs from the ipsilateral ear (coming in via NA and the contralateral LLDp). Depending on the relative strengths of excitation and inhibition, the responses of individual LLDp neurones decrease at different relative levels of ipsi- and contralateral sound, or ILD. Inhibitory

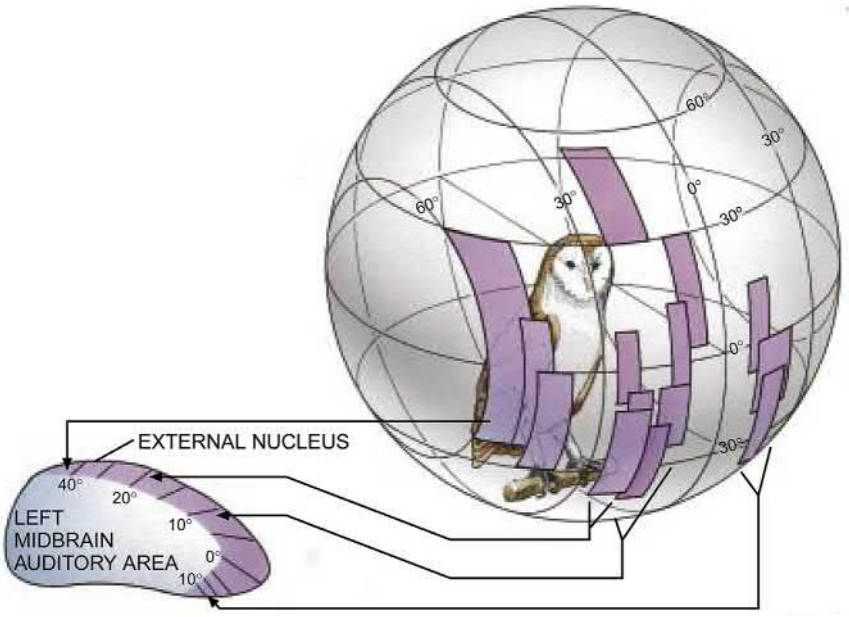

FIGURE 11.11 Auditory space map in the midbrain of barn owls. In the external nucleus of the inferior colliculus (colored purple) the auditory spatial receptive fields of neurones change systematically with position along the nucleus. Some examples of receptive fields are illustrated as purple rectangles on a sphere surrounding the owl. This spatial map is synthesized from auditory responses selective for specific interaural time and level differences. *From Konishi (1993), with kind permission from Jana Brennings.*

strength systematically decreases along the dorsoventral axis of the nucleus, and thus establishes a first topographic representation of ILD (review in Konishi, 2003). At the level of the ICc, the sigmoidal response functions of inputs from LLDp neurones sharpen into bell-like curves only showing responses to a restricted range of ILDs (Konishi, 2003; Singheiser et al., 2012).

Finally, in the ICx, a 2D map of space-specific neurones with receptive fields bounded both in azimuth and elevation is synthesized (Fig. 11.11, Knudsen and Konishi, 1978), where the azimuthal axis is based on the selectivity for ITD and the elevational axis on the selectivity for ILD (Konishi, 2003; Takahashi et al., 2003). At the level of the individual space-specific neurones, both inputs are combined by a multiplicative process that further sharpens their resulting receptive field (Peña and Konishi, 2001). This auditory space map is relayed from ICx to bimodal neurones of the optic tectum (or superior colliculus), forming a combined auditory-visual spatial representation that contributes to stereotypical orienting behaviors (Knudsen, 2002; Peña and Gutfreund, 2014).

11.4.3 Developmental plasticity: auditory space is calibrated by vision

As just outlined, the auditory space representation in the barn owl's midbrain is a computational map generated from indirect cues (ITD and ILD) to sound location. These cues vary with details of head size and shape and are thus to some extent individual (Keller et al., 1998). How does the bird know which ITD and ILD values to associate with precise locations in space? Experiments manipulating the auditory cues of young owls by plugging one ear showed that owls learned, over some weeks, to again precisely localize sounds under these conditions. If instead their visual world was shifted by fitting prism spectacles, it was still the sound localization behavior that slowly adapted to match the changed visual environment (Knudsen, 2002; Peña and Gutfreund, 2014). Thus, owls use vision to learn to associate certain ITDs and ILDs with the correct locations in space. The visual system, with its direct projection map of the retinal image provides the objective spatial representation of the outside world against which the computational map of the auditory system is calibrated. The site of this plasticity has been identified as the ICx, the site where the auditory space map is first synthesized (Fig. 11.12). Additional anatomical connections from the ICc can be induced here whose ITD selectivity matches the corresponding visual receptive field in the optic tectum, and those new connections come to dominate the response of ICx neurones over previously formed, now mismatched inputs (Knudsen, 2002). The required error signal appears to be provided by reciprocal projections from the optic tectum to the ICx, an area traditionally thought to be exclusively auditory. Like many forms of experience-dependent plasticity, this learning of the meaning of auditory cues is limited to young owls and gradually diminishes in early adult life (Knudsen, 2002). Many of the principles

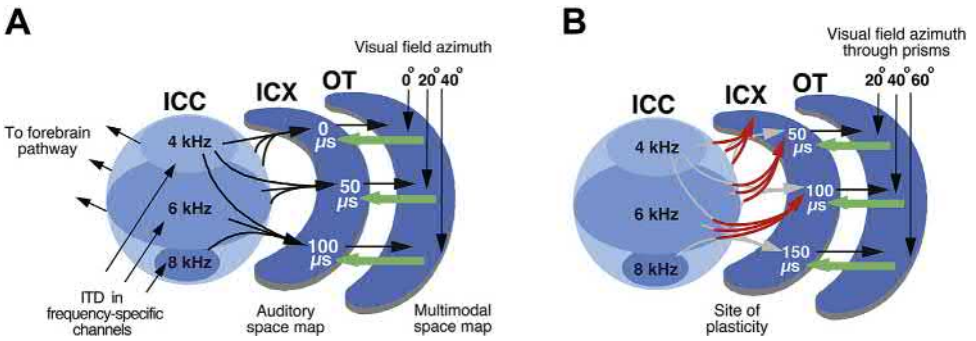

FIGURE 11.12 Schematic summary of adaptive plasticity in the auditory space map of the barn owl, after modified visual experience in early life. (A): Normally, different tonotopic regions from the ICc that share selectivity for a common interaural time difference converge in the ICx. Together, many such convergent projections contribute the azimuthal axis of the space map that is relayed and combined with matching visual receptive fields in the optic tectum (OT). (B): When visual receptive fields are artificially shifted by fitting prims goggles to the owl, the auditory space map shifts accordingly, by forming new and matching connections between ICc and ICx (*red arrows*). *Green arrows* represent an instructive feedback projection from the OT to ICx. *Figure 7 from Knudsen (2002), reprinted by permission from Macmillan Publishers Ltd.*

shown for the learning of auditory localization in the owl also apply to the mammalian auditory system (King et al., 2000; Keating and King, 2015).

11.4.4 The special processing of birdsong

Much of the research on higher-order auditory processing in birds has concentrated on songbirds, for two reasons. First, the behaviorally most relevant acoustic signals are clearly defined and can guide the design of stimuli to test. Second, birdsong is a learned vocalization, a rare trait shared only with human speech and few other avian and mammalian vocalizations (Bolhuis et al., 2010; Jarvis, 2004). Together, this makes the songbird auditory system a rich source for unraveling how vocalisations are processed and learned. Not surprisingly, songbirds have very well-developed auditory forebrain areas (Fig. 11.13A). However, in addition to that, a whole set of sensorimotor "song nuclei" is present, which are involved in vocal learning and plasticity and which have no clear equivalent in vocal nonlearning birds (Fig. 11.13B, review in Farries, 2004). Of central importance is the nucleus HVC, which appears to be the pivotal interface between the auditory input and the motor output for singing. It is also the nucleus where neurogenesis in adult animals was first shown to produce functional neurons, in this case seasonally (Nottebohm, 2004). In HVC, extremely selective auditory responses, not just for species-specific vocalisations but for the individual bird's own song, appear for the first time (Konishi, 2004). HVC is then the starting point of two major motor pathways (Fig. 11.13B): First, a fairly direct, posterior pathway projects to the robust nucleus of the arcopallium (RA) and from there to various brainstem motor nuclei controlling the syrinx and respiration (Farries, 2004). Second, the so-called anterior forebrain pathway eventually also leads to RA but via a whole set of intermediate nuclei that are believed to be homologous to the mammalian basal ganglia (Perkel, 2004). The anterior forebrain pathway has been shown to be critical for song learning in young birds (Brainard, 2004). In addition, there is evidence for an involvement in the plastic control of song, even in species that do not normally learn new songs as adults (Konishi, 2004). Therefore, it is believed that the anterior forebrain pathway, although not strictly necessary to produce song in an adult, continuously monitors what the bird actually sings and initiates corrections when necessary.

The purely auditory ascending forebrain pathway (Fig. 11.13A), which eventually feeds into the specialized sensorimotor song nuclei system, comprises the primary field L and the secondary CM, both shared with other birds, and the secondary NCM (caudal medial nidopallium), an area unique to songbirds. Responses in these auditory areas never show the particular selectivity for the individual bird's own song (Theunissen et al., 2004). However, selectivity for conspecific song arises. As a rule, neurones in the primary auditory area Field L are poorly driven by simple tones or noise but respond selectively to spectrotemporal features that characterize conspecific song and other natural sounds (Theunissen and Shaevitz, 2006). Many individual neurons appear to specialize in either spectral or temporal modulation selectivity and cluster accordingly in specific subregions (Nagel et al., 2011). The secondary auditory forebrain areas NCM and CM may add selectivity for familiar songs versus novel songs and have thus been implicated in auditory memory formation (Ondracek and Hahnloser, 2013; Theunissen and Shaevitz, 2006).

11.4.5 Echolocating birds

Among the fascinating curiosities of the bird world are some species that use echolocation. These are the neotropical oilbird, *Steatornis caripensis*, and the paleotropical swiftlets of the genera *Aerodramus* and *Collocalia*. Both groups have independently evolved echolocation as a

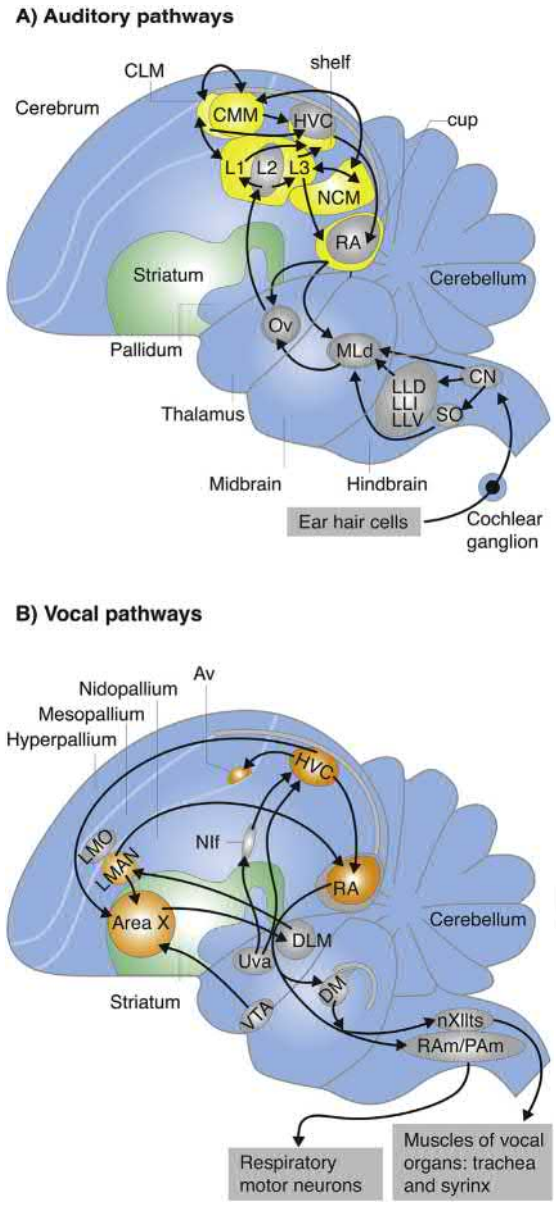

FIGURE 11.13 Schematic diagram of a composite view of parasagittal sections of a songbird brain, giving approximate positions of nuclei and brain regions. (A): Auditory ascending pathways, with brain regions that show increased neuronal activation when the bird hears song highlighted in yellow. (B): Vocal motor pathways. Depicted are connections between the nuclei, of both the direct posterior pathway and the anterior forebrain pathway. Both pathways together form the so-called song system. The orange nuclei in the song system show substantially enhanced neuronal activation when the bird itself is singing. Area X, Area X of the striatum; *Av*, avalanche; *CLM*, caudo-lateral mesopallium; *CN*, cochlear nucleus; *DLM*, medial subdivision of the dorsolateral nucleus of the anterior thalamus; *DM*, dorsomedial subdivision of nucleus intercollicularis of the mesencephalon; *HVC*, a letter-based name; *L1*, *L2*, and *L3* are subdivisions of Field L; *LLD*, lateral lemniscus, dorsal nucleus; *LLI*, lateral lemniscus, intermediate nucleus; *LLV*, lateral lemniscus, ventral nucleus; *LMAN*, lateral magnocellular nucleus of the anterior nidopallium; *LMO*, lateral oval nucleus of the mesopallium; *MLd*, dorsal part of the lateral nucleus of the mesencephalon; *NIf*, interfacial nucleus of the nidopallium; *nXIIts*, tracheosyringeal portion of the nucleus hypoglossus (nucleus XII); *Ov*, nucleus ovoidalis; *PAm*, nucleus paraambiguus medullaris; *RA*, robust nucleus of the arcopallium; *RAm*, nucleus retroambiguus medullaris; *SO*, superior olive; *Uva*, nucleus uvaeformis; *VTA*, ventral tegmental area. *Figure 1 from Moorman et al. means of navigating in the dark caves where they roost and nest (review in Brinkløv et al., 2013). This lifestyle has many superficial similarities with bats. However, the birds' echolocation calls are not ultrasonic but fall well within the typical avian hearing range. Due to this lower frequency range of the calls, avian echolocation cannot approach the spatial resolution of bat ultrasonic navigation, but few rigorous tests have been conducted (Griffin and Thompson, 1982; Konishi and Knudsen, 1979). Furthermore, the birds were reported to use echolocation only under conditions where they were unable to navigate by vision (Griffin, 1953; Novick, 1959), although anecdotal observations of foraging birds suggest this may be worth re-examining (Brinkløv et al., 2013).

Both the oilbird and the cave swiftlets use brief clicks that are produced by the syrinx (Suthers and Hector, 1982, 1985) and typically emitted in pairs or short trains (Konishi and Knudsen, 1979; Thomassen and Povel, 2006). The dominant frequencies in the clicks are in the range of several kHz and appear to match the birds' sensitive hearing range. However, due to their remote geographical distributions, very few species and individuals have been tested. From the studies available, it appears that the hearing capabilities of echolocating birds are unremarkable (Coles et al., 1987; Konishi and Knudsen, 1979). Anatomical data on the relative size of the auditory midbrain suggest a slight enlargement, which may indicate moderate specializations for echolocation processing (Cobb, 1968; Iwaniuk et al., 2006).

11.5 Summary

The sense of hearing has special meaning to many birds, be it for communication, hunting, or orienting in the dark. Avian hearing typically remains restricted to below 10 kHz, somewhat lower than human hearing and much lower than in a typical mammal. However, within that range, avian hearing is just as sensitive and discriminative. Important insights into auditory physiology have come from studies on birds, such as the mechanisms of regeneration of sensory hair cells after damage, the neural computations underlying sound localization or the neural processing, and learning of vocalizations. Some fascinating auditory specializations in birds are infrasound hearing in pigeons, asymmetric ears in owls, and echolocation in oilbirds and swiftlets.

Chapter 12

Chemesthesis and olfaction

Larry Clark[1] and Cynthia A. Smeraski[2]
[1]METIS, Ltd., Fort Collins, CO, United States; [2]Science Education and Literacy Foundational Program, Fort Collins, CO, United States

12.1 Chemical senses

The chemical senses generally fall into three categories: (1) chemesthesis (irritation and pain), (2) olfaction (smell), and (3) gustation (taste). Traditional emphasis in describing responsiveness to chemical stimuli has been placed on taste and smell. The reality is more complex. For example, the sensory afferents for chemesthetic perception are in close proximity with olfactory receptors in the nasal cavity and with gustatory receptors in the oral cavity. Because external chemical stimuli can be processed by multiple sensory systems, there has been a great deal of confusion in the behavioral and ecological literature on the importance of individual sensory modalities. Generally, the principal mediating sensory modality may be related to stimulus type, concentration, and presentation (i.e., nose, eyes, mouth). However, when perception of external chemical stimuli occurs across modalities, the combined perceptual quality is commonly referred to as flavor, which is a reflection of the cognitive integration of all inputs.

Early studies of bird chemosensory systems were descriptive from a neuroanatomical, physiological, and behavioral perspective. As methodologies have expanded, insights into behavioral and physiological mechanisms have been augmented with genomic and molecular studies. The later have formed the basis of most avian chemesthetic studies over the past 15 years. We follow this general pattern of organization in this chapter, realizing that from an information processing perspective at the animal systems and ecological levels, chemical signals may be simultaneously processed by multiple sensory systems and be further integrated with other sensory inputs before the bird behaviorally responds. Gustation is covered separately in this volume.

12.2 Chemesthesis

Nociception is the detection of potential or actual harmful stimuli (Julius, 2013). Nociceptors have three functions: (1) detection of endogenous inflammatory stimuli which is useful in initiating and promoting behaviors conducive to healing and repair, (2) detection of potentially damaging external noxious stimuli which is useful in warning an animal to the risk of injury, and (3) detection of neural damage and ectopic firing. This later function is a pathological condition of chronic pain. Nociceptors have high thresholds for exogenous stimuli presumably because it would be maladaptive to defensively respond to every external assault. Nociceptors also have low thresholds for endogenous stimuli. This is an adaptive response to promote healing once tissue damage has occurred (Patapoutian et al., 2009).

Chemesthesis is a subcategory of nociception and is the perception of chemically induced irritation. Examples of other nociceptive stimuli are temperature and pressure and are covered elsewhere in this volume. Generally, chemesthetic stimuli result in reflexive withdraw by the animal and does not require learning for the defensive action. In contrast, prolonged postingestional discomfort, malaise, or illness may involve chemosensory and other sensory systems and set up conditions for learned avoidance (Clark and Avery, 2013). Pain is the perception and integration of processes involved in nociception, malaise, or illness that result in behavior modifications by the animal (Sneddon et al., 2014).

Interest in chemesthetic function and properties in birds has largely been focused in four areas: (1) the evolutionary phylogenetic relationships of receptor mediated perception of noxious stimuli and its consequence to the foraging ecology of birds (Clark, 1998a; Saito and Tominaga, 2015); (2) the applicability of using aversive compounds in modulating feeding behavior of birds to develop repellents for prevention of crop damage or otherwise mitigating against damage caused by birds (Mason and Clark, 1997); (3) promotion of animal welfare in domestic poultry production (Kuenzel, 2007; Gentle, 2011); and (4) to gain a better understanding of pathologic pain and for the development of appropriate analgesics (Julius, 2013; Szolcsanyi, 2014).

12.3 Neural organization

The perception of noxious stimuli begins with activation of primary sensory nociceptors (Woolf and Ma, 2007). The primary sensory neurons are the interface between the internal and external environments. Nociceptors have cell bodies located in the dorsal root ganglion, a peripheral axon that innervates tissues, and a central axon that enters the spinal cord to transfer information to the central nervous system (Figure 12.1). Many nociceptive neurons respond to multiple stimuli (e.g., thermal and chemical). These are referred to as polymodal nociceptors.

A major component for the mediation of chemical nociception is the trigeminal nerve (TN). The TN is the principal somatic sensory nerve of the head, and its primary function is the coding of mechanical and thermal stimuli. However, the TN also contains chemoreceptive fibers that mediate the detection of chemical irritants (Silver and Maruniak, 1980). The somatosensory nerves are the primary somatic sensory system of the rest of the body. Like the TN, the somatosensory nerves in birds primarily code for mechanical and thermal stimuli, but they do have sensory afferents that are chemosensory (Gentle, 2011; Wild, 1985). Aspects of the avian TN neural architecture related to navigation and mechanoreception are reviewed elsewhere (Kishkinev and Chernetsov, 2014; Schneider et al., 2017; Wiltschko and Wiltschko, 2019).

In birds, chemosensitive fibers in the TN and somatosensory nerves are similar to mammalian afferents. Most are unmyelinated C-type polymodal nociceptors with conduction velocities of 0.3−1 m/s. However, some myelinated A-delta high-threshold mechanoreceptors with

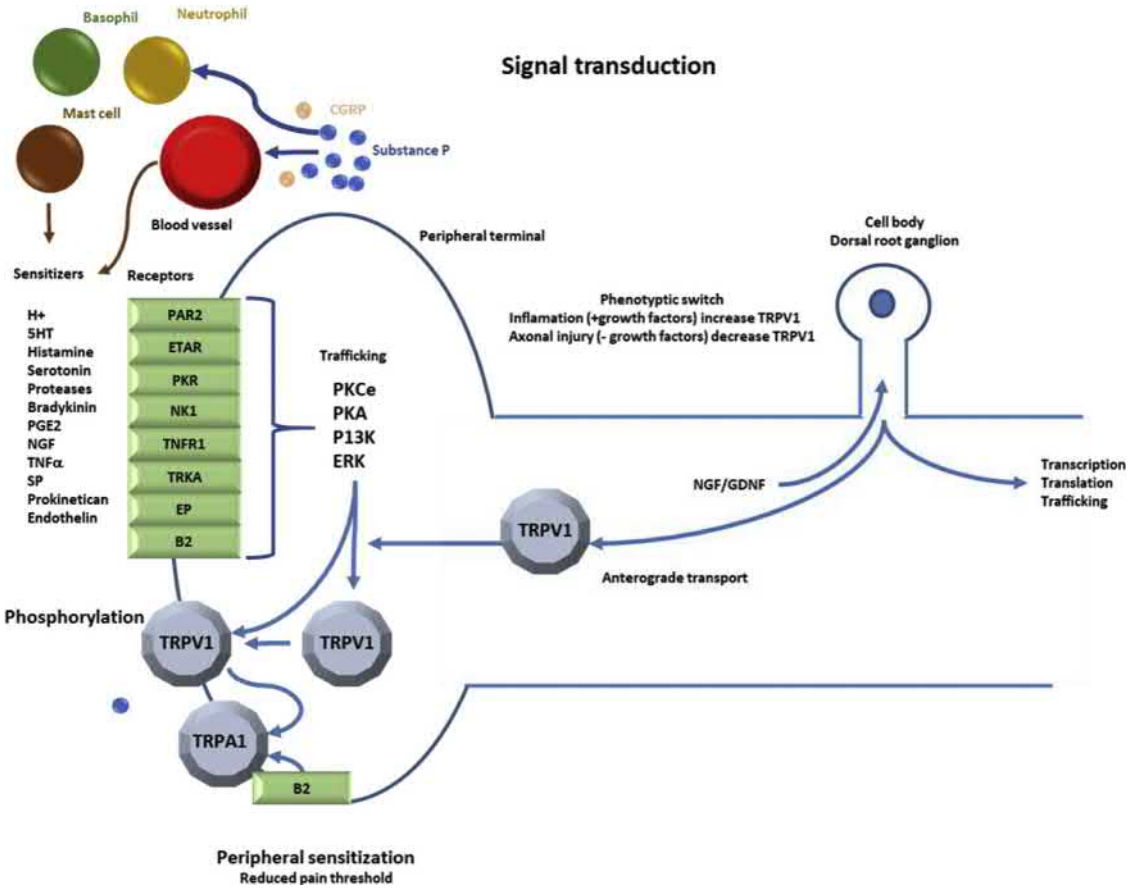

FIGURE 12.1 Sensitization and activation of primary afferent nociceptor. Nociceptors not only transmit peripheral signals but may also affect vasodilation and other responses from nearby cells, initiating a variety of local signaling (neurogenic inflammation), which enhances sensitivity to exogenous and mechanical stimuli. These endogenous sensitizers act on receptors expressed by nociceptors to activate intracellular signal transduction pathways that alter trafficking to the membrane, thresholds, and kinetics. Growth factors, e.g., nerve growth factor, are retrogradely transported to the cell body of the nociceptors. Through intracellular signaling pathways, expression of TRP channels is increased and they are transported to the peripheral terminal. Changes in transcription and translation of TRP channels and other proteins can switch the chemical phenotype of the neurons from their state in naive conditions to an altered state during inflammation. *B2*, bradykinin receptor; *ERK*, extracellular signal-regulated kinase; *ETAR*, endothelin receptor type A; *GDNF*, glial-cell-derived neurotrophic factor; *NK1*, neurokinin receptor 1; *PAR2*, protease-activated receptor 2; *PGE2*, prostaglandin E2; *PI3K*, phosphoinositide 3-kinase; *PK*, protein kinase; *PKR*, prokineticin receptor; *TNFα*, tumor necrosis factor α; *TNFR1*, TNF receptor 1; *TRKA*, tyrosine kinase receptor A. *Adapted from Patapoutian et al. (2009) and Julius (2013).*

conduction velocities of 5−40 m/s also respond to chemical stimuli. The discharge patterns and conduction velocities for the chicken, mallard (*Anas platyrhynchos*), and pigeon (*Columba livia*) are similar to those observed in mammals (Necker, 1974; Gentle, 1989).

The morphological organization of the peripheral TN in birds is similar to mammals (Dubbeldam and Karten, 1978; Dubbeldam and Veenman, 1978; Gottschaldt, 1985; Douglas and Paul Murphy, 2017; Faunes and Wild, 2017). The TN is the VIth cranial nerve in birds, arising from the rostrolateral medulla near the caudal surface of the optic lobe (Getty, 1975; Schrader, 1970).The TN travels along the trochlear nerve (IV), entering a fossa in the floor of the cranial cavity where the trigeminal ganglion (TG) is found. The TG is subdivided into a smaller medial ophthalmic region and a larger lateral maxillomandibular region from which the nerve splits into three branches. In the chicken (*Gallus gallus domesticus*), the ophthalmic branch innervates the frontal region, the eyeball, upper eyelid, conjunctiva, glands in the orbit, the rostrodorsal part of the nasal cavity, and the tip of the upper jaw. The ophthalmic branch as a communicating ramus with the trochlear nerve serves for motor control of the eye region. This aspect can provide for reflexive response to irritating stimuli to the ocular region. The larger medial ramus accompanies the olfactory nerve into the nasal fossa via the medial orbitonasal foramen. The maxillary branch provides sensory input from the integument of the crown, temporal region, rostral part of the external ear, upper and lower eyelids, the region between the nostrils and eye, conjunctival mucosa, the mucosal part of the palate, and the floor of the medial wall of the nasal cavity. The mandibular branch provides sensory input from the skin and rhamphotheca of the lower jaw, intermandibular skin, wattles, oral mucosa of rostral floor of the mouth, and the palate near the angle of the mouth (Getty, 1975; Schrader, 1970).

12.3.1 Peptides involved in pain perception

Though birds have slightly different neural architecture relative to mammals, the underlying functions of neural connections have been evolutionarily preserved (Butler and Cotterill, 2006; Dugas-Ford et al., 2012; Güntürkün, 2012). This also applies to the underlying physiological and biochemical processes of chemically induced pain. Generally, birds have the same classes of neuropeptides as mammals that serve similar functions, but their structures are not 100% homologous. Avian endogenous pain-promoting substances such as substance P, 5-HT, histamine, bradykinin, and acetylcholine evoke inflammation and pain-related behaviors in chickens, pigeons, rats, dogs, and guinea pigs (Figure 12.1; Szolcsanyi et al., 1986; Gentle and Hill, 1987; Gentle and Hunter, 1993; Koda et al., 1996; Hu et al., 2002; Ohta et al., 2006). In *Coturnix* quail, aromatase neurons were associated with the neurokinin 1 receptor and in is proximity to substance P-immunoreactive fibers, suggestive that aromatase neurons may participate in the control of nociception as well (Evrard et al., 2003). Prostaglandins that modulate the pain response in mammals also serve this function in birds, and their effects can be abolished by prostaglandin biosynthase inhibitors such as aspirin-like analgesics (Clark, 1995). Despite these physiologically mediated similarities, there are differences in how birds and mammals respond to some exogenous chemical stimuli. In mammals, chemicals such as capsaicin are potent trigeminal irritants. These irritants deplete substance P from afferent terminals and the dorsal root ganglion, producing an initial sensitization followed by desensitization to further chemical stimulation (Szolcsanyi, 1982). In contrast, birds are behaviorally insensitive to capsaicin (Mason and Maruniak, 1983). Peripheral presentation of capsaicin to pigeons and chickens does not cause release of substance P in avian sensory afferents (Pierau et al., 1986; Szolcsanyi et al., 1986; Sann et al., 1987). These taxon-specific responses to exogenous chemical stimuli underscore taxonomic differences in both endogenous neuropeptides and receptors whose significance has been implicated in the evolutionary ecology of the taxa (Mason et al., 1991).

12.3.2 Responses to chemicals

Birds consuming experimental solutions demonstrate an ability to detect acids, and their responses vary depending upon the acid and its concentration (Kare, 1954; Berkhoudt, 1985). Most birds are tolerant of acetic acid and hydrochloric acid (Rensch and Neunzig, 1925; Kare and Rogers, 1976). However, chickens, *Gallus domesticus,* may only experience weak pain from acid stimulation. The relative weak response of the chicken TRPV1 (cTRPV1) receptor as compared to the mouse TRPV1 (mTRPV1) appears to be related to differences at the C-terminal CaM binding site (Liang et al., 2019). This weak receptor response is consistent with the behavioral observations indicating chickens only experience mild discomfort or pain to acid stimulation.

Exposure to noxious vapors also evokes responses in birds. Ammonia gas, acetic acid vapor, and carbon dioxide administered to oral and nasal cavities evoke neural and behavioral responses in the chicken (Soudek, 1929; McKeegan, 2004). Changes in carbon dioxide concentration in the nasopharynx region can cause species-specific changes in reflexive breathing in birds (Hiestand and Randall, 1941). However, concentrations of carbon dioxide that are sufficiently high to be irritating to mammals have no effect on blood pressure, heart rate, tidal volume, breathing frequency, upper airway resistance, or lower airway resistance in geese and chickens. This is consistent

with the relative acid insensitivity of the cTRPV1 receptor (Liang et al., 2019). Geese and chickens respond differently than mammals to exposure to sulfur dioxide, but in a similar manner when exposed to ammonia and phenyl diguanide (Callanan et al., 1974; McKeegan et al., 2005).

Many aromatic molecules are aversive to birds when ingested orally (Kare, 1961; Mason et al., 1989; Crocker and Perry, 1990; Clark and Shah, 1991, 1993; Crocker et al., 1993). Direct contact with receptors through solution may occur or odor volatiles may diffuse into the epithelium and act through TN nociceptors in the mouth, or through retronasal stimulation of TN nociceptors in the olfactory cavity (Tucker, 1971; Silver and Maruniak, 1980; Keverne et al., 1986). Electrophysiological evidence shows that the TN responds to odors albeit generally with less sensitivity than the olfactory nerve (Tucker, 1963). Behavioral assays yield similar results. Pigeons trained to respond to odors fail to respond after olfactory nerve transections. However, odor responding can be reinstated if the odor concentration is increased (Michelsen, 1959; Henton, 1969; Henton et al., 1966). Odor sensitivity of pigeons decreased by two to four log units (vapor saturation) after olfactory nerve transaction (Walker et al., 1979). In European starlings, avoidance of anthranilate compounds was partially a consequence of olfactory cues. When the olfactory nerves were transected, avoidance was only mildly diminished. When the ophthalmic branches of the TN were transected, the starlings became insensitive to the aversive properties of the anthranilates (Mason et al., 1989; Clark, 1996). Thus, caution must be exercised in categorizing volatile chemicals as being mediated through olfactory or chemesthetic systems. A vapor could be mediated by both systems, with the primary effect being determined by concentration.

Several lines of evidence suggest that a variety of chemicals have intrinsic properties that cause them to be aversive on a purely chemesthetic sensory basis. First the aversive quality is unlearned, that is, avoidance occurs upon initial contact. Second, there is no evidence that consumption is altered by gastrointestinal feedback, i.e., intake of fluid treated with those sensory stimuli is constant over time. Third, unlike mammals, birds seem unable to associate aversive quality of the stimulus with other chemosensory cues, suggesting that conditioned flavor avoidance learning does not occur. Fourth, birds do not habituate to the stimulus, thus, avoidance persists in the absence of reinforcement (Clark and Mason, 1993; Clark and Shah, 1994; Clark, 1996; Clark and Avery, 2013).

Another area of research has been the investigation of plant compounds as either flavorings for feed additives or for their repellent properties (Clark, 1998c; Zeng et al., 2015). While many plant compounds are aversive across taxa, some mammalian irritants are not effective against birds and vice versa. The prototypical example is capsaicin, a plant derived compound first isolated by Thresh (1876), with pungency attributes to humans developed by Scoville (1912) and Nelson (1920), and structurally elucidated by Nelson and Dawson (1923). Birds are behaviorally insensitive to capsaicin (Mason and Maruniak, 1983; Szolcsanyi et al., 1986), whereas mammals are not (Figure 12.2). The possible ecological consequence to the pepper plant was presumably selective pressure favoring evolutionary incorporation of a chemical for protection against a seed predator (rodents), but non-noxious to a seed disperser (birds; Mason et al., 1991; Tewksbury and Nabhan, 2001).

12.3.3 Structure-activity relationships

The historical search for bird repellents has generally been opportunistic in the identification of compounds, with over 10,000 compounds having been evaluated over time (O'Hare et al., 2012). Clark (1998c) and colleagues took a more systematic approach. Using core structures, substituents with differing structural, electronic, and physicochemical attributes were systematically evaluated for repellency in feeding and drinking trial for 113 compounds. Within chemical classes (with a few exceptions, see below) European starlings (*Sturnus vulgaris*) demonstrated aversive responses to acetophenones, anthranilates, anilines, benzyl alcohols, and veratryl amines; whereas starlings were largely indifferent to benzaldehydes, thiozoles, N-heteocycles, acetates, benzoates, veratryls benzamides, and preferred benzoic acids, and amino acids (Figure 12.3). Pulegone has been identified as a potent bird repellent (Mason, 1990), but starlings were indifferent to 12 other menthone derivatives (Mason and Primus, 1996). Watkins et al. (1999) demonstrated repellency and indifference of cinnamaldehyde and their derivatives based on chemical structure. Such behavioral differences in response pose interesting evolutionary questions, but also provide background for using these exogenous chemical probes to elucidate structure-activity relationships and receptor mechanisms which might prove useful for rational design of species-specific repellents and analgesics (Clark, 1998a,b,c; Maatuf et al., 2019).

Despite the well-known behavioral insensitivity of birds to capsaicin, birds are averse to other vanilloid compounds, reflexively avoiding them (Figure 12.2). Aromatic compounds that are considered aversive by birds are qualitatively characterized as having an aromatic heterocyclic core, high degree of basicity, high degree of lipophilicity, and a high degree of electronegativity (Figure 12.3). The core aromatic heterocycle of a repellent compound is enhanced by substitutions that affect electron donation: amino > methoxy > methyl > hydroxyl groups. Resonance of lone pairs of electrons enhances repellency as a function of substituent position: ortho > para > meta. Acidic substituents in the electron withdrawing group detract from aversive qualities of the compound. Steric

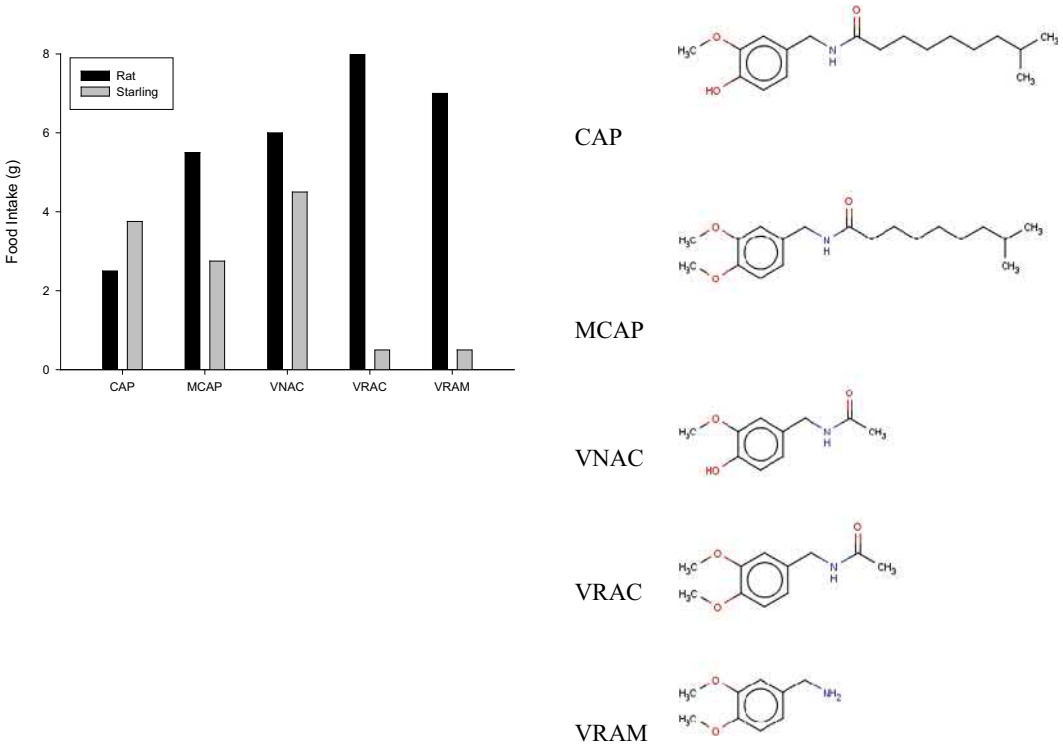

FIGURE 12.2 **Consumption of food treated with capsaicin (CAP), methyl capsaicin (MCAP), vanillyl acetamide (VNAC), veratryl acetamide (VRAC), and veratryl amine (VRAM) in rats and starlings.** Note the general inverse relationship of consumption as structure changes, suggesting functional receptor differences in the two taxa. Bird repellents are more basic and rigid (planar) than mammal aversive compounds. Concentration applied was 1000 ppm. Consumption of 4 g of untreated food is control baseline intake for both species. Compound structures from top to bottom are CAP, MCAP, VNAC, VRAC, and VRAM. *Data adapted from Mason et al. (1991).*

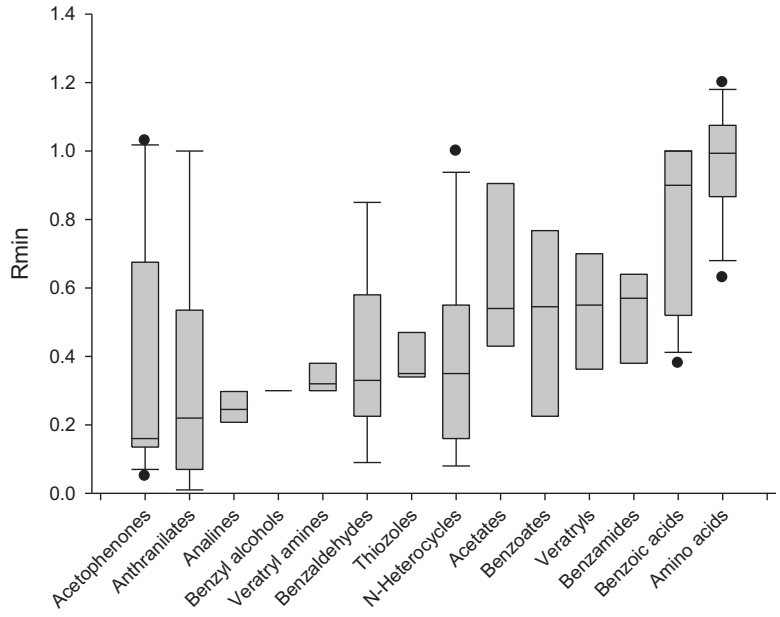

FIGURE 12.3 **The relative reduction of fluid intake for solutions as a function of chemical class, which assumes a benzene parent structure with the nomenclatural taxonomy defined by the principal electron withdrawing group.** Fluid intake is the asymptotic minimum intake in one-bottle six hour drinking trials (R_{min}). Stongly aversive solutions (where R_{min} is not statistically distinguishable from zero) have $R_{min} < 0.2$. Moderately aversive solutions have $0.2 < R_{min} < 0.4$, weakly aversive solutions have $0.4\ R_{min} < 0.6$, and solutions with $R_{min} > 0.6$ are not aversive at all (not statistically different from water controls). Median R_{min} (solid bars), R_{min} 25th−75th percentile (shaded box), R_{min} 5th−95th percentile (capped line), and the range of R_{min} (open symbols). *Adapted from Clark (1997).*

effects and extreme delocalization of lone pairs of electrons, as might occur in meta isomers and aromatic structures with multiple substituted electron donating groups, tend to interfere with repellency (Mason et al., 1989; Clark and Shah, 1991, 1994; Clark et al., 1991; Shah et al., 1991). In addition, good bird repellents tend to be lipophilic, presumably to gain better access to the lipid bilayer membrane (Mason et al., 1989).

Quantitative structure-activity relationships of aromatic compounds and repellency are consistent with earlier qualitative studies. The aversive properties of 14 derivatives of cinnamic acid compounds are characterized by heat of formation (DH(f)), polarizability (XY and YY), and super delocalizability (Sr). All of these descriptors are electronic (Watkins et al., 1999). These findings generally align with a reanalysis of the QSAR relationships of the 117 compounds described above. Canonical analysis of the relationship of physicochemical, topological, and electrostatic descriptors and the concentration-response shape of thefour-parameter fluid intake curve showed that 94% of variance in the response profile could be accounted for by five parameters: polarizability, ES2, ANC, KAPPA2, and CHI2. Polarizability is the relative susceptibility of the electron cloud of a molecule to be distorted by the presence of an external electric field. Owing to distortion, an induced electric dipole moment appears. Temporary dipoles induce dipoles in other molecules resulting in van der Waals intermolecular forces by orienting the temporary and induced dipoles with each other. ES2 is an electrotopological descriptor that describes electronic interactions between molecules. ANC is a partial negative electronic charge descriptor of electrostatic potential that influences molecular interactions (Clark, 1997). CHI2 and KAPP2 are valence connectivity and shape descriptors that may describe the rigidity of the molecule and accessibility of the molecule to receptor pockets (Chu et al., 2020).

12.3.4 Transient receptor potential channels

The almost ubiquitous responsiveness of species to acids across taxonomic orders suggests evolutionary conservation of this trait (Pattison et al., 2019). The ability to detect protons is critical for the regulation of ionic homeostasis so important for cell function, as is the ability to detect exogenous chemical conditions. This detection is accomplished through different mechanisms, i.e., acid sensing ion channels, proton sensing G protein-coupled receptors (GPCR; Ludwig et al., 2003) and two-pore potassium channels. While there is a strong conservation of histidine residues in extracellular portions of the GPCR receptor, some portions differ among species. Relative to mammals and amphibians, chicken GPCR-68 also responds to protons. However, unlike mammals and amphibia, chicken GPCR-65 is not proton sensitive (Mochimaru et al., 2018; Musha et al., 2019).

Nonselective transient receptor potential (TRP) cation channels are evolutionarily conserved membrane proteins involved in sensory neuron activation events, neurotransmitter release, release of inflammatory mediators, and other aspects of pain transduction (Julius, 2013, Figure 12.4). At least 28 such channels, divided into six subtypes based on sequence homology have been identified: vanilloid (TRPV1-6), ankyrin (TRPA1), canonical (TRPC1-7), melastatin (TRPM1-8), mucolipin (TRPML1-1-3), and polycystin (TRPP1-3) (Samanta et al., 2018). For taxa studied to date, TRP channels share six transmembrane across regions S1−S6 and a pore-forming loop between S5 and S6 (Moran and Szallasi, 2018). Because the subfamilies are based on homology, functional attributes of channels are dispersed across receptor type subfamilies (Figure 12.4). TRP receptor channels (TRPA1, TRPV1-4, TRPM-2, 4, 5, 8) serve a valuable function as thermal sensors important to a species' ecology and are activated across different temperature ranges across species (Saito and Tominaga, 2015; Oda et al., 2017). Moreover, many of these channels are polymodal (e.g., responding to temperature, endogenous chemicals, and exogenous chemicals). In particular, TRPA1 and TRPV1 have been extensively studied with respect to chemical sensitivity across taxa. While most of what is known about TRP channels is derived from work done on mammals (Holzer, 2011), a thorough and dynamic database is maintained on line that increasingly incorporates characterizations of other taxa (https://www.guidetopharmacology.org/index.jsp) (Startek et al., 2019; Walters and Williams, 2019).

TRPV1 (initially called VR1) was first cloned in mammals and found to respond to the exogenous vanilloid, capsaicin (Caterina et al., 1997), as well as endogenous agonists, anandamide, and 12-HPETE, which are structurally similar to capsaicin (Zygmunt et al., 1999; Hwang et al., 2000). TRPV1 is also activated by heat (>43°C) and acid (<pH 6). The sensation that TRPV1 activation evokes in humans via these polymodal nociceptors is one of tingling and burning, e.g., the sensation produced by capsaicin found in chili peppers (Jordt and Julius, 2002). Like its mammalian counterpart, the TRP receptor in birds (cTRPV1, chick dorsal root ganglion) responds to high temperature (>45°C) and extracellular acid solution (pH < 4). However, cTRPV1 is different, showing a 68% identity and 79% similarity to rat TRPV1.

Digital fluorescence imaging of intracellular calcium $[Ca^{2+}]_i$ in vitro preparations of chicken and rat trigeminal dorsal root ganglia show that there are separate and overlapping populations of neurons that are sensitive to the well-described avian irritant, methyl anthranilate, and capsaicin (Kirifides et al., 2004). In the chicken, 48% of

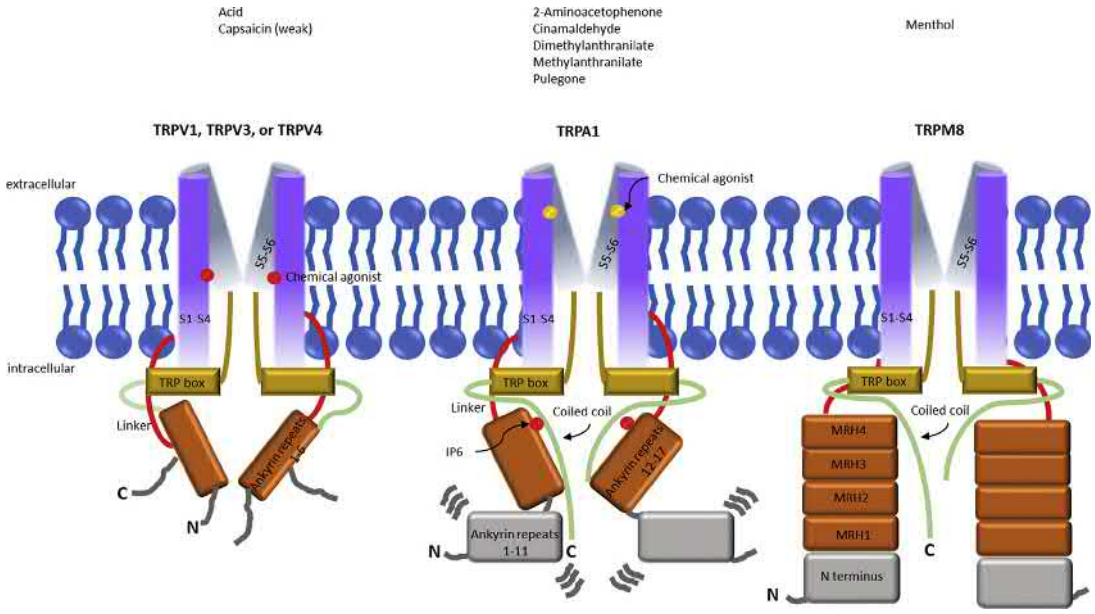

FIGURE 12.4 **Schematic diagrams of transient receptor potential (TRP) channels identified in avian chemesthesis.** Chemicals above the channels are known agonists for avian TRP channels. All follow the same color scheme from N- to C-terminus: N-terminal cytoplasmic domain, orange; linker, green; S1−S4, lilac; S5−S6, blue; TRP-box helix, gold; C-terminus, red; and flexible N- or C-terminal extensions, gray. TRPV1, TRPV3, and TRPV4 proteins contain six ankyrin repeats in their N-terminus. The C-terminus interacts with the ankyrin repeats, connecting the cytoplasmic regions. A chemical agonist (e.g., capsaicin or resiniferatoxin for TRPV1) binding site was identified at the interface of the S1−S4 and S5−S6 regions. TRPV4 contains a proline-rich region in its flexible N-terminal extension. TRPA1's unique structural features include a C-terminal coiled-coil region and 17 ankyrin repeats in the N-terminus; repeats 1−11 were not modeled in the cryoEM structure and are likely to connect to repeats 12−17 through a flexible link. An IP6 molecule bridges the N-terminal ankyrin repeats to the C-terminal coiled-coil. A chemical antagonist, A967079, binds within the S5−S6 pore region (*yellow circle*). Cysteines sensing reactive electrophiles are represented as black circles in the membrane-proximal N-terminal linker region that surrounds the TRP-box helix (red). No structure is yet available for TRPM8, but its transmembrane domain is homologous to that of TRPV1 and TRPA1. The N-terminal region contains "melastatin homology regions," and its C-terminus contains a predicted coiled coil (Moran and Sazalli, 2018).

neurons responded to methyl anthranilate, while only 16% responded to capsaicin. Moreover, there was a greater change in $[Ca^{2+}]_i$ to equimolar concentrations of methyl anthranilate (78%) relative to capsaicin (43%). Increases in $[Ca^{2+}]_i$ were dependent upon extracellular calcium for both methyl anthranilate and capsaicin. Like mammals, extracellular Na^+ can regulate TRPV1 activity in chickens presumably by inactivation of TRPV1 protein binding sites (Saito et al., 2014; Uzura et al., 2020). Birds certainly seem to be able to perceive capsaicin, however, they do not perceive it as painful. Mason and Clark (1995) showed that European starlings were indifferent to capsaicin but could be trained to responds to capsaicin in a behavioral conditioned avoidance paradigm. The response was mediated by the TN because the conditioned response did not occur with transection of the ophthalmic branch of the TN. Bilateral olfactory nerve cuts had no effect on shaping the response.

Substitution of glutamic acid (in the chicken) for analine (in the rat) at the 578 position of the S4−S5 helix was sufficient to induce sensitivity in cTRPV1. Substitutions of lysine, glutamine, or proline at residue A578 also resulted in capsaicin sensitivity in cTRPV1. The hydrophilic analog, Cap-EA, the cTRzPV1-A578E mutant suggesting that A578 may be involved in vanilloid binding. The hydrophilic zingerone did not activate A578 mutants, indicating the core vanilloid structure is not involved in binding (Chu et al., 2020). These results are consistent with the behavioral structure-activity behavioral studies of avian vanilloid responses (Mason et al., 1991; Shah et al., 1991).

Other common mammalian irritants that activate TRPV1 receptors have been examined. But birds remain largely unresponsive. cTRPV1 is not activated by allylisothiocynate (mustard oil) in chickens, This difference is due to the eight chicken-specific amino acid residues around transmembrane 3, which is the main site of capsaicin-binding in rat TRPV1 (Kawabata et al., 2017).

The transient receptor potential ankyrin 1 (TRPA1) is a phylogenetically ancient receptor ubiquitously found across taxa (Saito and Shingai, 2006). TRPA1 is a nonselective cation permeable receptor that responds to temperature as well as a variety of chemical stimuli in mammals (Gupta et al., 2016). TRPA1 responds to heat in frogs, reptiles, and birds, while it responds to noxious cold in mammals (Saito et al., 2012). In chickens, TRPA1 is highly co-expressed with TRPV1 (Saito et al., 2014). Similar to other taxa (Oda et al., 2017), avian TRPA1 is also responsive to a variety of exogenous chemicals. Chicken TRPA1 is responsive to the avian behavioral irritants, methyl

anthranilate, dimethyl anthranilate, 2-aminoacetophenone, cinnamaldehyde, and pulegone (Clark et al., 1991; Watkins et al., 1999; Banzawa et al., 2014; Saito et al., 2014; Majikina et al., 2018). cTRPA1 is not responsive to the bird irritant veratrylamine, which is structurally related to capsaicin (Shah et al., 1991; Saito et al., 2014). TRP channel activation was found to be more dependent on chemical reactivity relative to molecular shape (Hinman et al., 2006; Macpherson et al., 2007). However, the importance of gaining access to proximity of the TRP channels owing to influences of molecular flexibility and shape still remains to be more fully explored. As in other taxa, charged amino acid residues near the outer pore regulate intracellular Ca^{2+} concentration ($[Ca^{2+}]_i$) (Saito et al., 2014; Kurganov et al., 2017; Marsakova et al., 2017; Majikina et al., 2018). Agonistic and antagonistic actions are regulated by multiple amino acid residues in the TM domain and variations in these residues in part explain differential responsiveness among species (Banzawa et al., 2014).

Melastatin transient receptor potential (TRPM) receptors are involved in temperature sensing, chemosensation, ion homeostasis, and redox sensing across taxa (Clapham, 2003). For vertebrates, TRPM8 has been shown to be important for temperature and chemoreception that demonstrate diverse adaptation across species for fine-tuned sensation of environmental stimuli (Myers et al., 2009). Rat TRPM8 is activated by temperature <26°C and by menthol and eucalyptol (Behrendt et al., 2004). In chicken TRPM8, the activation is slightly higher (34°C), and the receptor was also responsive to menthol. In contrast, the cTRPM8 receptor was insensitive to the mammalian super stimulus, icilin. A series of chimera studies showed that the differences between rTRPM8 and cTRPM8 were attributable to small amino acid differences in the TM2 and TM3 regions (Chuang et al., 2004; Pertusa et al., 2014; Yin et al., 2019). The incilin insensitive cTRPM8 receptor is also insensitive to camphor whereas the rTRPM8 receptor is not (Selescu et al., 2013). It is noteworthy that cTRPm8 receptors are abundant in chickens and that cTRPM8 are sensitive to menthol (Yamamoto et al., 2016), yet birds seem to be behaviorally indifferent to this chemical as an irritating signal (Mason and Primus, 1996). Thus, the bird TRPM8 receptor may be a thermal and chemoreceptor, but it is unclear whether it is important as a nociceptor.

In summary, it appears that the TRPA1 receptor has been implicated in most of the avian responsiveness to exogenous chemical irritants in birds, though a better systematic coupling of the compound classes identified by structure-activity studies with molecular receptors studies seems warranted in order to more thoroughly evaluate the importance of other chemically activated nociceptive receptor channels in birds.

12.4 Olfaction

Birds have a well-developed functional sense of smell as evidenced by multiple research areas from the past 60 years. Fundamental platforms of neuroanatomical, morphological, neurophysiological, behavioral, and genomic studies have investigated a variety of avian species. Generally, the overall components of the avian olfactory system are like that of other vertebrates. As in other taxa, the avian olfactory literature exemplifies the variation in olfactory neural substrates (e.g., number of olfactory receptors/genes, olfactory bulb size/divisions, nasal cavity morphology, location of nares) as well as differences in olfactory behavioral capabilities of birds across and within avian families.

12.4.1 Olfactory morphology, neural architecture, and transduction of chemical signals

Air entering a bird's nasal cavity passes through a series of mucus-covered, invaginated chambers, called nasal conchae. Nasal conchae influence air flow dynamics and direct odors to the caudal-most chamber, which contains the chemically sensitive olfactory epithelium (Bang, 1960, 1961, 1963, 1964, 1965, 1966, 1971; Bang and Cobb, 1968; Cevik-Dermirkan et al., 2007; Farouk et al., 2017; Harem et al., 2018). As in other vertebrates, embedded in the olfactory epithelium are the goblet-shaped olfactory sensory neurons, which are surrounded by clusters of supporting cells and basal cells. Unlike amphibians, reptiles, and mammals, birds do not possess a vomeronasal organ or accessory olfactory system (Rieke and Wenzel, 1978). Odorant molecules that have dissolved into and diffused through the nasal mucus are detected by the olfactory receptors of the sensory neurons. Olfactory receptors are embedded in the 6–15 cilia that extend from the olfactory neuron's apical dendritic knob that projects to the mucus-nasal cavity interface. Length of olfactory cilia can vary by species, and perhaps by location in the epithelium. Black vultures, for example, have cilia of 40–50 μm, while domestic fowl have cilia of 7–10 μm (Shibuya and Tucker, 1967). A recent study in mice, however, found that cilia length is dependent on their location in the olfactory epithelium, with longer cilia located in regions with higher odor absorption (Challis et al., 2015). Whether this is also true in the avian olfactory epithelium remains to be seen. Mucous secretions covering cilia provide rapid flow for odor molecules. Mucous secretions from the olfactory glands (Bowman's) must be removed and replaced to maintain diffusion and avoid receptor habituation to odorant molecules. The traction of nearby respiratory cilia on epithelial cells facilitates movement of secretions.

In vertebrates, the binding of odorants to the olfactory receptors in the ciliary membrane is the first step of the olfactory transduction cascade. Olfactory receptors belong to the superfamily of guanine nucleotide-binding protein (G protein)-coupled receptors (seven-transmembrane receptors). Each olfactory sensory neuron expresses one type of G protein-coupled olfactory receptor. When an odorant binds to a G protein-coupled receptor, its activation alters the G protein conformation. This conformational change causes GDP to split from the subunit of the G protein, which then binds to GTP, with subsequent activation of adenylyl cyclase III and the formation of cyclic AMP. Increases in the second messenger cyclic AMP open cyclic nucleotide gated channels, allowing extracellular cations (calcium and sodium) to enter. Increases in intracellular cations generates local depolarization of the ciliary membrane (receptor potential), and opens calcium-activated chloride channels resulting in the flow of chloride anions to extracellular space causing further depolarization (Gomez and Celli, 2008; Antunes and de Souza, 2016). Sufficient membrane depolarization via several odorant/ligand binding events that reach the neuronal cell body will trigger action potentials in olfactory neurons' axons, and thus transmit odor signal directly to the brain via the olfactory nerves. Note that the formation of other second messengers (e.g., 1, 4, 5-triphosphate, IP3) by activation of different G proteins to increase intracellular calcium may additionally/alternatively be involved (Jung et al., 2005; Gomez and Celli, 2008). Thus, an extracellular chemical signal (odorant) is transduced to an intracellular electrical signal that travels to the next neuron located in the brain's olfactory bulb.

As noted above, axons of each olfactory receptor neuron directly innervate the olfactory bulb, located in the anterior region of the brain. The olfactory bulb is composed of concentric cell layers, with incoming olfactory nerve fibers constituting the outermost layer in birds. The endings of axons from olfactory receptor neurons that express the same type of olfactory receptor converge to form spherical structures called glomeruli in the outer layer of the olfactory bulb. Thus, each glomerulus may represent a subset of primary sensory neurons of a given receptor type. A given odorant may activate several different olfactory receptor types causing a unique pattern of activation across glomeruli specific to that odorant. Through using a combination of calcium imaging and single-cell RT−PCR to identify odorant receptors for odorants with related structures, Malnic et al. (1999) observed that one odorant receptor can recognize multiple odorants, and that one odorant is recognized by multiple olfactory receptors. Mitral and tufted cell bodies are located in the olfactory bulbs' deeper layers, but extend their dendrites into the glomerular layer, where they receive synaptic input from the primary olfactory neurons. In general, the cytoarchitecture of the avian olfactory bulb is similar to that of other vertebrates, with the exception that some layers may be less distinctive than in the mammals (Allison, 1953; Andres, 1970; Lee et al., 2019, Figure 12.5). Avian olfactory bulbs can appear a) fused, as in songbirds, b) sheetlike, covering the anterior portion of the telencephalon, as in the Kiwi, or c) appear as two separate lobes, continuous or separate from the telencephalon (Corfield et al., 2014, 2015, Figure 12.6). Corfield and colleagues additionally found that the organization of olfactory bulb layers are typically conserved across avian species they examined (Figure 12.6B). However, it was also observed that there were notable differences across species in the relative thickness and cell density of some layers. It appears that olfactory bulb size may relate to the relative thickness of layers, whether the layers are clearly defined, and whether the cells (e.g., mitral) are closely packed together.

Mitral cells are the main projections from the olfactory bulb to piriform cortex and other processing brain regions that integrate sensory information (Rieke and Wenzel, 1978; Reiner and Karten, 1985; Patzke et al., 2011; Atoji and Wild, 2014). The olfactory bulb is the first relay station in the brain for processing olfactory information. As such, there has recently been an increase in understanding the neuronal diversity and interconnections within the bulb itself (Nagayama et al., 2014). In the pigeon, bilateral projections from the olfactory bulb are to the prepiriform cortex, the piriform cortex, the dorsolateral corticoid area, and nucleus taeniae of the amygdala, while ipsilateral projections are to the medial septum (Patzke et al., 2011; Atoji and Wild, 2014).

12.4.2 Olfactory bulb size, olfactory acuity, and genomics of olfactory receptors

The extent of scrolling of caudal conchae correlates with the surface area of olfactory epithelium and the relative size of the olfactory bulb (Bang and Cobb, 1968; Bang, 1971; Bang and Wenzel, 1986; Roper, 1999; Hagelin, 2007a). Avian orders with relatively larger olfactory bulbs have lower detection thresholds, indicating they may be more sensitive to certain odorous compounds than those with relatively small olfactory bulbs (Clark et al., 1993, Table 12.1, Figure 12.7). However, this does not indicate that birds with small olfactory bulbs, such as passerines, have little olfactory capabilities. Passerines, for example, have detection values comparable to macrosmatic mammals such as rats and rabbits (Davis, 1973). While a larger olfactory bulb size or greater scrolling of receptor epithelium likely indicates greater functional capacity (e.g., more cells and neural circuits; Meisami, 1991), it is important not to dismiss avian species with relatively "unelaborate" olfactory systems (Hagelin, 2007b). Both field and laboratory tests indicate several taxa with relatively small olfactory

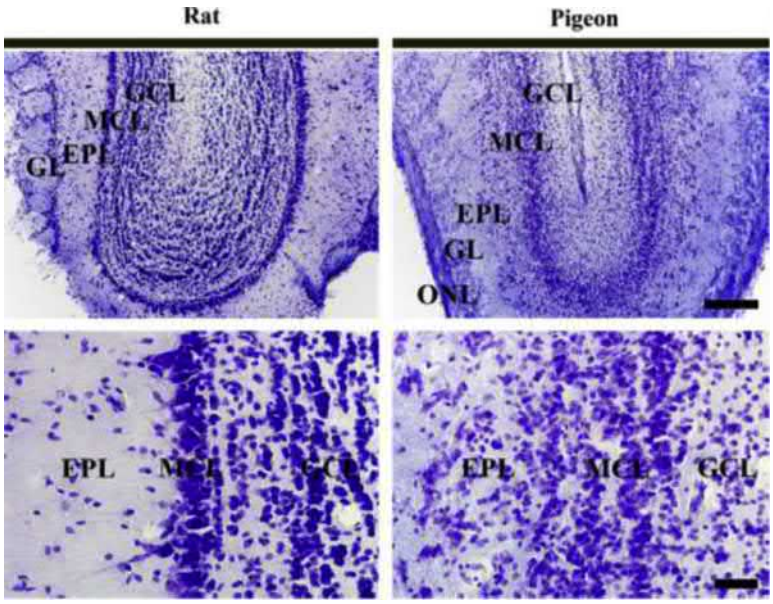

FIGURE 12.5 CV staining of the rat (A and a) and pigeon (B and b) OB. Layers in the pigeon olfactory bulb (OB) are not clear like those in the rat OB: although each layer can be identified. *EPL*, external plexiform layer; *GCL*, granule cell layer; *GL*, glomerular layer; *IPL*, internal plexiform layer; *MCL*, mitral cell layer; *ONL*, olfactory nerve layer. Scale bar = 200 μm (A and B) and 40 μm (a and b) (Lee et al., 2019).

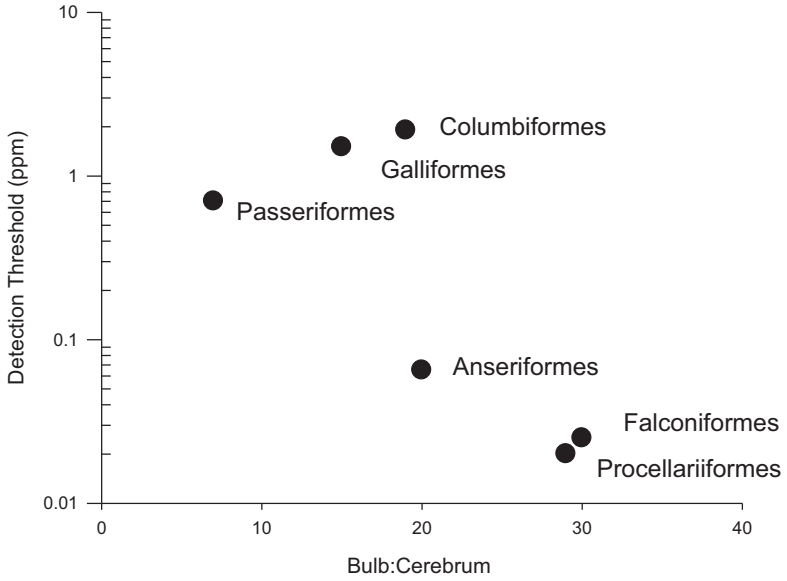

FIGURE 12.7 Relationship between olfactory detection threshold and relative size of the olfactory bulb for different orders of birds. *Adapted from Clark and Shah (1992).*

bulbs can discriminate between and/or adaptively employ certain odors, such as those related to breeding and nesting, or individual/conspecific recognition (e.g., crested auklets [*Aethia cristatella*] Hagelin et al., 2003; European starlings Clark and Mason, 1985, 1987, 1988; Gwinner and Berger, 2005, 2008; Corsican Blue Tit [*Parus caeruleus ogliastrae*] Petit et al., 2002; Zebra finch Caspers et al., 2017; Krause et al., 2018).

Olfactory bulbs vary in relative size across vertebrates, and the relative size is independent of the size of the rest of the brain in fish and mammals. In birds, the relative size of olfactory bulbs is typically described as size of bulb relative to size of brain, cerebral hemispheres, or specific brain regions (Bang and Cobb, 1968; Healy and Guilford, 1990; Zelenitsky et al., 2009; 2011; Corfield et al., 2015; Supplementary Material in Avilés and Amo, 2018). With the aforementioned caveats in mind, the olfactory bulb ratio has been used as a proxy for olfactory capabilities because it estimates the amount of forebrain or brain devoted to olfactory perception. Elaborated olfactory

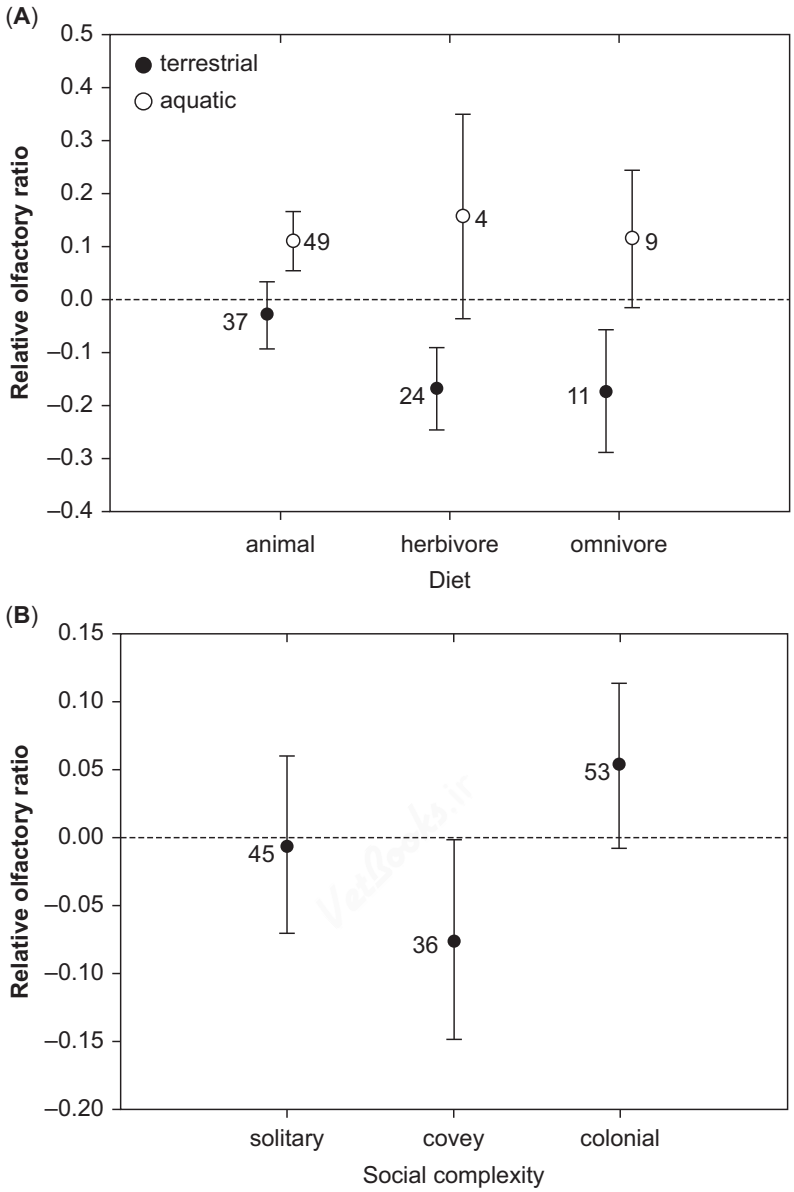

FIGURE 12.8 **Avian olfactory ratio (mean + SE) of aquatic and terrestrial species in relation to (A) diet and (B) social complexity (Aviles and Amos, 2018).**

systems typically belong to species with demonstrated reliance on odor cues in the field (Stager, 1964; Hutchison and Wenzel, 1980; Hagelin, 2004; Cunningham et al., 2009; Corfield et al., 2014; Grigg et al., 2017; Silva et al., 2020), and in some species, correlate positively with the absolute number of olfactory receptor genes (Steiger et al., 2008). Fossil evidence also indicates olfactory bulb size was relatively large early in bird evolution, revealing a previously unrecognized emphasis on smell (Zelenitsky et al., 2011). Evolutionary mechanisms that contribute to the diversity of bulb size remains a discipline of active research. Recent studies focus on the correlations between behavior, relative bulb size, phylogeny, habitat, and ecology (Corfield et al., 2015; Avilés and Amo, 2018). Corfield found that habitat (living and foraging in semi-aquatic environments) was strongly related to driving larger olfactory bulbs, while Avilés and Amo (2018) suggest that an interactive effect of aquatic habitat and diet is the driving force in the evolution of the olfactory apparatus (Figure 12.8). These scenarios may not be mutually exclusive, and the studies may differ in the sample size of species used in described environments and phylogeny used in analysis. Foraging behavior is contingent on ecological conditions, and therefore the interaction between ecological and behavioral characters that may be driving the olfactory bulb size.

Another metric that is reasonably correlated to olfactory bulb ratio and thus olfactory sensitivity is the number of potentially functional olfactory receptors. The number of olfactory receptor neurons (on one side of the nasal cavity) varies widely across avian species: from approximately 5,800,0000 in ducks, 2,700,000 gulls, 570,000 in quails, and 130,0000 in budgerigar, to 110,000 in the bengalee (Matsuzaki, 1995). In comparison, the approximate number in the rodent nose is five million olfactory receptor neurons (De Castro, 2009). The number of genes coding the olfactory receptors in the rat and mouse is estimated to be 1000−1300 (with 20% pseudogenes), ∼100−150 in fish, and approximately 100−650 in birds, depending on the species (Buck and Axel 1991; Ngai et al., 1993; Zhang and Firestein, 2002; Steiger et al., 2008, 2009a,b). For example, in the chicken, 479 gene homologs (with 111 pseudogenes) were identified and in the zebra finch there are 553 gene homologs (with 221 pseudogenes) (Steiger et al., 2009b). However, the range of olfactory receptors in similar diurnal species is only 55−109 (Steiger et al., 2009a). Nocturnal species known to rely on their sense of olfaction in foraging, such as the brown kiwi (*Apteryx australis*), and kakapo (*Strigops habroptilus*), respectively, have 478 and 312 genes identified (Steiger et al., 2009a). The greater the repertoire of olfactory receptors that a species possesses, the more glomeruli that are formed, which results in a larger olfactory bulb ratio, and subsequent olfactory sensibility. Identifying the repertoire of olfactory receptor genes across species may provide evidence of adaptive evolution for specialized olfactory functions. By comparing the functional olfactory receptor subgenome repertoire across a number of phylogenetically and ecological diverse birds, studies can identify which olfactory gene families are important for given ecological niche or behavior.

The olfactory receptor proteins in the primary sensory neurons are encoded by single-exon (intron-less) olfactory receptor genes that are divided into two major types: Type I includes Class I (α, β, δ, ε, and ζ groups) and Class II (γ group) genes, and Type II includes (η) (Figure 12.9). Within these classes, olfactory receptor genes are further grouped into families based on genetic similarity. Class I families code for receptor proteins that are thought to principally bind to water-borne molecules, and Class II families bind to air-borne molecules (Glusman et al., 2000; Hayden et al., 2010).

Molecular mechanisms shaping the patterns of avian diversification of olfactory abilities have been recently been revisited (Khan et al., 2015; Silva et al., 2020). There are 11 olfactory receptor gene families in birds and reptiles (1/3/7, 2/13, 4, 5/8/9, 6, 10, 11, 12, 14, 51, and 52) (Khan et al., 2015). The olfactory receptor gene family 14 was most abundant in birds (Steiger et al., 2009a,b). Overall, complete characterization of avian olfactory receptor genes into functional and nonfunctional genes point to patterns of gene gains and losses that had a crucial role in determining the olfactory receptor gene repertoires in individual species, and thus shape patterns of diversification of olfactory abilities (Supplementary Material online in Khan et al., 2015). For example, as stated above, chick and zebra finch, along with the budgerigar, have larger olfactory receptor repertoires which may reflect species-specific recent rapid expansion and positive selection of OR14 family. Phylogenetic analysis in Cory's Shearwater showed that a majority (85%) of the olfactory receptor genes identified belong to the avian-specific γ-c clade, pointing to gene duplication/conversion events (Silva et al., 2020). The application of olfactory receptor genomics has expanded our understanding of the potential interactive measures of ecology, habitat, and behavioral traits in relation to olfactory sense in birds and its adaption to different ecosystems.

12.4.3 Laboratory detection thresholds, discrimination, and seasonal change

It is no surprise that avian responsiveness to odors has been demonstrated using a variety of methods, stimuli, and species (Tables 12.2 12.3). Birds certainly have the anatomical organization that is suggestive of olfactory

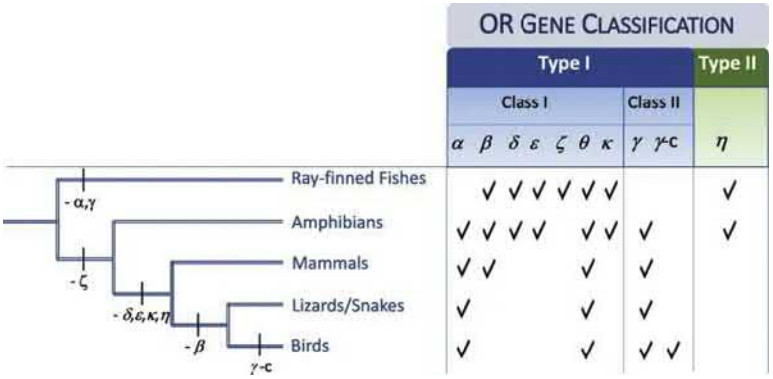

FIGURE 12.9 **Classification and schematic distribution of olfactory receptor genes in major vertebrate lineages (Silva et al., 2020).**

ability (above). Evidence from studies from single neurons, olfactory nerve fibers, and electroencephalograms all indicate odor signals are transmitted to the brain (Tucker, 1965; Sieck and Wenzel, 1966; Shibuya and Tucker, 1967, Shibuya and Tonosaki, 1972; Wenzel and Sieck, 1972; Shallenberger, 1975; Hutchison and Wenzel, 1980; Macadar et al., 1980; McKeegan, 2002, 2009). This odor stimulation, whether pure reagents, or volatile mixtures that

TABLE 12.3 Some avian orders considered to be very odorous by ornithologists.[1]

Order	Common Name	Number of Species
Procellariiformes	Petrels, shearwaters, diving petrels	16
Ciconiiformes	Herons, storks, new world vultures	12

Piciformes	Woodpeckers, barbets, tucans	33
Passeriformes	Grackles, starlings, ravens, finches, honeycreepers	46

[1]*Data compiled from Weldon and Rappole (1997).*

may be ecologically relevant, generates spontaneous physiological reactions such as changes in respiration and heart rate and have been observed in: wedged-tailed shearwaters, *Puffinus pacificus;* Manx shearwater, *Puffinus puffinus*; black-footed albatross, *Diomedea nigripes*; mallard, *Anas platyrhynchos*; turkey vulture, *Cathartes aura*; bobwhite quail, *Colinus virginianus*; chickens; pigeons, *Columbia livia*; and kiwi, *Apteryx australis* (Neuhaus, 1963; Snyder and Peterson, 1979; Smith and Paselk, 1986; Wenzel, 1967, 1971; Wenzel and Sieck, 1972). The yellow-headed Amazon parrot, *Amazona ochrocephala*; raven, *Corvus corax*; and canary, *Serinus canaria* did not exhibit spontaneous responses. Habituation to the stimulus under this paradigm, however, is problematic.

Less invasive studies that allow birds to freely feed, drink, or choose a location based on olfactory training can be useful. Operant conditioning (Michelsen, 1959, ; Henton et al., 1966; Henton, 1969) and poison avoidance learning (Clark and Mason, 1987) have proved to be more reliable assays for response relative to spontaneous response metrics (Passe, 1985). Hummingbirds can be trained to make discriminative fluid selections based on associated odors (Goldsmith and Goldsmith, 1982; Ioale and Papi, 1989). Similarly, domestic chicks can discriminate between palatable and unpalatable food based on associated odor cues (Marples and Roper, 1997; Roper and Marples, 1997). Care must be given when testing volatile compounds, however. Learned and nonlearned responses to methyl anthranilate are modulated by olfaction, but the principal response is mediated through avoidance of the irritating properties (Mason et al., 1989; Clark 1996; Burne and Rogers, 1999; Marples and Roper 1997).

Two process learning paradigms, such as cardiac conditioning, have proven to be a reliably successful technique for detection, discrimination, and threshold testing (Rescorla and Solomon, 1967; Walker et al., 1986; Clark and Mason, 1989; Clark and Smeraski, 1990; Clark, 1991a; Clark et al., 1993). For cardiac conditioning, an odor (the conditional stimulus) is paired with an aversive experience, for example, a shock (the unconditional stimulus). Heart rate is compared pre- and poststimulus presentation during training, until a level of cardiac acceleration is reliably achieved, indicating a bird has learned to associate the odor in anticipation of a shock. Thereafter, tests on detection or odor discrimination can proceed. Most birds tested with this paradigm have shown olfactory capabilities comparable to mammals (Davis, 1973). Even passerines, with the least developed olfactory system, demonstrate behavioral responsiveness to odors (Clark, 1991a; Clark et al., 1993).

European starlings offer an interesting case study of olfactory structure, function, and seasonality. Male starlings incorporate green plants rich in aromatic volatiles into nests, some of which act as a fumigant against parasites and pathogens (e.g., Clark and Mason, 1985, 1987, 1988; Clark, 1991b; Gwinner, 1997; Gwinner et al., 2000; Gwinner and Berger, 2005). Using conditioned avoidance learning, Clark and Mason (1987) showed that European starlings could discriminate between volatiles derived from plants and that after bilateral olfactory nerve cuts; they could no longer make odor-based discriminations. Starlings are most sensitive to, and can discriminate between, plant odors during spring only, rather than in summer and fall. Spring is coincident with nest building and suggests a hormonal influence (Clark and Smeraski, 1990). Birds treated with testosterone (T), a hormone that enlarges song-learning nuclei of the brain and alters behavior, exhibited enlarged olfactory bulbs year-round, indicating a proximate effect on bulb structure. However, perception of plant odor in T-implanted males was greatest during spring only,

indicating that perception was independent of T-treatment and olfactory bulb volume. One hypothesized but untested mechanism is that an increase in receptor cell density in starling olfactory epithelium occurs in spring (DeGroof et al., 2010).

12.4.4 Odor detection during development

Volatile compounds diffuse through avian eggshell (Rahn et al., 1979), providing an opportunity for odor exposure within the egg (Tolhurst and Vince, 1976; Sneddon et al., 1998). Many vertebrates, including birds, detect and learn chemical information as embryos (e.g., humans: Schaal et al., 2000; Mennella et al., 2001; other mammals: Hepper, 1988; Bilko et al., 1994; amphibians: Mathis et al., 2008; birds: Porter and Picard, 1998; Bertin et al., 2012). Zebra finch chicks transferred to another nest while still in the egg retain the chemosensory sense of their mother (Caspers et al., 2017) and provides further evidence that odors can transmit into the eggs and that sensory cues can be learned during the embryonic period (Caspers et al., 2015; Hagelin et al., 2013). Early exposure to chemical signals can cause changes in neuroanatomy, which alters chemosensory perception in a way that may adaptively shape responses later in life (e.g., to food, mates; Todrank et al., 2011).

Studies of domestic chickens, the avian model for development, indicate that odor detection can occur before or after young pierce the egg's air sac and begin breathing air (e.g., Tolhurst and Vince, 1976; Bertin et al., 2012; Hagelin et al., 2013). Olfactory receptor neurons are functional six days prior to air-breathing (on embryonic developmental day 13; Lalloué et al., 2003), when nasal passages are full of amniotic fluid. Embryos at this stage swallow frequently, facilitating fluid movement, which is similar to mammals in utero (Sneddon et al., 1998). Air-breathing begins two days prior to hatching during embryonic developmental day 19 (Tolhurst and Vince, 1976).

The magnitude of embryonic response varies relative to stimulus concentration and timing of exposure (Bertin et al., 2010). Later developmental stages show relatively greater responses to odors (Gomez and Celli, 2008; Bertin et al., 2012). Detectable stimuli include artificial odors (Sneddon et al., 1998), as well as naturally occurring scents, such nest materials (Gwinner and Berger, 2008), food-related odors (Burne and Rogers, 1999; Cunningham and Nevitt, 2011), and compounds found in plumage scent of at least one alcid species (Hagelin et al., 2013).

12.4.5 How do birds use olfactory cues?

While not physiological per se, it is important to summarize the different types of behaviors and ecological context for use of olfactory cues by birds. Appreciation of the diversity of behaviors and their context will help guide mechanistic studies on how odor information is received, processed, and acted upon. Olfaction has been shown to play an important role in foraging, food identification, navigation/homing, mate selection and advertisement, individual and species recognition, predatory avoidance, territorial scent marking, and social communication. Hagelin (2007a) made a distinction between environmentally derived odors (e.g., food, predators) and those produced by birds themselves (e.g., body odors, fecal odor, preen gland secretions). The latter can have social and reproductive implications. Below we provide some examples of the role of environmental chemical signals and odors derived from avian chemical substances, but how the chemical signals/cues are translated into adaptive behavior at the physiological level remains elusive. We provide this sampling of avian behaviors to inspire further studies in the physiology of behavior guided by olfactory cues.

The use of olfactory cues for locating food has been documented for numerous species, such as procellariids, vultures, corvids, hummingbirds, honeyguides, parrots, and kiwis (reviewed in Roper, 1999). Turkey vultures (*Cathartes aura*), for example, are attracted to ethyl-mercaptan, a volatile associated with decomposed carcasses (Stager, 1964, 1967), and can locate food without visual cues (Houston, 1987; Potier et al., 2019). Procellariforms also forage over considerable distances. Black-footed albatrosses *(Diomedea nigripes*) respond to bacon grease over 31 km away (20 miles; Miller, 1942), whereas Leach's storm petrel (*Oceanodroma leucorhoa*) theoretically home to scent targets at a distance of 1−12 km (Clark and Shah, 1992).

With regard to predators, scent of urine and/or feces has an aversive effect on some avian species (blue tits [*Cyanistes caeruleus*], Amo et al., 2008; house finches [*Carpodacus mexicanus*], Roth et al., 2008; red junglefowl [*Gallus gallus*], Zidar and Løvlie, 2012; house sparrows [*Passer domesticus*], Griggio et al., 2016), but not all (eastern blue birds [*Sialia sialis*], Godard et al., 2007; house wren [*Troglodytes aedon*], Johnson et al., 2011). Application of predator odor can deter breeding ducks and songbirds (Eicholz et al., 2012; Forsman et al., 2013) as well as evoke avoidance behavior in red-legged partridges (Mahr and Hoi, 2018). Responses appear to be innate, rather than learned (Amo et al., 2011b), though sleeping birds are unreactive (Amo et al., 2011a).

Odors are also germane to avian orientation and navigation (reviewed in Wallraff, 2005; Gagliardo, 2013). Homing pigeons, for example, exhibit larger olfactory bulbs than nonhoming breeds (Rehkämper et al., 1988, 2008). Investigators have also altered pigeon homing

behavior via experimental disruption of the olfactory system. Manipulations include olfactory nerve transection (Papi et al., 1971; Gagliardo et al., 2006, 2009), anesthesia of olfactory mucosa (Wallraff, 1988), ablating the central piriform cortex of the brain (Papi and Casini, 1990), and nostril plugging. The last of these manipulations indicates pigeons rely more on their right nostril for olfactory information (Gagliardo et al., 2007, 2011). ZENK, an immediate early gene expressed in olfactory neurons, also implicates the use of olfaction during the process of homing (Patzke et al., 2010) and may exhibit seasonal differences in migratory and nonmigratory songbirds (Rastogi et al., 2016). Emerging evidence for passerines species also supports olfaction during migration. For example, adult gray catbirds (*Dumetella carolinensis*) rendered temporarily anosmic (by washing the olfactory tissues with zinc-sulfate) oriented differently from adult controls, but similarly to juvenile birds, which were migrating for the first time and therefore unable to navigate (Holland et al., 2009). With regard to cellular mechanisms, black-headed buntings (*Emberiza melanocephala*) increase activation of olfactory tissues (as measured by c-fos immunoreactivity) during migration. These birds exhibit a seasonally enhanced emphasis on olfaction while migrating, compared to visual systems (Rastogi et al., 2011, 2016).

Many birds produce a variety of odorous compounds (reviewed in Campagna et al., 2012). For example, a seabird colony, with its dense numbers of birds, burrows, and feces, makes for a potent chemosensory experience. Pioneering work by Grubb (1974) on Leach's storm petrel showed differential return rates to nest sites after surgical manipulation, indicative of olfactory-based homing: controls = 91%, sham surgery: 74%, olfactory nerve section: 0%. Several petrel species have since been shown to discriminate between the odor of their own nest and conspecific burrows (Mínguez, 1997; De Léon et al., 2003; Bonadonna et al., 2003a,b). Attraction to home nest odor is also reported for passerines (Caspers and Krause, 2010; Krause and Caspers, 2012). More recently, there is a focus on the role of microbiota on the chemical cues used in olfactory evoked social communication (Maraci et al., 2018).

Avian chemical substances are linked with a variety of social contexts (reviewed in Hagelin, 2007a; Hagelin and Jones, 2007; Balthazart and Taziaux, 2009; Caro and Balthazart, 2010). Uropygial gland secretions, for example, show some level of hormonal control, and exhibit individual, sex, and age-specific patterns (e.g., Procellariiformes: Mardon et al., 2010, 2011; Anseriformes: Kolattukudy et al., 1987; Galliformes: Karlsson et al., 2010; passerines: Whittaker et al., 2010; Whelan et al., 2010; Shaw et al., 2011; Amo et al., 2012a). Pioneering work by Balthazart and Schoffeniels (1979) indicated male mallards decreased social displays and sexual behavior toward females when their olfactory nerves were sectioned, suggesting that an intact olfactory system is critical to courtship and mating. Crested auklets produce a seasonally elevated scent associated with a stereotyped behavior that focuses on the scented region of the body (the nape). Auklets are attracted to natural feather odor, a chemical cocktail of odor compounds, and to scented decoys, which suggests odor has a social function (Hagelin et al., 2003; Jones et al., 2004; Hagelin, 2007a). Mounting evidence suggests that preen gland secretions likely play a leading role in intraspecific communication (Campagna et al., 2012; Caro and Balthazart, 2010; Caro et al., 2015; Hagelin and Jones, 2007; Moreno-Rueda, 2017) even in song sparrows, a relatively nonsocial bird (Grieves et al., 2019).

Procellariiform seabirds show a surprising level of body odor discrimination of conspecifics, in that they are attracted to mate odors and avoid self-odor (Antarctic petrel [*Pachyptila desolata*] Bonadonna and Nevitt, 2004; blue petrels [*Halobaena caerulea*], Mardon and Bonadonna, 2009). Furthermore, preference for the odor of unrelated individuals over those of kin suggests body odors could provide a mechanism for inbreeding avoidance, known as self-referent phenotype matching (Mateo and Johnston, 2000; European storm petrel [*Hydrobates pelagicus*], Bonadonna and Sanz-Aguilar, 2012). This may be particularly important in petrels, as they are long-lived, philopatric species that mate for life. Petrels are also likely to encounter kin on their natal breeding grounds that they have never met before (Bonadonna and Nevitt, 2004; Bonadonna and Sanz-Aguilar, 2012). Responses of passerines to conspecific odor also appear to provide complex information, in that they correlate with social rank (house finch, Amo et al., 2012b), sex (European starling, Amo et al., 2012a), and body size (dark-eyed junco [*Junco hyemalis*], Whittaker et al., 2011).

12.5 Summary

The chemical senses across taxa have always seemed to be a side branch of sensory science. This is understandable in that auditory and visual cues have relatively more easily quantifiable signals that are largely received by well-defined sensory systems. Even taste (for birds) is a bit more straightforward in that sensory cues are brought to the mouth and involve more or less straightforward processes of interacting with receptors. In contrast, volatile cues, at lower concentrations for olfaction and higher concentrations for chemesthesis, emanate from a chaotic environment often making it difficult to precisely know what is in the signal and at what concentration, let alone the potential myriads of signals that are present and need processing. For the most part, scientists in this field "black box" the signal into broad categories, or deal with simplifying mixtures

down to one or two sensory cues. This is a difficult enough science for the well described human food and flavor industries, let alone the under studied field of avian chemical senses. Nonetheless, great strides have been made over time in our understanding how birds use chemical cues and what mechanisms they use to process these cues. In part this progress is owing to advances in technological capabilities. Beyond that, however, the current trends for multidisciplinary approaches to address scientific questions have allowed us to ask more interesting and complex questions. Together, we have a profoundly new appreciation of the role chemical signals play in the ecology and evolution of birds.

13.1 Introduction

13.1.1 What is taste?

Taste perception enables the animal to evaluate nutritional value and potential toxicity of food, and converts taste stimuli into physiological stimuli which in turn promote or suppress feed consumption. Taste research traditionally focused on mammalian model species, where taste research in avian was for the most part neglected and mainly descriptive. However, in the past two decades, we witness the emergence of new avian histological, molecular, and behavioral taste research using innovative techniques together with recent genomic data.

This chapter will discuss taste perception and mechanisms in birds in the following categories: the different taste modalities, taste buds anatomy, taste receptors and signaling molecules, measuring taste behavior in animals, extra gustatory taste receptors, and taste perception variation between different birds.

13.1.2 Taste perception

13.1.2.1 Role of taste

The sense of taste, a specialized chemosensory system, is the mechanism responding to specific chemicals in food and/or water. Why do birds have the ability to taste? Taste perception has evolved as a self-survival mechanism, which enables the bird the nutritional evaluation of food and water with its consumption. Research supports a direct relationship between taste signals and nutrition, by that all main natural taste agonists currently known are either nutrients or anti-nutritional factors. Avian are immensely diverse in habitats and dietary niches, which in turn creates a broad range of potential nutrients and toxins birds are encountered with in their diets. While some avian species rely in their diet on grains, plants, and insects (like wild chicken), other birds consume nectars and fruits containing sugars such as sucrose (Rowland et al., 2015).

13.1.2.2 The five taste modalities

Today, it is the consensus that sense of taste can be divided to five different taste modalities: sweet, umami, bitter, salty, and sour. While sweet and umami taste modalities indicate carbohydrates and several L-amino acids are palatable and as so encourage consumption, sour and bitter indicates

Sturkie's Avian Physiology. https://doi.org/10.1016/B978-0-12-819770-7.00051-7

potential spoilage or toxicity of the food ingested, causing an aversive and rejection responses. The fifth salty taste results from sodium salts (and some nonsodium salts) and is most likely representative for sodium and some other minerals in the food. This taste's palatability however is somewhat different and unique from the previously described, where it depends on the animal physiological state and needs together with salt concentrations in the food itself (Bachmanov and Beauchamp, 2007; Yarmolinsky et al., 2009; Roura et al., 2013; Liman et al., 2014). In the recent years, there is an increasing agreement on the existence of a sixth taste modality—fat or fatty acid taste. Furthermore, other potential new nonclassical taste qualities have been suggested such as calcium and water, which potentially work through taste perception mechanisms (Bachmanov and Beauchamp, 2007).

13.1.3 Anatomy of taste buds

13.1.3.1 Taste buds

What are the tissues responsible for taste sensation? Tastants (taste molecules) are recognized by taste receptors found in taste receptor cells (TRCs). TRCs are organized in an epithelial structures named taste buds located in the oral cavity of the animal. Avian taste buds, like mammalians, contain a group of fusiform cells which have a pear-like shape (reviewed Liu et al., 2018), with their longitudinal axis oriented vertically to the epithelium and the apical side composed of receptors situated in TRCs containing small or large receptor villi. These TRCs are compact modified epithelial cells extending taste perception into the apical surface of the epithelium, where taste buds pores enable the direct interaction of tastants present in the oral cavity (Liman et al., 2014).

13.1.3.2 Morphology

The morphology of avian taste buds has been described in crows, mallard ducks, pigeons, grebes, and starlings (Berkhoudt, 1992); however, the most researched avian on the topic of taste perception is the domestic chicken. Avian taste buds differ from mammals morphologically mainly by not being associated with gustatory papillae.

13.1.3.3 Types of taste buds

Taste buds can be divided into three types based on morphology (mainly shape)—Type I buds characterized as ovoid structures comprised of a central core of sensory and structural supporting cells called sustentacular cells surrounded by follicular cells. These can be found in chickens, pigeons, and songbirds (Berkhoudt, 1985, 1992; Rowland et al., 2015). Type II buds possess similar supporting follicular cells, are characterized by a more narrow-elongated morphology and can be found in ducks and waders (Rowland et al., 2015). The type III buds, which can be found only in parrots, are similar to mammalian taste buds but the supporting follicular cells are missing (Rowland et al., 2015).

13.1.3.4 Taste buds markers in chickens

Advances in histology and molecular biology together with new genomic data available enabled to shed more light into taste structures in birds. Recently markers such as Epcam, α-Gustducin, and Vimentin (intermediate filaments) have been used to identify taste bud cells in chickens (Venkatesan et al., 2016). There is a bimodal distribution of taste bud widths with diameters of around either 45 or 65 μm with an area and developmental stage association (Ganchrow and Ganchrow, 1985). Taste buds are in communication with the oral cavity via circular openings called taste pores (2−10 μm in diameter) in the epithelium (Kudo et al., 2008; Rajapaksha et al., 2016; reviewed Liu et al., 2018).

13.1.3.5 Taste bud number and distribution

13.1.3.5.1 Distribution in different vertebrates

In mammals, taste buds are located mostly in the tongue and in some cases soft palate (Liman et al., 2014); however, they can be found in other parts of the oral cavity in different vertebrates. Traditionally birds were thought of possessing poor sense of taste, mainly due to lower number of taste buds compared to other vertebrates. However, due to research in new oral cavity areas (areas beyond the tongue) which were not examined before it is known by now that birds have more taste buds than previously thought (Kudo et al., 2008; Rajapaksha et al., 2016).

Taste buds' morphology, count, and distribution holds great inter- and intraspecies variation (Northcutt, 2004)—from only 56 and 62 taste buds in pigeons and quails respectively, through 2000−8000 in humans (Roper, 2013; Roura et al., 2013) and up to ∼20,000 in cows and pigs (Roura et al., 2013, Table 13.1). Due to the nature of feeding in birds (no mastication and lower saliva secretion), taste buds in birds are uncommon on the tongue, but rather are most abundant in the anteroposterior extent of the upper beak epithelium (upper palate), the lower palate, and usually in proximity with salivary gland ducts (Ganchrow and Ganchrow, 1985, Figure 13.1).

13.1.3.5.2 Distribution in birds

The number and distribution of taste buds in chicken has been reported (Ganchrow and Ganchrow, 1985; Ganchrow et al., 1993). Chicken taste buds are found mainly around salivary glands in the soft epithelium of the palate, the base of the tongue and the pharynx with unique distribution where the majority of taste buds are located on the upper palate (69%) and lower palate (29%), and only small

TABLE 13.1 Abundance of taste buds in different vertebrates[a].

Species			Number of taste buds	Sweet/umami receptor genes	Number of *TAS2R* genes
Chicken (*Gallus gallus*)	Broiler	Embryo (E19)	~80		
		Adult	312–770	T1R1/T1R3	3
	Laying type: White Leghorn		192		
	Rhode Island		253		
Turkey (*Meleagris gallopavo*)			200	T1R1/T1R3	18
Quail (*Coturnix japonica*)			62		
Duck (Anatidae spp.)			350		
Parrot (Psittacidae spp.)			350		
Zebra finch (*Taeniopygia guttata*)				T1R1/T1R3	8
Medium ground finch (*Geospiza fortis*)					9
Sparrow (*Zonotrichia albiocollis*)					15
European starling (*Sturnus vulgaris*)			200	T1R1/T1R3	7
Blue tit (*Cyanistes caeruleus*)			24		
Human (*Homo sapiens*)			7902	T1R1/T1R2/T1R3	10
Pig (*Sus scrofa*)			19,904	T1R1/T1R2/T1R3	25

[a]*Adapted from Ganchrow and Ganchrow (1985), Roura et al. (2013), Li and Zhang (2014), Rajapaksha et al. (2016).*

percentage are found in the poster ventrolateral region of the anterior tongue (2%). Until recently, studies using standard morphological techniques showed counts of 250–350 taste buds in adult chickens (Berkhoudt, 1985; Kudo et al., 2010); however, recently the use of new and innovative techniques demonstrated the number to be a bit higher (~800) (Rajapaksha et al., 2016; Venkatesan et al., 2016). Other reports on bird's taste bud counts reveal similar lower numbers (Table 13.1). Yet, it seems that despite a lower number of taste buds compared to mammals (~10–30 times lower), birds oral cavity size scale is much smaller compared to mammals (~200 times), indicative that in birds a higher ratio of number of taste buds/gram of food ingested in a single bite. This can lead to the assumption that the capacity to taste consumed food is not compromised by taste buds distribution in birds (Roura et al., 2013).

13.1.3.6 Afferent nerves from the taste buds

As in mammals, there are three taste-related afferent nerves which transfer taste information from the oral cavity of the bird into the brain: (1). the chorda tympani in the mandibular, (2). greater superficial petrosal from the soft palate, and (3). the lingual branch of the glossopharyngeal nerves. These transmit information to the nucleus of the solitary tract (brain stem) then though the parabrachial nucleus and the ventral postermedial nucleus (VPM) to the primary gustatory cortex in the insula (Mason and Clark, 2000); reviewed (Yarmolinsky et al., 2009).

13.1.3.7 Changes in taste buds during growth and development

Based on electron microscopy, there are no changes in the number of TRCs during growth and development in chickens between hatching and adulthood (up to 140 days) (Kudo et al., 2008). Taste buds are first identified at day 17 of embryonic development. Numbers of taste buds increase rapidly between days 17E and 19E of the development of the chick embryo chicken (Ganchrow and Ganchrow, 1987, see Table 13.1).

13.1.4 Taste receptors

13.1.4.1 Overview

Taste receptors are chemoreceptors interacting with tastants initiating an afferent signal transmitted to the brain resulting in taste perception (Bachmanov and Beauchamp, 2007).

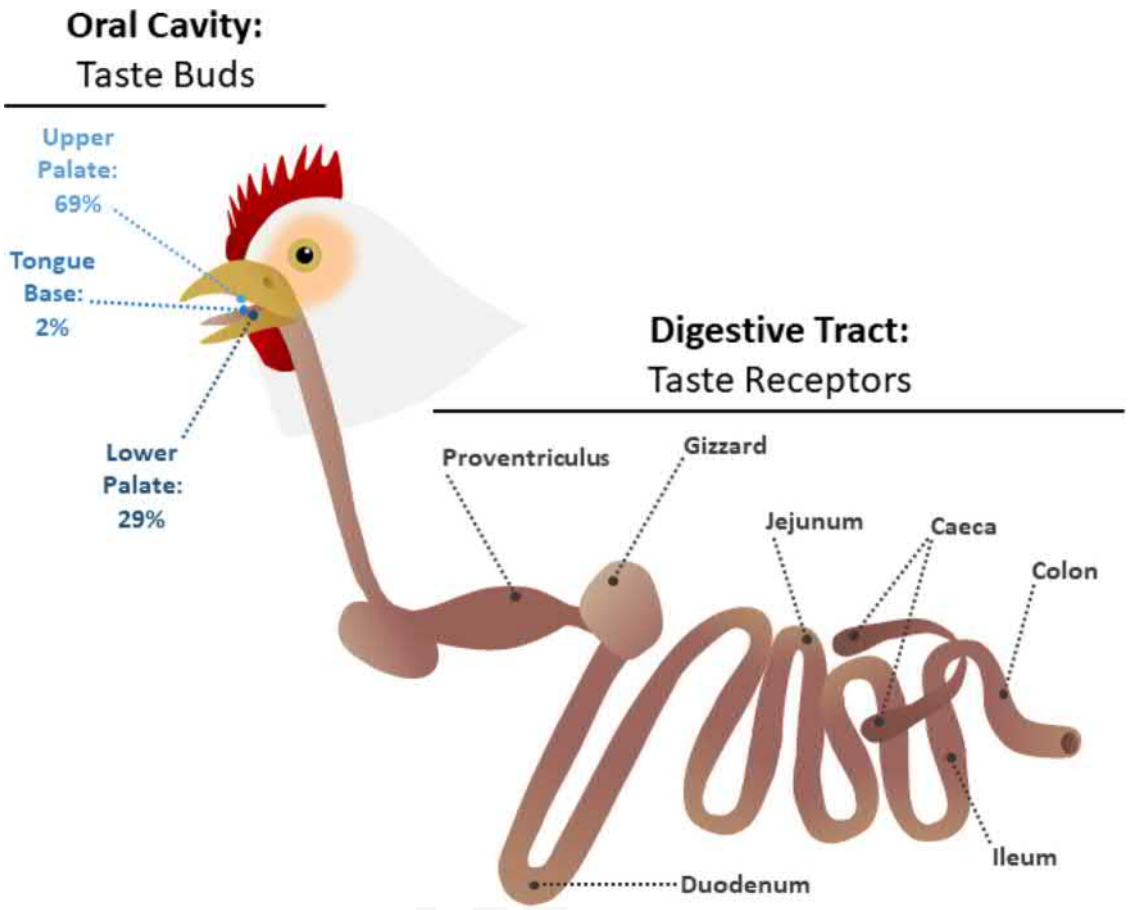

FIGURE 13.1 Taste buds distribution in the chicken oral cavity (as published by [Ganchrow and Ganchrow, 1985]) and gastrointestinal tract taste receptor expression sites (as published in [Cheled-Shoval et al., 2015]).

In the presence of the specific tastant, brain sites are ultimately signaled following binding to the receptors and subsequent signal transduction mechanism. It was shown that G-protein coupled receptors (GPCRs) are involved in the perception of sweet, umami, and bitter taste (as well as the potential sixth taste of fat) (Cygankiewicz et al., 2014), while salty and sour tastes are perceived by ion channels (sodium, potassium, or hydrogen) or ion exchanges (Mombaerts, 2004; Cygankiewicz et al., 2014). Based on mammalian studies, TRCs in the taste buds only express specific receptors for one tastant, respectively, sweet or bitter or umami or sour or salty tastants (reviewed Yarmolinsky et al., 2009). Based on the situation in mammals, taste buds contain 50 to 100 TRCs and can detect multiple tastants as the cells respond to different tastants (reviewed Yarmolinsky et al., 2009).

13.1.4.2 Caveat on taste receptors

The names employed for the taste receptors in this chapter will follow those employed by the authors of the papers cited. It is recognized that there are discrepancies with this approach with homologous proteins having different names.

13.1.4.3 Taste receptor type 1 receptors (tas1r family)

Taste receptor type 1 receptors (Tas1r) are G-protein coupled proteins consisting of three known receptors: Tas1R1, Tas1R2, and Tas1R3 (Li, 2009). This three receptors are responsible for the perception of sweet and umami as heterodimeric assembly by the arrangement of Tas1R1/Tas1R3 (a heterodimer receptor composed of Tas1R1 and Tas1R3 subunits) for umami and Tas1r2/Tas1R3 for sweet (Nelson et al., 2001, 2002; Li et al., 2002; Damak et al., 2003; Zhao et al., 2003).

13.1.5 Sweet taste

13.1.5.1 Overview

With the advances in genomic sequencing, it has been established that birds lack completely the Tas1R2 monomer (of the sweet taste heterodimer Tas1R2/Tas1R3) in their genome (chickens (Shi and Zhang, 2006); multiple avian species (Baldwin et al., 2014; Zhao et al., 2015)). Therefor it is not surprising that chickens nor jungle fowl can detect the sweet tastants, glucose, sucrose, and fructose at

concentrations mammals do (Halpern, 1962; Maller and Kare, 1967), or alternatively reject them at very high concentrations (Gentle, 1972; Cheled-Shoval et al., 2017b). Both suggesting insensitivity to sweet in galliforms and possibly alternative mode of sweet perception with different sweet tastants in these species (Table 13.2).

13.1.5.2 Sweet preferences in birds

Certain types of birds such as hummingbirds and sunbirds rely in their diets on nectar and fruits containing the disaccharide *sucrose*, the hexose monosaccharides *glucose* and *fructose,* and some more complex sugars (Vanwyk and Nicolson, 1995; Rowland et al., 2015). While in chicken and other galliforms, taste-related studies were mainly threshold related, in bird species that consume nectar and fruits; the studies focuses mainly on sugar type preferences at different concentrations. Sugar preferences in nectarivorous and frugivorous species can be concentration-dependent (Rowland et al., 2015). Even though Fleming et al. (2004) reported two nectivores—broad-tailed humming bird (*Selasphorus platycercus*) and white-bellied sunbird (*Nectarinia talatala*)—demonstrated very little discrimination between sucrose and hexose monosaccharides solutions, later on, different researches studying nectarivorous birds reported a shift from sucrose to hexose monosaccharides preference in lower solution concentrations (Lotz and Schondube, 2006, Fleming, 2008; Brown et al., 2010a,b). Village weavers (*Ploceus cucullatus*), a generalist passerine nectivores, demonstrated hexose solution preference at 5 and 10% over sucrose, but not at higher concentrations up to 25% (Odendaal et al., 2010). However, in the opportunistic nectivores, dark-capped bulbuls (*Pycnonotus tricolor*) a nonconcentration-related preference to hexose was demonstrated (Brown et al., 2008). These concentration-dependent shifts in preference may result from physiological causes as suggested by Lotz and Schondube (2006). It can be hypothesis that birds may prefer the easily absorbed hexose monosaccharides due to the extra energetically costs of sucrose hydrolyzes (Martínez del Rio, 1990).

Unlike specialist nectivores, generalist nectivores species usually display a nonconcentration-related preference for hexose monosaccharides (Rowland et al., 2015).

In frugivorous species, we can address two types—specialist and seasonal-generalist frugivores. In fruits, the most common sugars are hexose monosaccharides, fructose and glucose, while sucrose is accountable for only 8% of

TABLE 13.2 Different sweet taste responses in chicken.

Test (behavioral/electrophysiological)	Tastant	Concentration	Response
Behavioral	Glucose	>2.5%	None[a]
		5–30%	Rejection[a]
		30%	Rejection[b]
	Fructose	10%	Indifferent or rejection[b]
		20%	
		30%	
	Sucrose	1–30%	Preference[b]
		2.5–25%	Indifference[c]
		34.2%	Rejection[a]
Electrophysiological	Dextrose	2.5–25%	Indifference[c]
	Xylose	2.5–25%	Rejection
	Glucose	>2.5%	None[b]
	Fructose	10%	None[b]
		20%	
	Sucrose	1%	Rare response[b]
		10%

[c] *Kare and Medway (1959).*

total sugar content (Baker et al., 1998; Rowland et al., 2015). Some frugivores show preference to hexose monosaccharides over sucrose (Del Rio and Stevens, 1989; Brugger and Nelms, 1991; Del Rio et al., 1992).

Seasonal frugivores which do not rely on fruits as a main source of food seems to be less sensitive to solution concentrations (Rowland et al., 2015). Research done on red-winged blackbirds (relies more on grains) and starlings (relies on insects and fruits) showed insensitivity of the blackbird to fructose fitting their dietary niche while the starlings demonstrated a correlation between fruits and sugar preference (Espaillat and Mason, 1990; Rowland et al., 2015).

Regarding insectivore, omnivore and carnivore birds, ravens, as excepted from carrion eaters, did not show preference to five different sugar solutions compared to water (Harriman and Fry, 1990). Similarly, ducks and nonfrugivorous owls showed either rejection or indifference to sugar (Rowland et al., 2015). On the other hand, a preference for 7 and 14% glucose solutions was demonstrated in the great tit (*Parus major*) (Warren and Vince, 1963). It should be noted that the test conducted in this study was carried with choice, implying acceptance rather than preference. Similarly, other taste studies in these nonnectar or fruit eaters were done in manner that results demonstrate either acceptance, tolerance, or absorption rather than preference.

To that point, it is highly important, when talking on taste preference or taste threshold tests, to take into consideration the great variety of tests and the fact that most studies do not address the issues of viscosity (highly relevant in sweet taste), postingestive effects, and other important factors. This will be reviewed broadly later on.

13.1.5.3 The sweet dilemma

Despite the lack of Tas1R2 subunit in birds, we do see sweet taste perception in different birds as discussed above. So how do birds taste sweet? Baldwin et al. (2014) reported the hummingbirds anna's hummingbird (*Calypte anna*) and ruby-throated hummingbirds (*Archilochus colubris*) respond to sucrose due to repurposing their umami taste receptor Tas1R1/Tas1R3 such that it binds sucrose as well (discussed in more detail in Section 13.1.6 about the umami taste). In addition, birds might sense sweet tastants through only one of the sweet taste receptors subunit (Tas1R3) as suggested in mice (Treesukosol et al., 2011) or have an alternative mode of sensation for sweet tastants. This question warrants further study.

13.1.5.4 Evolutionary considerations of Tas1r2

It has been proposed that the loss of *Tas1r2* occurred in the carnivorous theropod dinosaurs that were ancestral to the avian lineage; carnivorous mammals having also lost (Beauchamp and Jiang, 2015; Antinucci and Risso, 2017). It is assumed that this is due to the relaxation of the selection pressure for maintaining a functioning TAS1R2 gene (Antinucci and Risso, 2017). When examining the evolutionary process, we see that the nonavian reptiles gained the Tas1R2 back, another hint that the loss occurred within Dinosauria. Taking into consideration the previous section, it seems that birds who rely mainly on nectar or fruit in their diets developed a Tas1R2-independent sweet taste perception mechanism (Baldwin et al., 2014).

13.1.6 Umami taste

13.1.6.1 Overview

Umami taste is related to dietary protein and senses some amino acids (AAs), such as glutamic acid (Glu). Similarly to the sweet and bitter taste, the umami taste is mediated by GPCRs. Avian umami taste receptor is a heterodimer composed of two GPCR subunits: Tas1r1 and Tas1r3. The umami taste receptors shares the same three-dimensional architecture described for the sweet taste receptor (Pin, 2013) and switches between an "open-open/inactive" conformation to a "closed-open/active" conformation (Cascales et al., 2010).

The Tas1r1 and, therefore, the ability to detect umami is not present in all avian species. Reports on the Adelie penguin (*Pygoscelis adeliae*) and emperor penguin (*Aptenodytes forsteri*) show that Tas1r1 is a pseudogene (Zhao et al., 2015). Similarly, the Tas1r1 is not found in the red-throated loon (*Gavia stellata*) (Zhao et al., 2015).

The chicken umami receptor responds to *alanine* and *serine* (known to stimulate the umami receptor in rodents and fish). Studies on European starling (*Sturnus vulgaris*) and red-winged blackbird (*Agelaius phoeniceus*) demonstrated the ability to taste L-alanine (Espaillat and Mason, 1990; Werner et al., 2008). Response to alanine, and to a less extent serine, is detected in the insectivorous chimney swift (*Chaetura pelagica*) and in chicken (Baldwin et al., 2014). In contrast, the umami receptor in hummingbirds (Anna's hummingbirds [*Calypte anna*]) responds to sugars (sucrose > fructose >> glucose) and to alanine, albeit poorly (Baldwin et al., 2014). Thus, it is suggested that the umami receptor in birds has acquired the ability to respond to sugars while losing their ability to respond to alanine or serine (Baldwin et al., 2014).

The chicken umami receptor responds to L-glutamate (L-Glu), first discovered as an umami tastant in by Ikeda (1909). Glutamate umami taste intensity can be strongly potentiated by purine ribonucleotides, such as 5′-monophosphate (IMP) and guanosine 5′-monophosphate (GMP) (Zhang et al., 2008; Dang et al., 2014). Glutamate, IMP, and GMP are the most renowned modulators of the umami taste receptor, but many other substances, including peptides and free AAs, can elicit and/or enhance the umami taste (Yu et al., 2017; Zhang et al., 2019).

A functional umami taste receptor heterodimer (Tas1r1/Tas1r3) has been predicted in most mammalian, bird, and fish with some exceptions (Shi and Zhang, 2006; Roura et al., 2008; Zhao et al., 2010; Jiang et al., 2012). This wide distribution across vertebrate species makes the umami taste an important and highly conserved taste. Accordingly, it is rational to hypnotize that the chicken umami taste might be activated by a broad array of AA. Identifying the umami compounds that might be driving protein-specific appetite in chickens is a fundamental question to improve feed intake and efficiency of feed utilization in poultry diets and to adopt new alternative feedstuff to poultry diet.

13.1.6.2 Umami preference test in birds

Preference for Glu has been described in several animal species including chickens (Roura et al., 2008, 2013). Moran and Stilborn (1996) found that L-Glu increased feed intake and growth in broiler chickens fed minimal crude protein with adequate essential AA (Moran and Stilborn, 1996). Similar results are reported for turkey poults (Boling and Firman, 1997). However, supplemental Glu to broiler diets without adequate AA balance may have a negative impact on appetite (Kerr and Kidd, 1999).

Sensing of lysine, methionine, and tryptophan was demonstrated in a choice-feeding situation, were broiler chicks showed an immediate preference for a balanced diet containing synthetic AA compared to a similar diet deficient in lysine, methionine, and tryptophan (Picard et al., 1993).

13.1.7 Taste receptor type 2 receptors

Bitter taste receptors are seven transmembrane domain GPCR family termed taste 2 receptors (TAS2Rs) which was identified in 2000 (Adler et al., 2000; Matsunami et al., 2000) and their downstream signaling components (Sanematsu et al., 2014). This gene family varies widely between species from none to ~80 (Li and Zhang, 2014), with ~25 functioning genes in humans, and only 1 in turkeys (see Table 13.1). Within avian, the number of TAS2R genes also varies markedly:

- *Galliformes*: chicken (*Gallus gallus*)—3, respectively TAS2R1, TAS2R2, and TAS2R7 (Zhao et al., 2015).
- *Sphenisciformes*: penguins—0 (Zhao et al., 2015).
- *Passeriformes*: white-throated sparrow—17 (15 para-orthologs of zebra finch *TAS2R1 resulting from gene duplication* [Davis et al., 2010]).

TAS2R genes are unusual in lacking introns (reviewed Antinucci and Risso, 2017) and are ~900 base pairs. TAS2Rs have short extracellular N-terminal domain (Maehashi and Huang, 2009) and are characterized by highly conserved motifs in the transmembrane domains, while variable in the extracellular region enabling the recognition and binding of chemically divers bitter substances (Maehashi and Huang, 2009; Yarmolinsky et al., 2009). Following its complete sequencing in recent years, it was shown that the chicken genome contains only three TAS2Rs—ggTAS2R1, ggTAS2R2 (both similar to the human hTAS2R39 and hTAS2R40 gene groups), and TAS2R7 (similar to the human hTAS2R7 and hTAS2R9 gene groups) (Go and SMBE Tri-National Young Investigators, 2006; Lagerstrom et al., 2006).

13.1.8 GPCRs' taste signal transduction

13.1.8.1 Overview

Studies in mammalians demonstrate that TAS1R and TAS2R receptors share a similar signaling pathway following the activation of the receptors although TRCs can express only one type of receptor, i.e., bitter, sweet, or umami taste receptors but not simultaneously together (Ishimaru, 2009; Cygankiewicz et al., 2014). The binding of a taste molecule (or a tastant) to either TAS1Rs or TAS2R receptors found on the apical membrane of TRCs leads to the activation and dissociation of the heterotrimeric G-protein subunits, which include α-gustducins Gαi2, Gα14, Gβ3, and Gγ13, and are co-expressed together with bitter, sweet, and umami receptors in TRCs (Ishimaru, 2009). This leads to the activation of two major signaling pathways: (i) the dissociated Gα14 and/or Gβ3/Gγ13 activate phospholipase C (**PLC**)-β2. This initiates the hydrolysis of phosphatidylinositol 4,5-biphosphate (PI(4,5)P_2) to inositol triphosphate (**IP_3**) and di-acylglycerol, followed by binding of IP_3 to IP_3R3 (IP_3 receptor 3). This binding causes the release of Ca^{2+} from intracellular stores and the subsequent opening of transient receptor potential melastatin 5 (**TRPM5**) channels, Na^+ influx, and the final depolarization of the TRCs (Yamamoto and Ishimaru, 2013). (ii) in the second pathway, which involves **cAMP**, it is suggested that the α subunit causes two opposite reactions: increase of cAMP levels by the activation of adenylyl cyclase (**AC**) and decrease of cAMP level by phosphodiesterase activation. While the decreased cAMP levels are thought to lead to Ca^{2+} release as well together with the PLCβ2 pathway, the elevated cAMP levels from AC activate PKA kinase which in turn phosphorylate K^+ channels which inhibits them causing the TRCs membrane polarization and neurotransmitter secretion (Cygankiewicz et al., 2014, see Figure 13.2).

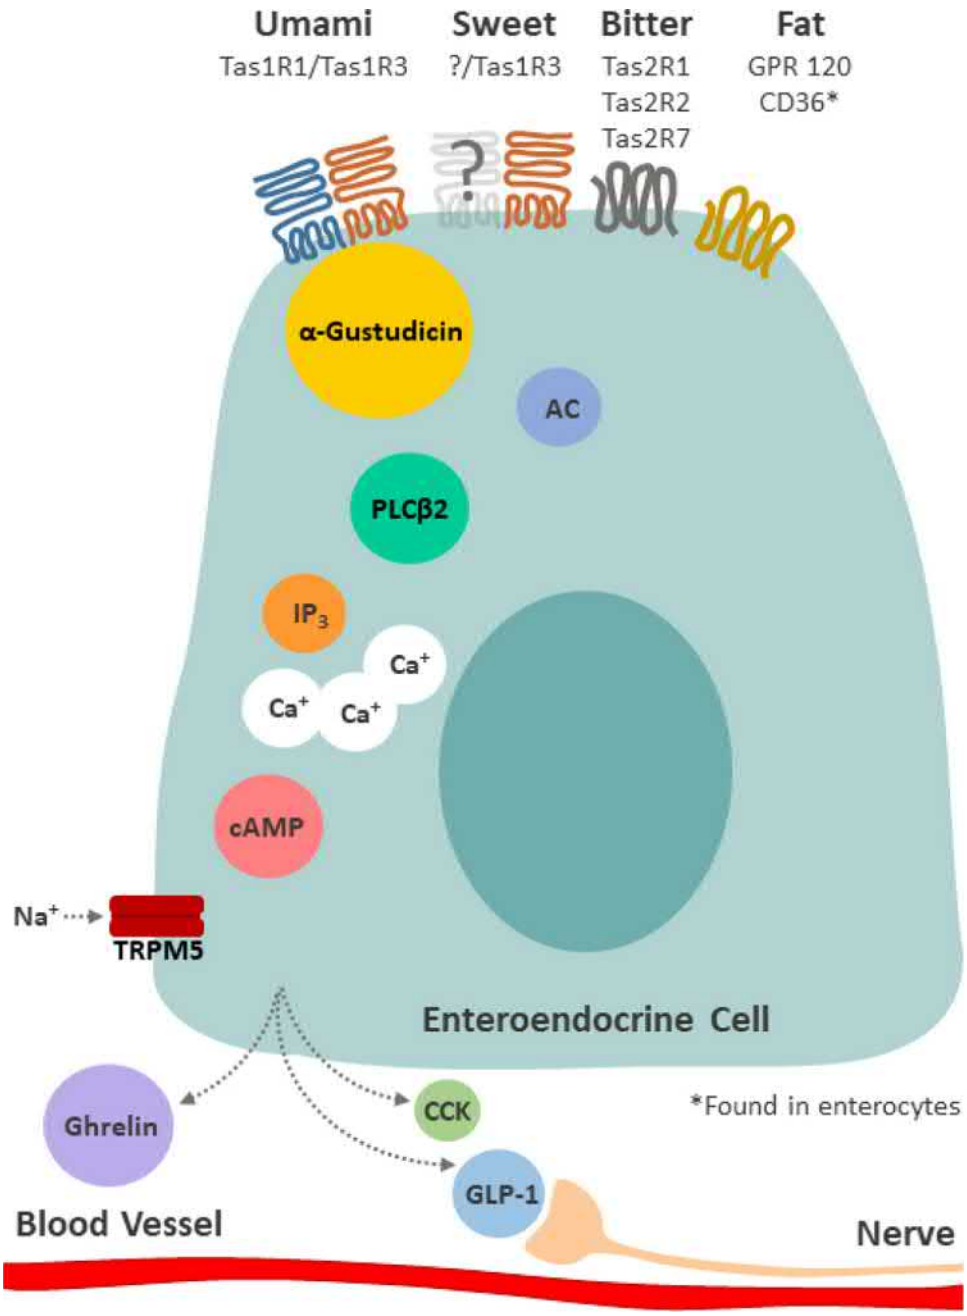

FIGURE 13.2 Basic illustration of extra-gustatory taste-receptors' chemosensory pathways, located in enteroendocrine cell of chicken GIT. Tastants are recognized by different taste receptors (sweet, bitter, amino-acids), inducing signaling pathways which in turn initiates, with the gustducin/transducin protein, the PLCβ2-mediated synthesis of IP3, causing the release of Ca^{2+} from intracellular storage together with reduction in cAMP levels through phosphodiestrases, all leading to the release of GI peptides involved in food intake and gut functionality regulation. *Adapted from Rozengurt (2006), Janssen and Depoortere (2013).*

13.1.8.2 Sequencing of taste receptor type 2 receptors (TAS2R) in birds

13.1.8.2.1 TAS2R1 and TAS2R2

Wang and Zhao (2015) examined 48 genomes of birds representing all but three avian orders for bitter taste receptor genes. The number of TAS2R genes ranged from 1 in the domestic pigeon to 12 in the bar-tailed trogon. An average of four TAS2Rs repertoire was identified. Interestingly, the diet of the birds and number of putative functional TAS2Rs showed positive correlation, with herbivorous and insectivorous having more functional TAS2Rs than carnivorous, with less potential toxins in their diets.

The sequences of both TAS2R1 and TAS2R2 in birds have been reported:

- TAS2R1 [*Galliformes*: chicken—Genbank KT377152; *Casuariiformes*: emu (*Dromaius novaehollandiae*)—Genbank AB608217; Northern fulmar (*Fulmarus glacialis*)—Genbank KP121490; *Gaviiformes*: red-throated loon (*Gavia stellata*)—Genbank KP121495; *Passeriformes*: western yellow wagtail (Motacilla flava)—Genbank GU815912]
- TAS2R2 [*Galliformes*: chicken—Genbank KT377157; *Casuariiformes*: emu (*Dromaius novaehollandiae*)—Genbank AB630153; *Procellariiformes*: e.g., Hawaiian black-footed albatross (*Phoebastria nigripes*)—Genbank KP121501; Northern fulmar (*Fulmarus glacialis*)—Genbank KP121500]

13.1.8.2.2 Other TAS2R genes

The sequences of amino acid residues for other TAS2R proteins have been reported in birds: namely, chicken TAS2R7 (NM_001080719); turkey TAS2R9 like (Genebank XM_003204660) and mallard duck TAS2R9 like (XM_027455347). These TAS2R proteins exhibit marked homologies (see Figure 13.3) suggesting the terminology needs revision.

13.1.8.2.3 Evolutionary aspects of taste receptor type 2 receptors

With the emergence of genomic data availability, it can be concluded that the avian TAS2R genes repertoire was submitted to vigorous changes (either expansions or deletions) through evolution (Go and SMBE Tri-National Young Investigators, 2006; Dong et al., 2009; Wang and Zhao, 2015). Despite the lower average TAS2R numbers in birds, it has been demonstrated using in vitro cell-based models, that the promiscuity of the receptors enables the recognition of a broad bitter tastant repertoire, similar to that in other vertebrates with higher numbers of putative functional TAS2Rs (Behrens et al., 2014).

In Passeriform birds, the TAS2R1 gene has undergone multiple gene duplications resulting in the increases in the number of TAS2R genes (see Table 13.1 and Figure 13.4). Moreover, the white-throated sparrow has 15 para-orthologs of zebra finch TAS2R1 (Davis et al., 2010). Similarly, it would appear that the TAS2R1 gene underwent multiple (four) gene duplications in humming birds (Anna's humming bird [*Calypte anna*]) (Wang and Zhao, 2015; Wang et al., 2019).

Bitter taste receptors are not present in either penguins or gaviiform birds with all the TASR2 genes having undergone pseudogenization in the ancestors to penguins and/or gaviiform birds (Zhao et al., 2015). The loss of functioning TAS2R in these two avian groups may be independent. Similarly, in aquatic mammals, there are no functioning TAS2R genes in cetacean species (Li and Zhang, 2014).

13.1.9 Bitter taste

13.1.9.1 Overview

Bitter tastants are a part of birds' nutrition originating in plants, insects, and even nectars. Studies on bitter taste thresholds focused mainly on more traditional bitter tastants

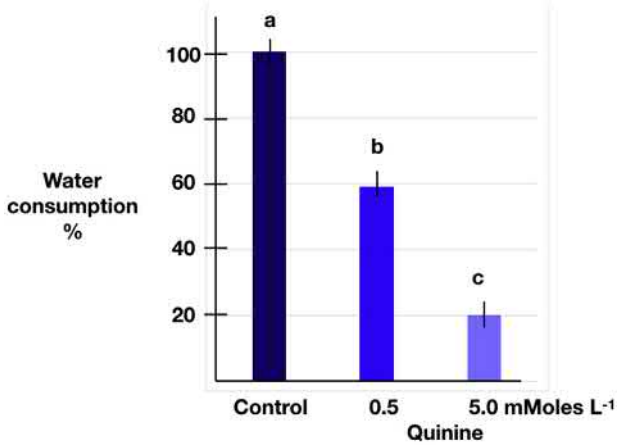

FIGURE 13.3 Comparison of the sequence of amino acid residues in chicken TAS2R7 (NM_001080719) with turkey TAS2R9 like (Genebank XM_003204660) and mallard duck TAS2R9 like (XM_027455347). [Yellow Chicken and identical to chicken in turkey and duck; Green identical between turkey and duck; Blue Difference between turkey and chicken; Red Difference between duck and chicken].

in mammals such as quinine. Chickens, probably the most researched bird regarding bitter taste, demonstrates a dose-dependent and strain-dependent behavioral aversion responses to bitter tastants from embryo to adult (Gentle, 1975; Vince, 1977; Ganchrow et al., 1990; Kudo et al., 2010; Cheled-Shoval et al., 2014, 2017b). Quinine threshold, based on in vivo trials, was identified by Matson et al. (2004) to be 100 μM for quinine in cockatiels. In the egg laying type chickens, White Leghorn and Rhode Island Red chicken, quinine threshold was 2.0 mM (Kudo et al., 2010), while broilers demonstrated a lower threshold of 0.3 mM (Cheled-Shoval et al., 2014). Electrophysiological tests demonstrated lingua nerve responses between 0.01 and 0.02 M (Kitchell et al., 1959; Halpern, 1962) and chorda tympani responses to higher quinine concentration of 0.1 and 0.05 M (Gentle, 1981, 1983). In vivo quinine thresholds in chickens, also confirmed by in vitro cell-based techniques, demonstrated 0.01 mM threshold (Cheled-Shoval et al., 2014, Table 13.3). These variations in threshold emphasize the need of a unified and clear protocol for threshold termination tests, as suggested and reviewed in depth by Cheled-Shoval et al. (2017b).

13.1.9.2 Agonists of bitter receptors (TAS2R)

Different TAS2R exhibits differential responsiveness to various TAS2R agonists (Behrens et al., 2014), information regarding chicken bitter ligands also accessible via the BitterDB database http://bitterdb.agri. huji.ac.il/dbbitter.php (Wiener et al., 2012). Although quinine is viewed as the "classical" agonist for TAS2R, there are TAS2R agonists that are more potent (Table 13.4).

In chicken, several ggTAS2s ligands were identified by using both in vitro and in vivo methods, such as quinine, (+)-catechin, (−)-epicatechin and epicatechin gallate (Cheled-Shoval et al., 2017a).

In addition, a comprehensive study (Behrens et al., 2004) using cell-based methods specifying the chicken three ggTAS2Rs ligand repertoires, with three compounds are conserved between all three ggTAS2R2. Comparing these ligands to their human homologous receptors, it is evident that while ggTAS2R1 and ggTAS2R2 repertoires are similar in sizes to their human homologs, they are also mostly different in the identity of their ligands. The ggTAS2R7 repertoire, however, differs both in ligand numbers (higher number of ligands) and in their identity (Di Pizio and Niv, 2015). These changes in the chicken receptors in ligands suggest a possible positive selection acting on the ligand recognition and binding regions of the ggTAS2R7 receptor, which may explain this diversification in ligand phenomenon.

Similarly, Wang et al. (2019) demonstrated in hummingbirds a different level of sensitivity together with new functions in the hummingbird TAS2R gene copies proposing positive selection in these genes. The study suggested the hummingbird bitter taste evolution enabled increased sensitivities and specialized abilities to detect bitter-tasting nectar in order to maintain specificity of pollinators.

13.1.9.3 Ecological influence on bitter taste

It has been argued that the retention of multiple functioning TAS2R genes in hummingbirds is advantageous facilitating

TABLE 13.3 In vivo thresholds for sweet, umami, and bitter in chickens and different mammals

detection of nectar that is bitter containing deleterious toxicants, e.g., plant alkaloids or polyphenolic tannins or insect secretions or is spoiled (Glendinning, 1994; Wang and Zhao, 2015). The absence of a functioning TAS2R in sphenisciform or gaviiform birds presumably reflects a lack of utility of detecting bitter tastants in these waterbirds.

The threshold for rejection of bitter-tasting potential foods varies with the species of bird's diet (Glendinning, 1994). Carnivores have a low threshold and reject foods with even low concentrations of bitter-tasting chemical agents. In contrast, herbivores have a high threshold to bitter tastes (Glendinning, 1994).

13.1.10 Salt and sour taste

Different from sweet, bitter, and umami tastes which are mediated by GPCRs, gustducin, and downstream signaling cascades, the salty and sour tastes modulate taste function by direct entry of H+ and Na+ ions through specialized membrane ion channels. For sensing salty and sour, the epithelial sodium channel (ENaC), the polycystic kidney disease (PKD) channels, the transient receptor potential (TRP) channel M5 (Trpm5) are utilized.

13.1.10.1 Salt taste receptor in birds

The receptor for salty taste is a heteromer consisting of subunit sodium channel monomers, specifically Scnn1a, Scnn1b, and Scnn1g (Zhao et al., 2015; Antinucci and Risso, 2017). These are members of the sodium channel gene family (SCNN) (Zhao et al., 2015). Salty taste receptors are present in all avian species including penguins (Zhao et al., 2015).

Deduced sequences of Scnn1a have been reported in multiple avian species: *Anseriformes*: black swan (*Cygnus atratus*)—Genbank XM_035571576; *Galliformes*: chicken—Genbank NM_205145; *Pelecaniformes*: little egret (*Egretta garzetta*)—Genbank XM_009639112; *Passeriformes*: New Caledonian crow (*Corvus moneduloides*)—Genbank XM_032098703. The SCNN1a gene is located on chromosome 1 (chicken (Habermann et al., 2001)).

13.1.10.2 Salty preferences tests

Preferences tests show that birds respond to sodium chloride (NaCl). High concentrations elicit aversion, whereas low concentrations are usually attractive, particularly after sodium depletion (Kare and Mason, 1986). In a diet choice situation, chickens on Na-deficient diet will select NaCl solutions up to 9 g/L while higher Na concentrations are rejected. Aversion starts with solutions of 250 mM while preferences are between 85 and 100 mM (Duncan, 1962). Avoidance to a 5% NaCl inclusion (870 mM) was reported by Balog and Millar (1989).

13.1.10.3 Sour taste receptor in birds

The receptors for sour taste are the transmembrane channels that are selective for H+ ions. Several of these channels have been identified in mammals (Bachmanov and Beauchamp, 2007). Both ENaC and H+ ion channels orthologous genes are present in chicken genome databases. The sour sensing is mediated by Pkd2l1 (PKD2L1 gene) and HCN1 receptor proteins. PKD2L1 was identified in each of the 16 bird genomes examined (Zhao et al., 2015) and is a member of the TRP channel gene family.

13.1.10.4 Sour preferences tests

Sensitivity to acids changes with avian species and with age (Mason and Clark, 2000). Chickens were tolerant to medium acidic or alkaline solutions but avoided solutions with

extreme pH (acid or alkaline) (Fuerst Jr and Kare, 1962). Chicken also avoid 0.2 M (or higher) hydrochloric and acetic acid solutions (Gentle, 1972) and avoid as well high concentrations (6%) of citric acid (Balog and Millar, 1989) and some acid blends (Viola et al., 2008). It might be interesting to reconsider the sour taste modality since there are indications on some positive preferences for acidic pH in chickens (Kare and Mason, 1986; Mason and Clark, 2000).

13.1.11 Fatty acid taste

Evidence in human and rodents supports the existence of a unique taste for fat and suggest that oral perception of fatty acid is a sixth basic taste quality (Gaillard and Kinnamon, 2019). Fat taste starts when triglycerides in the oral cavity are hydrolyzed into free fatty acids (FFAs), by lingual lipases, which in turn stimulates taste cells in the taste buds. At the surface of the cell membrane, the FFA ligand binds to two types of proteins, a G-protein-coupled receptor 120 (GPR120) and CD36 (Cartoni et al., 2010). This binding triggers a cascade of signaling events, leading to an increase in intracellular calcium which in turn mediates the depolarization of the cell and the release of neurotransmitters onto gustatory nerve fibers (Reed and Xia, 2015).

There is evidence that birds can detect fat. The structure of one of the putative receptors for fatty acids, GPR120, has been reported in chickens (Sawamura et al., 2015).

As for fat taste preference, gustation plays a key role in determining oil preferences in chickens (Furuse et al., 1996). Furthermore, chickens prefer feed containing oleic acid and linoleic acids than feed with mineral oil added instead (Sawamura et al., 2015).

13.1.12 Extra gustatory taste in birds

13.1.12.1 Overview

One of the major breakthroughs of taste research in the past two decades is the revelation of taste receptors and taste signaling components such as TRPM5, PLCβ2 and the G-protein subunits in extra-gustatory tissues. These taste-related molecules were found to be expressed not only in taste buds but also on varied extra-oral cells such as brush cells or enteroendocrine cells in different tissues such as the respiratory system, testis, heart, liver, pancreas, brain, and the gastrointestinal tract (GIT). Even though their exact function in each tissue is still to be determined, it is clear that taste receptors sense nutrients in these extra-gustatory tissues and that the signaling components participate in transduction pathways similarly to those in gustatory tissues (Yamamoto and Ishimaru, 2013) suggesting these pathways are not restricted to taste perception per se alone (Figure 13.2). Indeed, these sweet, bitter, and umami taste pathways were shown to be involved in many gut physiological mechanisms (Jang et al., 2007; Jeon et al., 2008; Janssen et al., 2011; Shirazi-Beechey et al., 2014; San Gabriel, 2015), all are key factors in gut functionality and feed intake regulation.

Despite the importance of taste pathways in these intestinal pathways and its great potential implications in birds in general and chicken production and nutrition as an agriculture animal particularly, the research of avian taste perception in the GIT has only started to thrive very recently, with focus on chicken.

13.1.12.2 Gene expression of taste receptors and signaling molecules in extra-gustatory tissues in chicken

With the release of the chicken full genome (Hillier et al., 2004), the three bitter taste receptors were identified in its genome, together with the lack of Tas1r2 (Lagerstrom et al., 2006; Shi and Zhang, 2006). The identification of taste-related genes outside of the oral cavity in chickens was reported only almost a decade later. In 2010, Byerly et al. identified T1R1 expression in the chicken hypothalamus, with higher expression in fat broilers compared to lean. Between 2014 and 16, publication reported the expression of the three chicken bitter taste T2Rs—*ggTAS2R1*, *ggTAS2R2,* and *ggTAS2R7*, 2 sweet/umami T1Rs—*ggTAS1R1* and *ggTAS1R3*, and the downstream signaling effectors *α-gustducin*, *PLCβ2,* and *TRPM5* along the chicken GIT (Cheled-Shoval et al., 2014, 2015), the expression of the umami taste receptor *mGluR* in the chicken GIT (Yoshida et al., 2015) and the expression of the fatty acid receptors GP43 GPR120 and CD36, suggesting that taste pathways are involved in the chicken GIT's sensing of different nutrients such as carbohydrates, amino-acids, and bitter compounds (potential toxins). These taste-related genes, detected by real-time PCR, were found at different expression levels in the GIT's different sections, palate, tongue, ventriculus (gizzard), duodenum, jejunum, ileum, cecum, and colon (Figure 13.1). In recent years, more publications reported the expression on additional taste-related genes in both the oral cavity and extra-gustatory tissues in birds (Mazzoni et al., 2016). Differences in taste-related genes expression were observed between two developmental stages (embryo ver. mature broiler), both in the oral cavity and in the GIT.

13.1.12.3 Effect of tastants on gene expression

Investigation on how taste-related genes expression is affected by tastants in both oral cavity and extra-gustatory tissues such as the GIT or in cell-based methods is scarce. Cheled-Shoval reported an elevation in *ggTAS2Rs*, *PLCβ2*,

and *α-gustducin* expression in the palate and duodenum of chickens following bitter tastant administration together with a subsequential elevation in sensitivity to the tastant (Cheled-Shoval et al., 2014).

13.1.13 Measuring taste perception in birds: aversion or preference testing

13.1.13.1 Methods for taste perception tests

Methods include (i) gustatory nerve recordings following chemical stimuli and electroencephalogram (EEG) analysis of arousal patterns (Halpern, 1962; Gentle, 1972, 1983) (ii) cell-based assays using Ca^{2+} imaging technology (Behrens et al., 2014; Cheled-Shoval et al., 2014; Dey et al., 2017; Su et al., 2019) (iii) behavioral responses to oral stimulation such as beak movements, head shaking, beak clapping, etc., in both embryos and mature chickens (Vince, 1977; Gentle and Harkin, 1979; Gentle, 1981; Ganchrow et al., 1990), and (iv) detection or preference taste threshold determination using aqueous solutions via no-choice, double choice, or multiple choice. In these tests, the tastants are dissolved in distilled water usually and consumption is recorded throughout the trial (Pfaffmann, 1956; Jacobs and Scott, 1957; Kare and Medway, 1959; Fuerst Jr and Kare, 1962; Gentle, 1972; Kudo et al., 2010).

These methods, mainly examining sweet, bitter, and sour tastes varied greatly in their choice manner (no-choice, 2-AFC, or multiple choice), their length (min, h, days, or weeks), their developmental stage (embryos, young chicks, or mature chickens), strains tested (hens vs. broilers) and included various perception measurements including behavioral indications, consumption sometimes together EEG analysis of arousal patterns. Notably, choice tests results are not considered as an acuity threshold but only a preference/avoidance threshold representing a changed behavior (preferring or aversion) to a stimulus solution over water.

It is highly important to note that due to this high diversity of methods (behavioral, consumption, and physiological responses) and the use of different strains, ages, and tests-length, the results of these studies of taste perception in birds show inconsistency and great variability.

13.1.13.2 Preference tests in birds

Choice or preference systems have demonstrated that generally birds avoid water containing bitter tastants, while in nectar consuming birds increased consumption of sucrose containing water was identified. Given a choice between water and water containing quinine hydrochloride, chickens avoid the quinine water in a concentration-dependent manner (Cheled-Shoval et al., 2017b, see Figure 13.5). The threshold for this effect is between 0.1 and 0.2 mM (Cheled-Shoval et al., 2017b). In contrast, the threshold for chickens avoiding water containing monosodium glutamate is between 300 and 500 mM (Cheled-Shoval et al., 2017b). Moreover, there was preference for plain water or avoidance for inosine 5′-monophosphate containing water (Cheled-Shoval et al., 2017b). In choice studies, chickens avoided solutions containing the umami tastes, serine, alanine, and glutamate together with inosine 5′-monophosphate (Yoshida et al., 2018). Chickens exhibited a preference for water rather than water containing bitter tasting, TAS2R agonists, with marked differences in the threshold (Table 13.5, Cheled-Shoval et al., 2017a). Hummingbirds exhibit increased drinking of water when it contains sucrose or fructose broad-billed hummingbird (*Cynanthus latirostris*) (Medina-Tapia et al., 2012); ruby-throated hummingbird (*Archilochus colubris*), Anns's hummingbirds (*Calypte anna* (Baldwin et al., 2014). Comparisons of chicken thresholds to humans and rat showed that while bitter threshold is similar, chickens are less sensitive to umami and even less sweet tastes, which is in agreement with the lacking of the Tas1R2 unit from the chicken genome (Table 13.4).

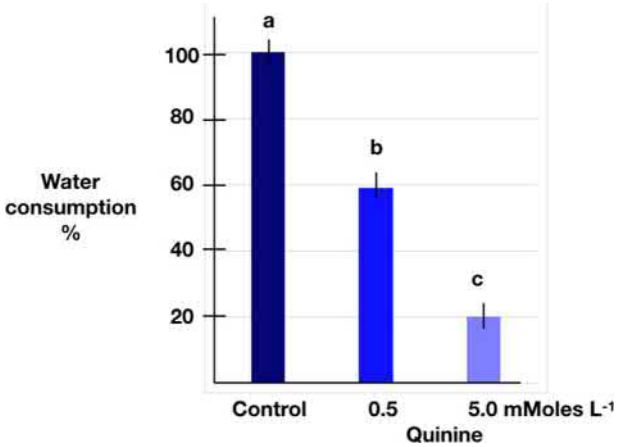

FIGURE 13.5 Consumption of quinine containing water in chicks in a preference system (provided with a choice between water and quinine containing water expressed as a percentage [a, b, c difference letters indicate difference $P < .05$]. *Adapted from Cheled-Shoval et al. (2017a).*

TABLE 13.5 Preference for water compared to agonist containing water by chickens (Cheled-Shoval et al., 2017a).

Receptor activated in vitro	Specific agonist	In vivo threshold mM
TAS2R1	Nicotine	0.33
TAS2R2	Caffeine	10
TAS2R7	(+)-catechin	3
TAS2R7	Erythromycin	0.1
TAS2R1,R2,R7	Quinine HCl	0.3

13.1.13.3 In vivo versus in vitro thresholds

In recent years, one of the most common in vitro method used in taste perception studies of birds is the cell-based functional expression assays for the determination of a receptors' activation by taste potential ligands (Behrens et al., 2004, 2009, 2014; Brockhoff et al., 2007, 2010; Reichling et al., 2008; Meyerhof et al., 2010; Dey et al., 2017). These in vitro cell-based threshold tests indicate only activation of the receptor and not guaranteed actual perception threshold of the bird. Taste receptors can be either broad (activated by a large number of ligands) or narrow (activated by a small number of ligands) or even singular (activated by a single ligand). A comparison of chicken in vivo and in vitro thresholds between TAS2R-selective and TAS2R-promiscuous ligands and the difference between ligands activating individual ggTAS2Rs showed that no simple relationship between in vivo and in vitro thresholds exist. Even same-receptor activators with similar in vitro thresholds (for example, (+)-catechin and erythromycin for ggTAS2R7) had different in vivo avoidance thresholds Cheled-Shoval et al. (2017a).

These results demonstrate that even in the simplest possible TAS2R system such as chicken, the relation of these two methods is complicated and the strength of the in vivo response could not be accurately predicted from cellular data.

13.1.14 Conclusions

It was commonly assumed birds have limited sense of taste mainly as a result of lower numbers of taste buds and of bitter taste receptors and the lack of the sweet taste receptor subunit Tas1R2 in the avian linage. However, accumulating data including behavioral, genomic, genetic, and molecular studies demonstrates clearly that birds possess a well-developed sense of taste governing nutritional evaluation and feed choices as in other vertebrates (see Table 13.3). In addition to taste perception, per-se taste receptors and their downstream proteins signals have been identified in birds outside the oral cavity, mainly along the GIT as well as in other extra-gustatory tissues such as the airways. These taste receptors, which are located in enteroendocrine cells in the GIT (Figure 13.2), have been shown to be involved in different gut functionality, metabolic and endocrinic pathways in mammals, and it can be assumed to be involved in a similar manner in birds.

There is substantial scope for future research on taste in birds. Questions that may be poised include the following:

- Why have birds so few taste buds? Is it related to the lack of chewing?
- What is the correct terminology for avian TAS2R genes?
- When did the sweet receptor lost in avian evolution?
- Why is advantageous to have more than one bitter taste receptors?
- Why are there more functioning TAS2R2 genes in passerine birds?
- Can the ability of poultry to detect different tastants be employed to increase feed intake?
- What is the relevance of taste receptors in the gastrointestinal tract and other organs?

Future research on the molecular mechanisms governing eating behavioral responses, taste perception and intestinal functionality and their interactions, all key features in both wild and domesticated avian nutrition and production, will help elucidate the role of taste in avian feed-intake regulation, feed choice, and acceptance, both ecologically and evolutionary.

Chapter 14

Avian nociception and pain

N.J. Beausoleil, S.E. Holdsworth and H. Lehmann
Animal Welfare Science and Bioethics Centre, School of Veterinary Science, Massey University, Palmerston North, Manawatū, New Zealand

14.1 Introduction

14.1.1 What is pain and what is it for?

Animal pain is defined as "*an aversive sensory and emotional experience representing an awareness by the animal of damage or threat to the integrity of its tissues … it changes the animal's physiology and behavior to reduce or avoid damage, to reduce the likelihood of recurrence and to promote recovery*" (Molony and Kent, 1997). Thus, the ultimate function of pain is to protect the animal from current and future tissue damage (Viñuela-Fernández et al., 2007). This function is achieved through two inter-related processes: nociception and the emotional experience of pain. Nociception is the sensory component and involves the sensory and motor systems that detect and respond to damaging or potentially damaging (noxious) stimuli (Dubin and Patapoutian, 2010). The emotional component of pain, the unpleasant "pain experience", arises only when nociceptive signals are transmitted to areas of the brain associated with generating emotions and with motivational learning (Bateson, 1991, Fig. 14.1). The emotional and cognitive components of pain are proposed to provide the animal with long-lasting motivation to avoid noxious stimuli and better protect itself from damage in the future (Bateson, 1991; Elwood, 2011).

14.1.2 Why does pain matter?

Birds are exposed to many situations, conditions, and procedures that result in tissue damage and thus have the potential to cause pain. Clinically, common causes of damage in wild and pet birds are predator attacks, vehicle collisions, self-mutilation, and diseases (Malik and Valentine, 2018). In production systems, birds are subject to damage due to husbandry procedures such as debeaking and dubbing, injuries related to transport, shackling and feather pecking, and conditions such as keel fractures, osteoarthritis, footpad dermatitis, and myopathies associated with breeding for production traits and/or management conditions (e.g., Gentle, 2011; Hothersall et al., 2016; Norring et al., 2018; Thøfner et al., 2020). Thus, there is clearly scope for many birds to experience pain, which may impact on their welfare, productivity, and behavior.

Because of the inherent unpleasantness of the pain experience, understanding and avoiding animal pain is important for safeguarding their welfare. An animal's welfare state represents the sum of all its mental experiences; these arise due to interpretation, by the animal's brain, of sensory information about its internal and external environment (Beausoleil and Mellor, 2017). Unpleasant experiences motivate the animal to act to rectify the problem and/or reduce the risk of future reoccurrence (Elwood, 2011; Williams et al., 2019). Problems that cannot be effectively rectified through behavioral and physiological responses will have a greater detrimental impact on welfare than acute experiences. Thus, chronic pain is of greater concern for bird welfare than acute pain, which is relatively short-lived. Chronic pain arises when the nociceptive pathways are sensitized following damage, resulting in hyperalgesia (noxious stimuli are more painful) and/or allodynia (innocuous stimuli are painful) (Dubin and Patapoutian, 2010). This state can last long after the original damage has healed. Because of its greater significance to the animal, chronic pain is more likely than acute pain to result in long-term changes in behavior and motivation and to confer survival benefits in terms of reducing the likelihood of future damage (Crook et al., 2014).

Likewise, longer-lasting pain will have greater impacts on productivity. These arise because of pain-related alterations in behavior (e.g., reduced feeding Gentle et al., 1997; Davis et al., 2004) or because prolonged physiological stress responses cause a metabolic shift, sacrificing growth, immune and reproductive functions (Virden and Kidd, 2009; Williams et al., 2019). Finally, pain can affect important behaviors, sometimes in ways that impair

Sturkie's Avian Physiology. https://doi.org/10.1016/B978-0-12-819770-7.00028-1

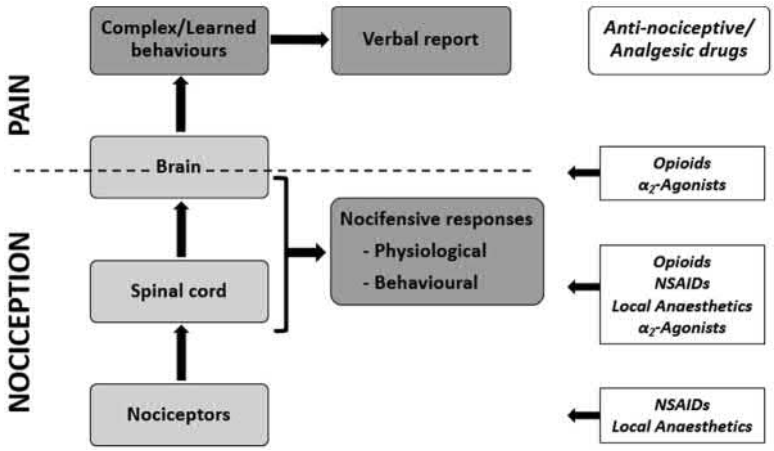

FIGURE 14.1 Generic schema of the neuroanatomical structures and pathways necessary to sense, transmit, integrate, and modulate nociceptive information to generate the experience of pain and observable responses. Verbal report is possible only from humans. Types of exogenous anti-nociceptive/analgesic drugs acting at different levels of the pathway are noted: nonsteroidal anti-inflammatory drugs (NSAIDs), alpha-2 adrenoreceptor agonist drugs (α_2-agonists).

recovery (Paul-Murphy and Hawkins, 2015). For example, animals in pain may become more aggressive or reluctant to interact with conspecifics or their human carers. Thus, there are ethical, economic, and conservation reasons for considering avian pain.

14.2 What evidence is required to demonstrate the capacity for pain?

The capacity of birds to experience pain is usually assumed. For example, birds are considered to be sentient in the animal welfare legislation of many jurisdictions (e.g., New Zealand Government, 2015; McCulloch, 2018; Australian Capital Territory, 2019), implying that they have the capacity for mental experiences, including pain (Mellor, 2019). However, many claims about birds' capacity for, and experience of, pain are based largely on extrapolation from mammals. Because of potentially relevant differences in neuroanatomy and physiology (Kuenzel, 2007; Shanahan et al., 2013; Zehnder et al., 2014) and the fact that we are apparently less well able to recognize indicators of pain in birds (Hawkins, 2006; Paul-Murphy and Hawkins, 2015), such extrapolation may not be appropriate. In fact, central processing of information about noxious stimuli, and thus the potential for the pain experience, is less well understood in birds than it is in fish (Williams et al., 2019).

Recent reviews provide detail of the physiology and expression of nociception and pain in birds (Gentle, 2011; Machin, 2014; Douglas et al., 2018; Baker et al., 2019). Here, we present a brief, systematic summary of the evidence that birds are capable of both the sensory and emotional components of pain (Bateson, 1991; Elwood, 2011; Sneddon et al., 2014; Burrell, 2017). The evidence is organized according to the neural apparatus required for nociception and observable evidence that nociception is occurring, followed by the structures and processes required to generate the emotional and cognitive components of the pain experience and the kind of evidence required to demonstrate the capacity for pain per se. General explanation of each component is followed by a summary of the specific evidence that birds do, in fact, possess that particular function. Table 14.1 summarizes key literature for different types of evidence supporting, or failing to support, each component in birds. We also consider evidence of how nociception or pain would be modified through the application of mitigation strategies such as analgesic drugs.

14.2.1 What is needed for nociception?

The required components for nociception are sensory receptors to detect damaging stimuli and transduce those inputs into electrical impulses, neural pathways to transmit those impulses from the periphery to CNS, and from there to integrating centers within the CNS to facilitate generation of reflex protective (nocifensive) responses.

14.2.1.1 Transduction, transmission, and modulation of nociceptive information

Nociceptors are free (unspecialized) nerve endings of peripheral fibers that act as sensory receptors for noxious stimuli. Found in various tissues, they encode the stimulus modality, intensity, and duration. Fast pain is associated with rapid transmission of impulses from the periphery to the spinal cord in large diameter, myelinated Aδ fibers while slower-arising and longer-lasting pain (dull/aching) is due to transmission in smaller, unmyelinated C fibers

*indicates evidence that fails to support the existence of a particular component or manifestation of nociception or pain in birds.

(Dubin and Patapoutian, 2010). Nociceptive fibers synapse onto spinal cord neurons in the outermost layers of the dorsal horn. Here, the release of neurotransmitters activates neurons which project up the spinal cord to the brainstem and other structures (Willis, 1985; Cortelli et al., 2013).

Following injury or infection, nociceptors become sensitized by inflammatory chemicals released by immune cells (Burrell, 2017). Peripheral "anti-nociception" can be achieved using anti-inflammatory drugs to reduce the production of these chemicals or using local anaesthetics to block transmission in the nociceptive fibers; both reduce inputs to the spinal cord (Williams et al., 2019, Fig. 14.1). Centrally, the dorsal horn of the spinal cord is the primary site for modulation of nociceptive signals. Ascending spinal nociceptive fibers, as well as neurons from higher brain regions, stimulate modulation centers in the brainstem and hypothalamus which then exert descending control on dorsal horn neurons (Cortelli et al., 2013). Opioids and endocannabinoids produced by the brain in response to nociceptive inputs or other "stressors" bind to receptors in other parts of the brain and spinal cord to reduce subsequent signals reaching the brain, i.e., endogenous analgesia (Baker et al., 2019). Many drugs that produce central anti-nociception or analgesia act on these opioid receptors or stimulate other components of the descending inhibitory pathways (Burrell, 2017, Fig. 14.1).

The capacity of birds for nociception and modulation of nociceptive signals is well-established (reviewed by Machin, 2014; Sneddon et al., 2014; Douglas et al., 2018; Baker et al., 2019; Williams et al., 2019). Briefly, various nociceptors have been found in the skin, ankle joints, skeletal muscles, nasal and oral epithelium, and other beak structures of poultry, waterfowl, or starlings (Table 14.1). Mechanical, thermal, and polymodal (mechanothermal and mechanochemical) nociceptors have been identified (Dubbeldam, 2009). These respond similarly to those of mammals, although there are differences in sensitivity to chemicals (e.g., capsaicin) and in the high and low temperatures that activate thermal receptors (Machin, 2005; Saito et al., 2014).

Likewise, the organization of the ascending sensory pathways up to the brainstem and thalamus appears to be similar in birds and mammals (Shanahan et al., 2013; Douglas et al., 2018), although there is little specific information on nociceptive pathways within the brain and that from only a few avian species (Table 14.1). The neurochemicals and receptors required for endogenous modulation have been demonstrated in birds; the proportions of the various opioid receptors differ from those of mammals, and this influences the efficacy of opioid drugs in birds (Singh et al., 2017; Douglas et al., 2018). Overall, birds and mammals seem to have similar capacities to detect, transduce, transmit, and modulate noxious signals.

14.2.1.2 Nocifensive responses

Nocifensive responses are the immediate, automatic (reflex) behavioral and physiological responses to noxious stimulation designed to remove the animal from immediate danger and restore homeostasis (Cortelli et al., 2013). These responses are facilitated by multiple interactions between ascending nociceptive neurons and neurons in other systems at both spinal and supraspinal levels. Inputs from the spinal cord and trigeminal nerves activate multiple areas in the brainstem, hypothalamus, thalamus, and amygdala. These "subcortical reflex centers" stimulate physiological responses from the autonomic nervous system and hypothalamic pituitary adrenal axis and behavioral responses such as limb withdrawal and other rapid avoidance or defensive movements (Cortelli et al., 2013; Baker et al., 2019).

Birds demonstrate nocifensive behavioral and physiological responses to potential or actual tissue damage (Table 14.1). Behavioral withdrawal reflexes can be elicited by noxious thermal, electrical, and mechanical stimuli in various species, even when the birds are anesthetized (e.g., Machin and Livingston, 2002). Coordinated escape behaviors to some noxious events are shown even by chickens lacking a forebrain (Gentle and Wood-Gush, 1976; Gentle, 1981), supporting the idea that these behaviors are organized in the brainstem. Likewise, rapid changes in heart and respiratory rates and blood pressure follow feather removal, comb pinching, beak trimming, and other noxious stimuli in chickens and ducks. Beak trimming and formalin injection elicited sustained increases in circulating stress hormones (corticosterone) in chickens.

There is also evidence of exogenous modulation of nocifensive responses in birds. Behaviorally, birds become less responsive in withdrawal threshold tests after administration of opioid drugs and more responsive following inflammation; the latter sensitization can be reversed by both anti-inflammatory drugs and opioids. Similarly, nonsteroidal anti-inflammatory drugs (NSAIDs) and opioids reduced cardiorespiratory responses to noxious stimulation in ducks and parrots. In summary, birds demonstrate both the necessary neural anatomy and the behavioral and physiological manifestations of nociception, which is supported by evidence of anti-nociception.

14.2.2 What is needed for pain?

For animals to become aware of noxious sensations and experience the unpleasant emotion proposed to give pain its adaptive value, further brain processing of nociceptive inputs is required. Evidence of that processing comes from the presence and activation of the necessary brain areas and from the flexible expression of behavior indicative of

complex integration of information, learning, and memory, and changes in motivation due to the unpleasant nature of the experience (Elwood, 2011; Sneddon et al., 2014).

14.2.2.1 Higher brain processing of nociceptive inputs

In general terms, the required components are ascending pathways from the thalamus to telencephalic (forebrain) areas involved in sensory processing and generation of emotion, memory, and avoidance learning that are activated by noxious stimulation and that exert descending control on other brain areas involved in producing motor responses and modulating nociception. In humans and other mammals, a network of cortical areas, referred to as the "pain matrix," is considered to be responsible for generating pain from nociception (reviewed by Cortelli et al., 2013); measuring activity in this network using neuroimaging may provide an objective reflection of the pain experience (Borsook et al., 2010; Da Silva and Seminowicz, 2019).

The architecture of the avian forebrain is very different from that of mammals, and the brain structures that might be involved in a "pain matrix" are not yet known (Dubbeldam, 2009; Williams et al., 2019). However, some functional homologies (Kuenzel, 2007; Baker et al., 2019) and similar connectivity among brain areas involved in sensory association and executive and motor functions have been found in pigeon and mammalian brains, including a network resembling the human subnetwork for processing internal sensory information (Shanahan et al., 2013). This suggests similar forebrain organization for processing of sensory information and higher cognitive functions in birds and mammals (Güntürkün, 2012), which may include generation of pain.

Several studies have explored the global electrical responses of the chicken brain to nociceptive inputs using the electroencephalogram (EEG). Thus far, these methods have failed to detect changes in the EEG like those observed in mammals (Murrell and Johnson, 2006). While Gentle and Hunter (1991) reported qualitative changes in the EEG response of chickens to feather removals, these were in the opposite direction to those expected and correlated with periods of behavioral immobility rather than with stimulus application per se. In contrast, Woolley and Gentle (1987) found no responses to a comb pinch or noxious thermal stimulus. Likewise, neither surface recordings (McIlhone et al., 2018) nor recordings from electrodes placed in subregions of the hyperpallium and nidopallium (Trebilcock, 2015) revealed quantitative EEG responses to noxious electrical, mechanical, or thermal stimulation. The difference may relate to the differences in forebrain architecture, particularly the deeper location of relevant structures in birds (Williams et al., 2019). Further neuroimaging studies are required to elucidate the brain networks involved in avian pain processing.

14.2.2.2 Complex behavioral responses

Because nociception can cause a range of acute physiological and behavioral responses that don't require higher brain processing (Cortelli et al., 2013), these nocifensive responses by themselves provide weak evidence of the cognitive and emotional aspects of pain. Stronger evidence comes from behaviors which are more complex and prolonged and the expression of which is influenced by other motivational states and vice versa, i.e., motivational tradeoffs (Gentle and Corr, 1995). Examples include changes in the animal's normal behavioral repertoire or the expression of specific behaviors that reflect awareness of the site of damage or reduce further stimulation of that area (Bateson, 1991). However, care is required in interpreting these "pain-related" behaviors as some have been observed in animals lacking a forebrain (Matthies and Franklin, 1992; Gentle, 1997), suggesting that they can be organized in the brainstem without the higher processing necessary for the pain experience. Thus, observing the effects of manipulating other motivations (e.g., hunger) on such responses can provide stronger evidence of pain. Examples include stress-induced and attentional analgesia, in which stress or a shift in attentional focus reduces responsiveness to noxious stimulation (Baker et al., 2019). Perhaps even more compelling are tests of associative learning and memory, in which animals are asked to demonstrate their unpleasant experience of a noxious event or condition through their subsequent responses to places or signals associated with that event/condition or its relief (Gao et al., 2004; Dunlop et al., 2006; Elwood, 2011; Gerber et al., 2014; Sneddon et al., 2014).

Most of the avian research on complex behavioral responses has been done on poultry following procedures, or with conditions, expected to cause chronic pain. Following debeaking, chickens show prolonged changes in general activity, locomotion, feeding, drinking, preening, and pecking at objects (Table 14.1); such changes can persist for many weeks depending on trimming age, method, and severity. Broiler chickens and turkeys with naturally occurring or induced inflammatory arthritis show changes in gait (limping) or weight-bearing (e.g., one-legged standing). Altered behavior following debeaking and abnormal gait due to arthritis is improved by the administration of local anaesthetics, NSAIDs or opioids.

Tests explicitly designed to create motivational conflict provide support for chickens' ability to weigh the unpleasantness of pain against other priorities (Table 14.1). For example, lame broilers were slower to traverse an obstacle course to access food and sat more quickly in a

mildly aversive water bath than did sound birds. NSAIDs improved the performance of lame birds, suggesting they were able to attend to the other motivational priorities when pain was reduced. While little work has been done on stress-induced or attentional analgesia in birds, there is some evidence that it occurs and is mediated by endogenous opioids. Introduction into a novel environment suppressed the pain behavior of layer hens with induced arthritis (Gentle and Tilston, 1999). Likewise, increased feeding motivation and preparation to egg-lay suppressed arthritis-related pain behavior, and this effect was reversed by naloxone (Wylie and Gentle, 1998).

Little work on associative learning and memory related to tissue damage has been undertaken on birds. Of three studies, two provide compelling evidence that chickens with injuries likely to cause chronic pain learned to associate a place or color with analgesia (relief learning), supporting the cognitive and emotional significance of their experience. In one study, layer hens with healed keel fractures showed a preference for a place they had learned to associate with injection of an opioid analgesic, while sound hens showed no preference (Nasr et al., 2013). Similarly, naturally lame broilers preferentially selected colored feed treated with an NSAID shown to improve lameness, and the amount of feed consumed increased with the degree of lameness (Danbury et al., 2000). In contrast, Freire et al. (2008) found no evidence of a learned preference for an NSAID-treated food by debeaked layer hens, despite birds showing pain-guarding behavior, and the observation that consumption of large doses of carprofen reduced this behavior. It is possible that the type or consumed dose of analgesic was not effective in facilitating a learned association for that type of chronic pain.

Overall, the results of various behavioral studies examining motivational trade-offs and associative learning support the capacity of chickens to experience an unpleasant emotion due to noxious stimulation that alters their subsequent decision-making and behavior; however, direct evidence of the brain processing facilitating that capacity has not yet been demonstrated.

14.3 Conclusions

Thus far, nociception and pain have been studied in only around 15 of the estimated 10,000 bird species in 6 of 40 avian orders. Relevant differences exist among species, for example, in the neural pathways carrying sensory information to the forebrain (Kuenzel, 2007), thus pain studies should be extended within the Aves class. In those species studied, the capacity for nociception is well-established, supported by evidence of the neuroanatomical and neurochemical substrates for nociceptive signaling and modulation, and by observation of nocifensive responses to potential or actual tissue damage. Most of the neurological research has been undertaken in chickens and pigeons, probably because of the availability and low value of individuals of these species, the potential for welfare compromise in the poultry industry and because the pigeon brain atlas is the most detailed and accurate.

Evidence of the cognitive and emotional components of pain comes largely from behavioral studies on chickens; most explore spontaneous expression of complex behaviors following tissue damage and its mitigation by analgesics. Very few studies have been undertaken to provide evidence of higher brain processing of nociceptive information in birds, and more of these kinds of studies are needed. A few demonstrate endogenous alterations in pain sensitivity reflective of cognitive processing or associative learning indicative of the unpleasantness of chronic pain. While neuroimaging evidence of higher brain processing of nociceptive inputs has not yet been found, the available behavioral evidence supports the capacity of chickens, at least, to experience pain emotionally. As pain, particularly when chronic, can impact detrimentally on animal welfare and productivity, there is a need for continued research into pain and its alleviation in a wider range of avian species.

Chapter 15

Magnetoreception in birds and its use for long-distance migration*

Henrik Mouritsen[1,2]

[1]Institut für Biologie und Umweltwissenschaften, Universität Oldenburg, Oldenburg, Germany; [2]Research Centre for Neurosensory Sciences, University of Oldenburg, Oldenburg, Germany

15.1 Introduction

The Earth's magnetic field provides potentially useful information, which birds and other animals could use for directional and/or positional information. It has been clearly demonstrated that many birds are able to sense the compass direction of the Earth's magnetic field and that they can use this information as part of a compass sense. More recently, it has also been demonstrated that at least some birds can use magnetic information to determine their approximate position on the Earth based on magnetic cues. In addition to direct uses for orientation and navigation, magnetic information also seems to be able to influence other physiological processes such as fattening and migratory motivation as a trigger for changes in behavior. While the behavioral responses to geomagnetic cues are relatively well understood, the physiological mechanisms enabling birds to sense the Earth's magnetic field are only starting to be understood and understanding the magnetic sense(s) of animals including birds remains one of the most significant unsolved problems in biology. It is very challenging to sense magnetic fields as weak as that of the Earth using only biologically available materials. Only two basic mechanisms are considered theoretically viable in small terrestrial animals: iron-particle–based magnetoreception and radical-pair–based magnetoreception. Based on current scientific evidence, both iron-particle–based magnetoreception and radical-pair–based magnetoreception mechanisms seem to exist in birds, but they seem to be used for different purposes. Plausible primary sensory molecules and a few brain areas involved in processing magnetic information have been identified in birds for each of these two types of magnetic senses. Nevertheless, we are still far away from understanding the detailed function of any of the at least two different magnetic senses existing in at least some bird species, and, at present, no primary sensory structure has been identified beyond reasonable doubt to be the source of avian magnetoreception. This is an exciting but challenging field requiring a highly multidisciplinary, stringent, scientific approach in which a number of major discoveries are likely to be made in the next one–two decades.

15.2 Magnetic fields

Moving electric charges such as electrons produce magnetic fields. On the microscopic scale, electron (and nuclear) spins can generate magnetic fields. On the macroscopic scale, a magnetic field, **B**, is, for instance, generated around a wire when current runs through it. The magnetic field at a given location can be described as a three-dimensional (3D) vector, whose strength, **B**, is measured as magnetic flux density using the unit "Tesla [T]" $1T = 1(V*s)/m^2 = 1\ (N*s)/(C*m) = 10{,}000$ Gauss [V = Volt, s = second, m = meter, N = Newton, C = Coulomb]. Some materials, which are called "ferromagnetic," can be permanently magnetized by a magnetic field, and this magnetization remains after the magnetizing field

* Since the classical findings in magnetoreception do not change, there is significant text and content overlap between the present edited chapter and the original chapter as well as with another book chapter focusing on magnetoreception in all kinds of organisms titled "The Magnetic Senses," which I wrote for the textbook "Neurosenses": Mouritsen, H., 2013. The Magnetic senses. In: Galizia, C.G., Lledo, P.M. (Eds.), Neurosciences—From Molecule to Behavior: A University Textbook. https://doi.org/10.1007/978-3-642-10,769-6_20, © Springer-Verlag Berlin Heidelberg, pp. 427–443. The Springer Verlag has permitted the reuse of significant parts of the "Neurosenses" textbook chapter text in the present chapter. Specific references to this text is not given at every location where text is reused, since such references would compromise readability, and could be misunderstood to be referring to primary research findings.

Sturkie's Avian Physiology. https://doi.org/10.1016/B978-0-12-819770-7.00040-2

has been removed. Magnetite [Fe_3O_4], an iron-oxide, is a well-known example of a ferromagnetic mineral (Mouritsen, 2013).

15.3 The Earth's magnetic field

The Earth generates its own magnetic field (the geomagnetic field), which is mostly caused by electric currents in the liquid outer core of the Earth (the "dynamo effect"). The magnetic field measured at the Earth's surface is similar to the magnetic field one would expect to see if a large dipole magnet was placed in the center of the Earth (see Fig. 15.1). The Earth's magnetic field currently has a magnetic field South pole near the Earth's geographic north pole (referred to as "Magnetic North" or "Magnetic North Pole" in biology). Throughout this chapter, I will follow the convention used in the bird orientation research literature and use the term "Magnetic North" or "Magnetic North Pole" to refer, not to the physical magnetic North Pole, but to the magnetic pole located closest to the geographic North Pole. Likewise, the magnetic field North Pole near the Earth's geographic South Pole will be referred to as "Magnetic South" or "Magnetic South Pole" (Mouritsen, 2013).

The magnetic field lines leave the Magnetic South Pole and re-enter the Magnetic North Pole. The polarity of the magnetic field lines on the Earth's surface always points toward magnetic North, and they can therefore provide a highly reliable directional reference, which can be used as the basis for a magnetic compass anywhere on planet Earth except at the magnetic poles. At the magnetic poles, the field lines point directly into the sky (at the Magnetic South Pole) or directly into the Earth (at the Magnetic North Pole). At the magnetic equator, the magnetic field lines are parallel to the Earth's surface. The angle between the magnetic field lines and the Earth's surface is called "magnetic inclination." Thus, magnetic inclination changes gradually from −90 degrees at the magnetic South Pole to zero degrees at the magnetic equator to +90 degrees at the magnetic North pole (see Fig. 15.1). The Earth's magnetic field intensity ranges from ca. 30,000 nT (nano-Tesla = 10^{-9} T; 1 T = 1 V m^{-2}; 1 nT = 10^{-5} Gauss) near

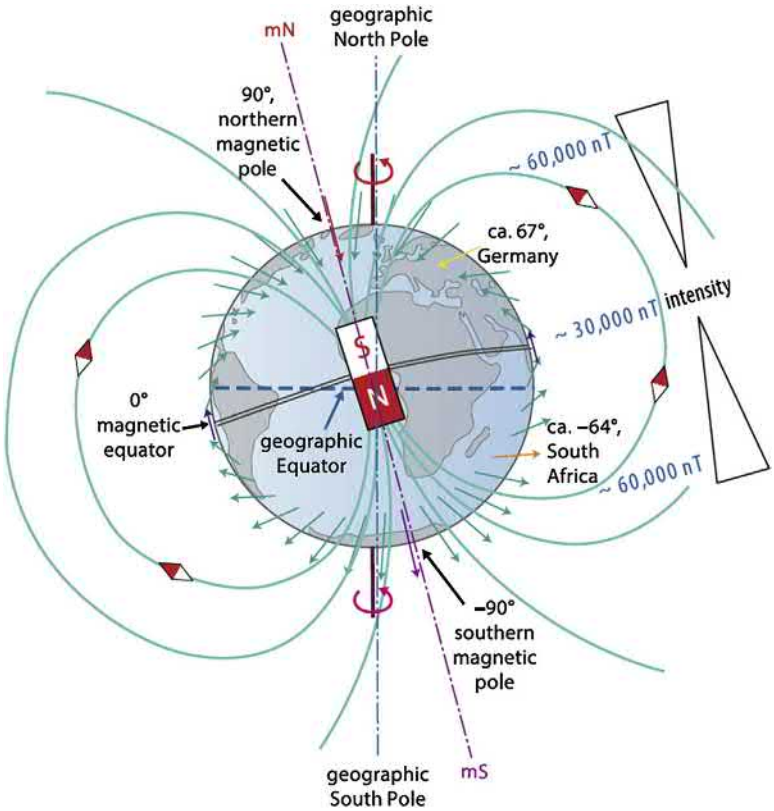

FIGURE 15.1 The Earth's magnetic field (the geomagnetic field). Notice that the southern and northern magnetic poles and the Magnetic Equator do not coincide with the geographical poles and the Geographic Equator. Also notice that the magnetic field lines intersect the Earth's surface at different angles depending on the magnetic latitude (*blue-green lines and vectors*). The intersection angle is called the magnetic inclination. Magnetic inclination is, for instance, +90 degrees at the magnetic North Pole (*red vector*), ~+67 degrees at the latitude of Germany (*yellow vector*), 0 degree at the magnetic equator (*dark blue vectors*), ~−64 degrees at the latitude of South Africa (*orange vector*), and −90 degrees at the magnetic South Pole (*magenta vector*). The magnetic intensity varies from ca. 60,000 nT near the magnetic poles to ca. 30,000 nT along the magnetic equator. *Adapted with permission after Wiltschko and Wiltschko (1996) and Mouritsen (2013).*

the magnetic equator to ca. 60,000 nT at the magnetic poles. Earth-strength magnetic fields are usually measured with a calibrated 3-axial Flux-Gate magnetometer. Both magnetic inclination and magnetic intensity can, in theory, be useful for determining one's position, but, on most parts of the Earth, magnetic inclination and intensity changes predominantly from North to South but not much from East to West. It therefore seems easier to determine latitude than longitude from geomagnetic field information (Mouritsen, 2003, 2013), even though recent studies have shown that Eurasian reed warblers, *Acrocephalus scirpaceus* (a night-migratory songbird), can also use magnetic cues to compensate for East−West displacements (Kishkinev et al., 2015; Chernetsov et al., 2017; Pakhomov et al., 2018).

The Magnetic North Pole is currently located in Northern Canada, and the Magnetic South Pole is currently located south of Australia. Consequently, the geographic and magnetic poles do not coincide (see Fig. 15.1). The deviation between geographic and magnetic North is called the "magnetic declination." Magnetic declination is the angle between magnetic north, i.e., the direction in which the north end of a compass needle points in, and geographic north. The declination is positive when Magnetic North is east of geographic North and negative when Magnetic North is west of geographic North. Declination is mostly small, but near the magnetic poles, declination can pose a serious problem for navigating birds using a magnetic compass, unless they find a way to compensate for it. On the other hand, magnetic declination could be a useful parameter to determine, e.g., East−West position if it would be combined with other map cues (Mouritsen, 2013; Kishkinev et al., 2021; Chernetsov et al., 2017, 2020).

15.4 Changing magnetic fields for experimental purposes

The direction of the magnetic field around a wire can be determined by the "right hand rule": if you grasp around the wire with your right hand so that your thumb is pointing in the direction of the current, the magnetic field around the wire runs in the direction in which your fingers are pointing. The magnetic field decreases with distance as you move away from the wire. If you create a coil of wire, the magnetic field created is much stronger inside the coil than on the outside of the coil because many parallel magnetic field lines created by different parts of the wire coincides and thus add up in the center of the coil. This is the reason why coil constructions are typically used to produce and alter magnetic fields (Mouritsen, 2013).

The typical coil constructions, which are used to produce Earth-strength magnetic fields for scientific experiments, are so-called "Helmholtz coils": a pair of parallel coils placed one radius apart from each other (Kirschvink, 1991). In a pair of Helmholtz coils, the magnetic field is very homogeneous within a central space of ca. 60% of the radius of the coils (Kirschvink, 1991). The magnetic field generated in the center of a pair of Helmholtz coils is $\mathbf{B} = (0.9*10^{-6}$ T m/A * n *I)/R; where T is the unit Tesla, n is the number of turns in each coil, I is the current flowing through the coils measured in Ampere (A), and R is the radius of the coils measured in meters (m) (Kirschvink, 1991). One pair of Helmholtz coils can alter the magnetic field along one axis only. To make any desired 3D magnetic field, ideally three pairs of Helmholtz coils oriented perpendicular to each other are needed. If one adds an artificially created field to an existing field (such as that of the Earth), the resultant field is calculated by simple vector addition of the two fields (see Fig. 15.2; Kirschvink, 1991). Therefore, it is also possible to use a single pair of Helmholtz coils to make any 3D magnetic field, but in that case, this single pair of coils must be oriented very precisely in 3D space (see Fig. 15.2, Mouritsen, 2013).

While the Helmholtz arrangement is easy to calculate and construct, the central homogeneous space can be increased to ca. 110% of the radius of the coils by using more elaborate coil designs such as the Merritt-4-coil system (Kirschvink, 1991; Zapka et al., 2009, Figure 20.2 in Mouritsen, 2013; Schwarze et al., 2016). To control for artifacts, one would—independent of the coil design chosen—expect the coils to be "double wound" (Kirschvink, 1991; Kirschvink et al., 2010). This means that during construction of the coils, each coil contains two separate, but identically wounded, wires each with separate connectors, so that one can either run current through both halves of the windings in the same direction (then the magnetic field in the center of the coil will change), or one can run the current through one half of the coils in one direction but in the opposite direction through the second half of the windings. In that case, the current running through one half of the windings will create a magnetic field, which exactly cancels the magnetic field produced by the other half of the windings, and the background field is not changed. By using double wound coils, exactly the same amount of current is sent through the coils whether the magnetic field is being changed or not. Double-wounded coils also allow for truly double-blinded experiments (Kirschvink, 1991; Zapka et al., 2009; Harris et al., 2009; Hein et al., 2010, 2011; Engels et al., 2012; Mouritsen, 2018). An excellent presentation of the theoretical background as well as practical instructions on how to construct various coil designs for changing Earth-strength magnetic fields can be found in Kirschvink (1991).

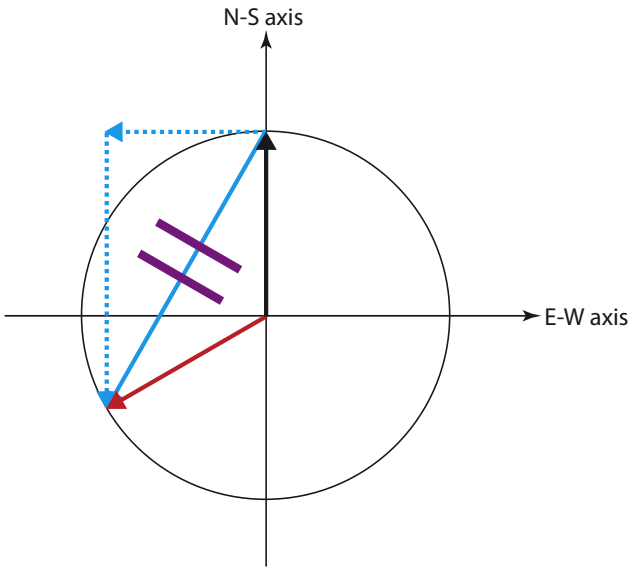

FIGURE 15.2 Magnetic fields are vector fields and can easily be turned with pairs of coils. If we consider the geomagnetic field, it will point toward North (0 degree) and have a vertical and a horizontal component. Let's say that we want to create a magnetic field with the same strength and inclination as the geomagnetic field but which is turned horizontally 120 degrees counterclockwise. In that case, the vertical component of the field should remain unchanged, and we only have to consider the two dimensions in the horizontal plane. Let's say that the Earth's magnetic field at the relevant location has a horizontal field component of 18,000 nT pointing toward magnetic North (*black vector*). If we want to turn the field to point toward 240 degrees (a 120 degrees counterclockwise turn, *red vector*), we need to produce a magnetic field vector (the *blue vector*) that connects the tip of the *black vector* to the tip of the *red vector*. The needed field can be produced by a single pair of Helmholtz coils (symbolized by the *violet lines*) if the coil frames are oriented on the axis defined by half the wanted angular turn (in this case 120 degrees/2 = 60 degrees) given that the final wanted intensity remains unchanged. Simple trigonometry can be used to calculate the needed field strength, B_{blue}, of the *blue vector*. In this case: $B_{blue} = (((\cos(\alpha_{black})*B_{black}) - (\cos(\alpha_{red})*B_{red}))^2 + ((\sin(\alpha_{black})*B_{black}) - (\sin(\alpha_{red})*B_{red}))^2)^{1/2}$, where $\alpha_{black} = 360$ degrees, $\alpha_{red} = 240$ degrees and $B_{black} = B_{red} = 18{,}000$ nT => $B_{blue} = ((\cos(360 \text{ degrees})*18{,}000 \text{ nT} - \cos(240 \text{ degrees})*18{,}000 \text{ nT})^2 + (\sin(360\text{degrees})*18{,}000 \text{ nT} - \sin(240 \text{ degrees})*18{,}000 \text{ nT})^2)^{1/2} = (((27{,}000 \text{ nT})^2 + (-15{,}588 \text{ nT})^2)^{1/2} = 31{,}177$ nT. If the strength of the final vector should have a different intensity than the original vector, or if the vertical component needs to be changed as well, again a single pair of coils can in principle do the job (the needed calculations are three-dimensional [3D]), but accurately orienting this pair of coils is very difficult in real life. Therefore, if excellent control of static magnetic fields is required, usually 3D systems of perpendicularly oriented coils are used. Since magnetic fields are vector fields, which all need to be added up to get the total resultant field, instead of producing the direct vector (the *blue vector*) that connects the tip of the *black vector* to the tip of the *red vector*, we can produce two vectors (the *dashed blue vectors*) along the two coil axes, which in total connects the tip of the *black vector* to the tip of the *red vector*. With such systems, each of the needed vectors are much more easy to calculate. The needed N−S component is: $\cos(\alpha_{black})*B_{black} - \cos(\alpha_{red})*B_{red}$ and the needed E−W component is $\sin(\alpha_{black})*B_{black} - \sin(\alpha)*B_{red}$. If one uses a 3D magnetometer oriented with the x-axis toward North and the Y-axis toward East, and one just wants to calculate the values that should be on the display when the wanted field is present, X should read $\cos(\alpha_{red})*B_{red}$ and Y should read $\sin(\alpha)*B_{red}$. In the case of a 120 degrees counterclockwise turn of the above-mentioned field, X should thus read cos(240 degrees)*18,000 nT = −9000 nT, and Y should read sin(240 degrees)*18,000 nT = −15,588 nT. All formulas presented here are valid for geographical angles (North = 0 degree = 360 degrees; East = 90 degrees, South = 180 degrees; and West = 270 degrees) but have to be modified if mathematical angles are used (East = 0 degree; North = 90 degrees; West = 180 degrees; and South = 270 degrees). What should the same magnetometer read on X and Y, if the same geomagnetic field is turned horizontally to 165 degrees? (X = −17,387 nT; Y = +4659 nT).

15.5 Birds use information from the Earth's magnetic field for various behaviors

15.5.1 Orientation and navigation

Orientation and navigation skills are essential for the survival of all migratory birds. All first-time migrants are faced with the challenge of finding an unfamiliar wintering area, often thousands of kilometers away (Berthold, 1991; Mouritsen and Mouritsen, 2000; Mouritsen, 2003, 2018). Many bigger birds are day migratory and travel in groups, which means that young birds of these species might simply follow experienced birds that know the way. However, most small songbirds are night-migratory and travel alone without contact to their parents. Consequently, all their navigational skills must be based on inherited sensory capabilities and strategies (Mouritsen, 2003; Holland, 2014). No cues requiring previous experience with the goal can be involved in the orientation strategies of solitary, first-year migrants. These considerations strongly limit the number of possible orientation cues to a few classes of globally or at least regionally consistent cues (Mouritsen, 2003; Holland, 2014):

(a) celestial cues, including the sun, the stars, and maybe the polarized light pattern of the sky

and

(b) geomagnetic cues

In addition to these cues, some authors have suggested that chemical cues (odors, Wallraff and Andreae, 2000; Wallraff, 2005; Gagliardo et al., 2006, 2008, 2009; Gagliardo, 2013), infrasound (sound with frequency below ca. 20 Hz; Hagstrum, 2013, but see Wallraff, 1972 and Holland, 2014), and/or Coriolis forces (The phenomenon that moving liquids and moving air are deflected slightly to the right on the Northern Hemisphere and slightly to the left on the Southern Hemisphere because of the Earth's rotation; Coriolis, 1835) might also be used for orientation and navigation.

However, there seems to be no physiological structure inside birds, which would enable them to detect the

Coriolis effect with a reasonable signal-to-noise ratio (Rosenblum et al., 1985; Adair, 1991; Kirschvink et al., 2010). Likewise, it is difficult to imagine how an inexperienced migrant could know, in advance, what the infrasound or odor "landscapes" along its migratory path looks like, and it is difficult to imagine that the infrasound and/or odor landscapes would be simple and consistent enough to be used by inexperienced birds as a primary map cue over thousands of kilometers (but see Wallraff and Andreae, 2000). Furthermore, because the width of the bird's head is much smaller than the wavelength of infrasound, it would be challenging for a small bird with a 2 cm wide head to determine from which direction infrasound originates (Mouritsen, 2013).

Thus, the primary orientation system of young inexperienced migrants on their first autumn migration is likely to be based primarily on celestial and magnetic cues, and it is known that when first-time autumn migrants are displaced away from their migration route, they are unable to correct for displacements (e.g., Drost, 1938; Perdeck, 1958; Mouritsen and Larsen, 1998; Mouritsen, 2003; Thorup et al., 2007; Holland, 2014). Instead, they choose a migration route parallel to their normal route and thus do not seem to possess a map sense (see Fig. 15.3). The migratory program of first-season solitary migrants can be described as a "clock-and-compass," "calendar-and-compass," or "vector navigation" strategy (Mayr, 1952; Perdeck, 1958; Schmidt-König, 1965; Rabøl, 1978; Berthold, 1991; Mouritsen, 1998b, 2003; Mouritsen and Mouritsen, 2000), where the birds fly in a specific direction for a given amount of time independent of their present location. Since the system include little (see below under magnetic signposts) or no location-related feedback, the orientation strategy of first-time solitary migrants can be mathematically described as a directed random walk: the birds choose their flight direction randomly from a normal-like distribution pointing in their mean migratory direction each evening independent of previous events (Mouritsen, 1998b; Mouritsen and Mouritsen, 2000; Mouritsen et al., 2013). This strategy predicts that the statistical distribution of first-time migrants should be parabolic, and it has been shown that this prediction fits very well with the actual distribution of ringing recoveries of free-flying, first-time migrants in Western Europe (Mouritsen, 1998b; Mouritsen and Mouritsen, 2000).

The orientation task facing adult migrants and young migrants on their first spring migration is fundamentally different from the task faced during their first autumn migration (Kramer, 1957; Rabøl, 1978; Berthold, 1991; Mouritsen, 2003, 2018; Holland, 2014). Adult migrants and young migrants on their first spring migration are migrating back toward a region they have had previous experience with and therefore their orientation system is likely to include local (map) information gained through previous migration experience. Birds that would use sensory information from all useful senses, which would improve their ability to find their way (e.g., magnetic sense, olfaction, vision, and hearing), should have an evolutionary advantage over birds that would only use a single cue or sense. Thus, it is likely that the orientation strategies of experienced migrants are multisensory and involves learned maps (Mouritsen, 2003, 2013, 2018; Holland, 2014).

Indeed, in contrast to first-time migrants, experienced migrants are able to correct for displacements (Perdeck, 1958; Mewaldt, 1964; Thorup et al., 2007; Chernetsov et al., 2008, 2017; Kishkinev et al., 2010, 2013, 2015; Pakhomov et al., 2018) and thus have added a learned map to their orientation program (see Fig. 15.3). Interestingly, this map is also functional at locations that have not been visited previously: birds can correct their orientation appropriately when they are experimentally displaced to far away locations, where they have certainly never been before (Perdeck, 1958; Mewaldt, 1964; Thorup et al., 2007; Chernetsov et al., 2008, 2017; Kishkinev et al., 2010, 2013, 2015; Kishkinev et al., 2021). If their learned map would have been based exclusively on previously experienced local landmarks, it should not have worked at unfamiliar locations.

Even though the functional basis of this map sense is not yet understood (Holland, 2014; Mouritsen, 2018), it is almost certainly based on multiple cues and it must involve the detection of larger scale gradients, which can be extrapolated and thus enable birds to return from unfamiliar locations. Furthermore, it is important to stress that navigational cues that can be used over thousands of kilometers differ from those that are useful over a few kilometers, meters, or centimeters over time-scales of a few seconds, minutes, or hours (Mouritsen, 2018). In fact, any long-distance navigational journey to a previously visited location consists of at least three different phases: a long-distance phase, a homing phase, and a pinpointing-the-goal phase (see Fig. 15.4; Mouritsen, 2018). The cues used during these three phases mostly differ. For instance, magnetic fields or global celestial cues will in most cases be of no use during the pinpointing-the-goal phase. It is therefore clear that no single cue or mechanism can explain how a long-distance migratory bird finds its way back to a known breeding or wintering location (Mouritsen, 2018).

15.6 The magnetic compass of birds

Friedrich W. Merkel and Wolfgang Wiltschko discovered that birds have a magnetic compass sense in the mid-1960s (Merkel and Wiltschko, 1965; Wiltschko, 1968). When birds are placed in a round cage at night, they show migratory restlessness (or "Zugunruhe" in Kramer, 1949): the birds primarily jump/flutter in their migratory direction, and when the magnetic field is rotated horizontally in the absence of celestial cues, the birds turn their orientation

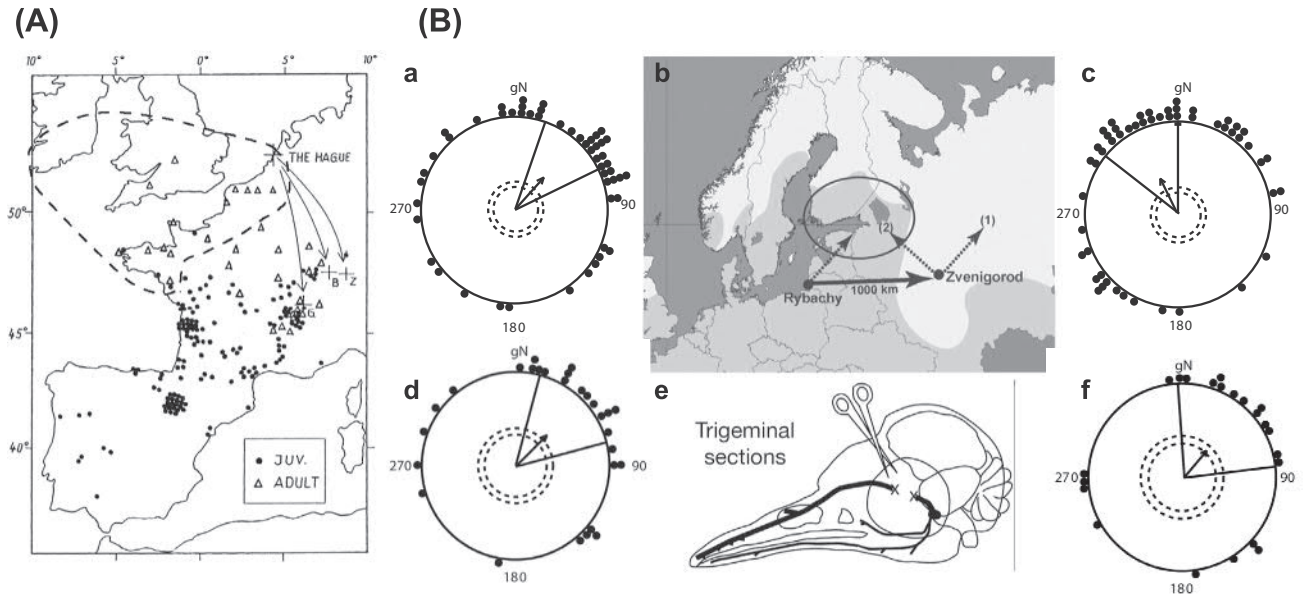

FIGURE 15.3 Displacement experiments provide key evidence for understanding the spatiotemporal orientation strategies of migratory birds. (A) Perdeck's classical experiments where he displaced >10,000 starlings from Holland S/SSE (→) to Switzerland during autumn migration showed that young starlings (●) on their first autumn were unable to correct for the displacement. The young birds show a parallel-displaced migration pattern relative to the wintering area of nondisplaced controls (*Dashed area*), whereas adult starlings (Δ) orient directly back to the normal population-specific wintering area of non-displaced controls. (B) Displacement experiments (Chernetsov et al., 2008; Kishkinev et al., 2013), in which Eurasian reed warblers (Acrocephalus scirpaceus) were tested in Emlen funnels (Emlen and Emlen, 1966; Mouritsen et al., 2009) before and after displacement, showed that young birds on their first spring migration are already able to correct for a 1000 km eastward displacements to a location where they have certainly never been before (b). (a) Orientation of birds at the capture site (Rybachy). (c) Orientation of the same birds after the 1000 km eastward translocation to Zvenigorod. Each *dot* at the circular diagram periphery indicates the mean orientation of one individual bird. The arrows show group mean directions and vector lengths. The *dashed circles* indicate the length of the group mean vector needed for significance according to the Rayleigh test (5 and 1% level for inner and outer *dashed circles*, respectively). The *lines* flanking group mean vectors indicate the 95% confidence intervals for the mean direction. gN—geographic North. On (b), a map of the displacement region is shown. The *shaded light gray* zone represents the breeding range of Eurasian reed warblers, and the *dashed arrows* show the expected results in case of (1): no compensation for the displacement, or (2): compensation toward the eastern part of the breeding range. Notice that intact birds compensate for the displacement, whereas birds which had the ophthalmic branch of the trigeminal nerve cut (d-f) could no longer compensate for the displacement (re-assembled after Chernetsov et al., 2008 and Kishkinev et al., 2013). The same results were obtained in virtual displacement experiments where the birds were exposed to the magnetic parameters of Zvenigorod inside coil systems but without being physically moved from Rybachy (Kishkinev et al., 2015; Pakhomov et al., 2018). *(A) From Mouritsen (2003) after Schmidt-Koenig (1965) and Perdeck (1958).*

with the magnetic field (see Fig. 15.5). This is the behavioral evidence required to show that a migratory bird species possesses and is able to use a magnetic compass (Wiltschko and Wiltschko, 1995). A magnetic compass has been found in more or less every migratory bird species properly tested for it (Wiltschko and Wiltschko, 1995), and it is therefore quite safe to presume that at least all night-migratory songbirds and potentially birds in general possess a magnetic compass.

It is important to note that there are at least two different magnetic field properties, which could potentially be used as input for a magnetic compass sense. A magnetic *polarity* compass (like the human ship compass) uses only the horizontal component of the field lines, which points toward magnetic North anywhere on Earth. Alternatively, a magnetic *inclination* compass detects only the angle between the geomagnetic field lines and the Earth's surface or gravity—not the polarity of the field lines. The smallest angle between the Earth's surface and the geomagnetic field lines indicates the direction "toward the magnetic equator," whereas the greatest angle indicates "toward the magnetic pole." Since the inclination is opposite on the northern and southern hemisphere, respectively, this holds on both hemispheres. All bird species properly tested so far have a magnetic inclination compass (Wiltschko and Wiltschko, 1972, 1995; see Fig. 15.5). Thus, the magnetic compass of night-migratory birds does not separate between North and South like our ship compass, but distinguishes between "toward the magnetic equator" and "toward the magnetic pole" (The Magnetic North Pole in the Northern Hemisphere and the magnetic South Pole in the Southern Hemisphere). Furthermore, the birds' magnetic compass sense seems to have a rather narrow functional intensity window, but this window seems to be extendable to new intensities after a few hours of adaptation to a changed magnetic field intensity (Wiltschko, 1978).

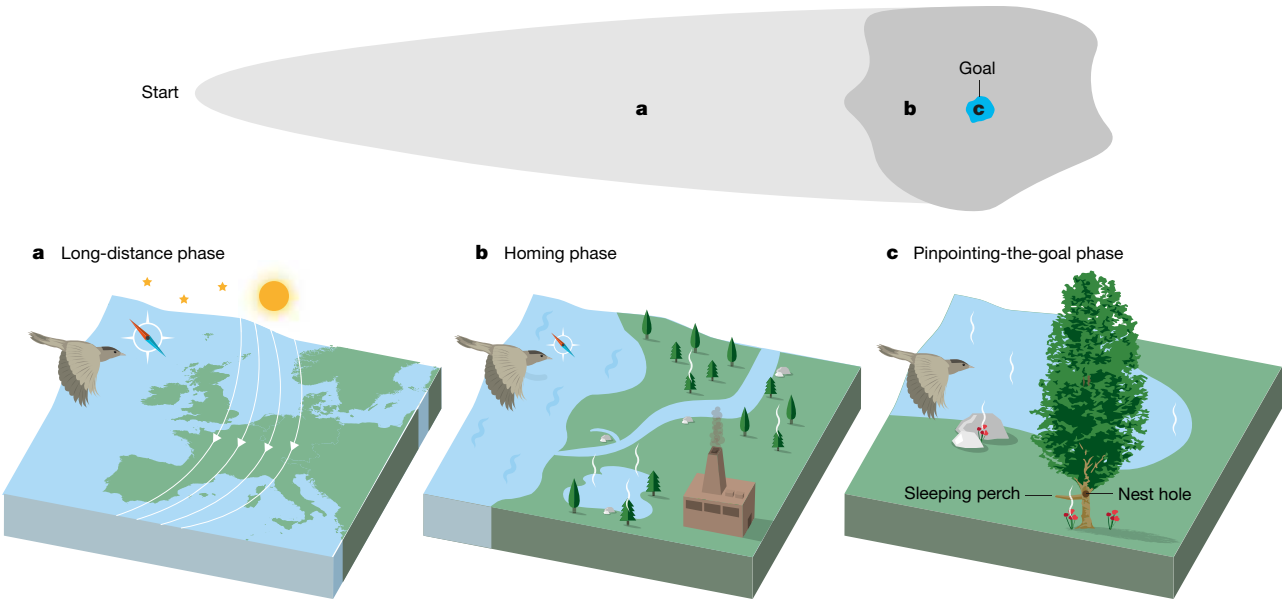

FIGURE 15.4 **Long-distance navigational tasks back to a previously visited location usually involve at least three different phases.** (A) During the long-distance phase, celestial and magnetic compass and map cues are usually important and landmarks such as coastlines can function as physical constraints. (B) During the homing phase, compasses still tends to be important and regional map cues such as olfactory and visual landmarks, olfactory gradients, strong magnetic anomalies, and maybe even soundscapes become important. (C) During the pinpointing-the-goal phase, very local cues such as a specific tree, a cave entrance, or a smelly swamp can help locate, for example, a sleeping perch or nest hole. *From Mouritsen (2018).*

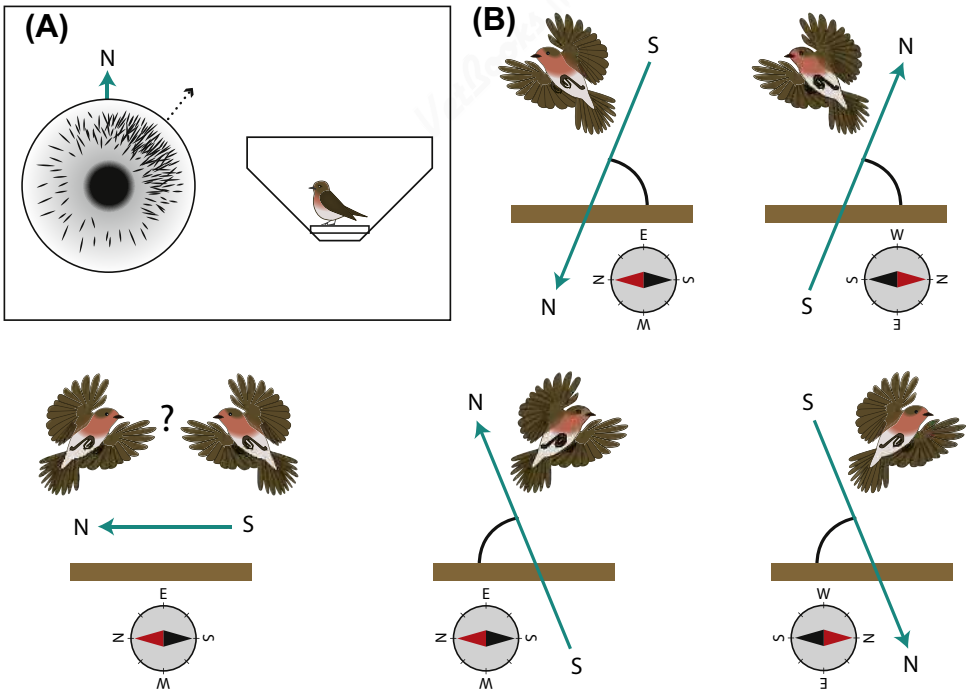

FIGURE 15.5 **The Emlen funnel and the inclination compass.** (A) The so-called Emlen funnel is the most commonly used orientation cage (Emlen and Emlen, 1966). The mean jumping direction of the birds are recorded on scratch-sensitive paper lining the inclined wall of the funnel (Mouritsen et al., 2009). (B) Early experiments by Wiltschko and Wiltschko (1972) have shown that night-migratory birds have an inclination compass, which means that they measure the angle between the magnetic field lines and the Earth's surface or gravity. Thereby, the birds separate between poleward and equatorward, not between North and South like a polarity compass would do (if birds use a polarity compass, they should have oriented in the direction indicated by the red end of the inserted technical compass). Birds are disoriented in a horizontal magnetic field like the one occurring at the magnetic equator. The flight direction of the inserted bird indicates the springtime mean direction chosen by all bird species tested so far in the given magnetic field (Wiltschko and Wiltschko, 1995). The *green arrows* indicate the direction if the magnetic field lines. Brown bar = The Earth's surface. N = geographic North. S = geographic South. *Figure and legend is reused from Mouritsen (2013).*

15.7 Do birds possess a magnetic map?

Many studies have reported that magnetic cues play an important role in birds' sense of position, i.e., that birds have a "magnetic map." However, the existence of a magnetic map used to be heavily debated and the views among researchers ranged from a magnetic map with a precision of a few kilometers being an established fact (e.g., Walcott, 1991; Wiltschko and Wiltschko, 1995; Wiltschko et al., 2010a) to a magnetic map sense being an evergreen phantom (Wallraff, 2001; Gagliardo et al., 2009). Recent virtual displacements to simulated magnetic locations, which were usually matched to previous actual displacements (Chernetsov et al., 2008; Kishkinev et al., 2013), have now demonstrated that at least some long-distance night-migratory songbirds are able to use magnetic information to determine their approximate large-scale position on the globe (Kishkinev et al., 2015, 2021; Chernetsov et al., 2017; Pakhomov et al., 2018). Furthermore, by correlating yearly changes in magnetic inclination with >60 years of colony recruitment data from Manx shearwaters (Puffinus puffinus) banded as chicks, this tube-nosed seabird seems to imprint on the magnetic inclination of their natal colony and to use this cue when they return to breed (Wynn et al., 2020), as do Pacific salmon (Putman et al., 2013).

Pigeons with opaque lenses that prevented them from detecting any local visual landmarks can return to within ca. 5 km of their loft (Schmidt-Koenig and Walcott, 1978). Thus, the precision of non-landmark-based navigation seems to be a few kilometers, but which cue(s) enable pigeons to home to within about 5 km of their loft without being able to use visual landmarks? At present, informed neutral observers of the olfaction contra magnetic map controversy agree (e.g., Able, 1996; Mouritsen, 2013 [both are orientation researchers who have never performed a pigeon release and thus have no vested interest in any of the camps]) that the evidence suggesting that chemical cues (odors) play an important role in the non-landmark-based part of pigeons' map sense (e.g., Papi, 1991, Wallraff and Andreae, 2000; Wallraff, 2001, 2005; Gagliardo et al., 2006, 2008, 2009) is much more convincing than the evidence supporting an important role of magnetic cues in the pigeons' map used during the homing phase (e.g., Walcott, 1991; Wiltschko and Wiltschko, 1995; Dennis et al., 2007; Wiltschko et al., 2010a; Holland, 2010). But remember, in the end, both camps may be right. The map will be multifactorial since a bird using all available input from all its senses will have an evolutionary advantage over a bird using only a single cue for a task so essential for the survival (Mouritsen, 2018). In any case, it remains very difficult to understand how a magnetic field-based map sense should be able to function on a scale <10 km. Why is that?

The problem for a bird wanting to use a magnetic map is that the average change in magnetic field intensity is only ca. 3 nT/km on the North–South axis: the geomagnetic field changes ca. 30,000 nT (nT) from one of the magnetic poles to the magnetic equator, which are ca. 10,000 km apart. Likewise, magnetic inclination changes only about 0.009 degrees/km along the North–South axis (a 90° change over 10,000 km). On the East–West axis, there is mostly very little change in magnetic field intensity and magnetic inclination. Thus, any magnetic field-based input to a reasonably precise map would require a very accurate magnetic sensory system and a very accurate sense of gravity. However, even if birds have such a system, daily, partly stochastic, natural variations in the geomagnetic field in the order of 30–100 nT in more or less random directions mean that it is very difficult to imagine, how a magnetic-field-based map sense could have a precision <10–30 km (Mouritsen, 2013, 2018) (during magnetic storms generated primarily by the sun, the geomagnetic field variability can reach 1000 nT; Courtillot and Mouël, 1988).

It is therefore expected that magnetic parameters can help determine position only where the expected differences in the magnetic field parameters are consistently larger than the daily magnetic variations (Mouritsen, 2013). Thus, even though a few studies have suggested that more accurate magnetic maps can be realized (Phillips et al., 2002; Dennis et al., 2007), magnetic maps are most likely only relevant during the long-distance navigation phase and maybe during part of the homing phase, at least in fast-moving animals (Mouritsen, 2018). Other cues such as odors and familiar landmarks may be more significant map parameters at shorter distances.

Intriguing data also exists that suggest that some songbirds can use magnetic cues as approximate geographic "signposts," which, for example, tells the birds when to increase their fat reserves before crossing the Sahara Desert (Fransson et al., 2001) or when to change their migratory heading (Henshaw et al., 2010). Cases, where specific magnetic parameters trigger a change in behavior is referred to as a magnetic "signpost" (Mouritsen, 2013).

15.8 Interactions with other cues

As mentioned previously, in most orientation-related contexts, magnetic cues interact with several other sources of similar and/or conflicting information. For instance, night-migratory songbirds do not only have a magnetic compass but also have a sun compass and a star compass (Emlen, 1975; Schmidt-König et al., 1991; Mouritsen and Larsen, 2001; Cochran et al., 2004; Zapka et al., 2009). They only need information from any one of these compasses to orient in the appropriate direction

(e.g., Mouritsen, 1998a; Muheim et al., 2006b; Chernetsov et al., 2011; Liu and Chernetsov, 2012). If the three compasses provide conflicting information, it is not consistent which compass the birds prefer. The preference is probably dependent on the ecological context and on details of the experimental setup and the conditions under which the birds were housed and tested, and it is likely that calibrations are taking place in nature, see Fig. 15.6 (Cochran et al., 2004; Muheim et al., 2006a; Liu and Chernetsov, 2012). The few experiments with truly free-flying birds performed so far suggested that two species of North American, night-migratory songbirds used the magnetic compass as their primary compass in midair during spring migration, but that they calibrate this compass based on celestial cues during the sunset period (Cochran et al., 2004; but this mechanism is not universal (Chernetsov et al., 2011)). Other evidence suggests that polarized light cues might be crucial for this calibration (Muheim et al., 2006a), but so far, it is not understood how a bird's eyes can detect polarized light.

In pigeon homing or any other shorter-distance, map-related task, the interactions between different cues seem to be even more complicated. Homing pigeons have been shown to use olfactory cues (Papi, 1991; Wallraff and Andreae, 2000; Wallraff, 2001, 2005; Gagliardo et al., 2006, 2008, 2009, 2018), visual landmarks of various kinds (e.g., Guilford et al., 2004), outward journey information (reviews in Wiltschko and Wiltschko, 1995; Wallraff, 2005), and maybe magnetic cues (Walcott, 1991; Wiltschko and Wiltschko, 1995; Dennis et al., 2007; Wiltschko et al., 2010a) to estimate their position relative to home when released from a previously unknown location. The relative importance of these map cues is hotly debated with many apparently contradictory results occurring in the literature. One reason may very well be that in one location, one type of cue may be particularly reliable; whereas another cue is more reliable in a different location and that the animals therefore predominantly rely on different cues in different locations. The most convincing experiments performed to date involved cutting of the olfactory nerves or cutting of the ophthalmic branch of the trigeminal nerves in both experienced and inexperienced pigeons. The experiments showed that homing pigeons tested in Italy need intact olfactory nerves but not intact "magnetic" nerves (see below) to home (Gagliardo et al., 2006, 2008, 2009; Gagliardo, 2013). In procellariiform seabirds such as albatrosses and shearwaters, olfactory cues also seem to be much more important for navigation than magnetic cues (Mouritsen et al., 2003; Nevitt and Bonadonna, 2005; Bonadonna et al., 2005; Gagliardo et al., 2013; Pollonara et al., 2015; Padget et al., 2017). However, recent data suggest that Manx Shearwaters do use magnetic inclination to imprint on and return to their natal colony (Wynn et al., 2020).

15.9 How do birds sense the Earth's magnetic field?

It is challenging to detect the weak geomagnetic field with biological materials. Considering the anatomical constraints and known structures found within small birds, careful models of putative sensory mechanisms often find it hard to explain how a 50,000 nT magnetic field can result in reliable signals in the presence of thermal fluctuations (kT) and other sources of noise. In fact, any biological mechanism that can, in principle, allow detection of 50,000 nT fields is noteworthy (Ritz et al., 2010; Mouritsen, 2013, 2018; Hore and Mouritsen, 2016; Hore, 2012). Only three basic mechanisms are currently considered to be physically viable: (1) induction in highly sensitive electric sensors, (2) iron-particle–based magnetoreception, and (3) radical-pair–based magnetoreception.

15.10 The induction hypothesis

Electromagnetic induction is the production of voltage across an electric conductor situated in a changing magnetic field or a conductor moving through a stationary magnetic field. Thus, in practical terms, if one has an electric wire and one moves this through a magnetic field, a current will be generated in the wire. If this wire is ring or coil-shaped, directional sensitivity can be achieved. In biological tissues, one would need conductive, liquid-filled, ring-like structures of sufficient size and diameter to generate measurable electrical signals, which can be picked up by an electrically sensitive receptor cell. For electromagnetic induction, Lorenzini ampullae are a concrete realization of an electrically sensitive cell operating in saltwater fish (von der Emde, 2013; Newton et al., 2019). Their function uses the fact that saltwater is electrically conductive, and aquatic animals could potentially use induction to sense the geomagnetic field (Kalmijn, 1981; Molteno and Kennedy, 2009). However, no strong evidence currently exists that fish actually use their electric sense to deduce information from the geomagnetic field (Kirschvink et al., 2010; Mouritsen, 2013). In land-based animals, it is difficult to imagine how induction could be used to sense the geomagnetic field since air has low conductivity and the needed structures therefore would have to be realized inside the animals themselves. Several authors have stated that the required physiological structures filled with conductive liquid in birds are too small to function as magnetic induction sensors (Kirschvink et al., 2010; Mouritsen, 2013). However, some recent calculations have suggested that the semicircular canals of pigeons might just be large enough if very fast head movement speeds are assumed (Nimpf et al., 2019). The semicircular canals of almost all night-migratory songbirds, which navigate better over large distances than pigeons, would, however, have too small

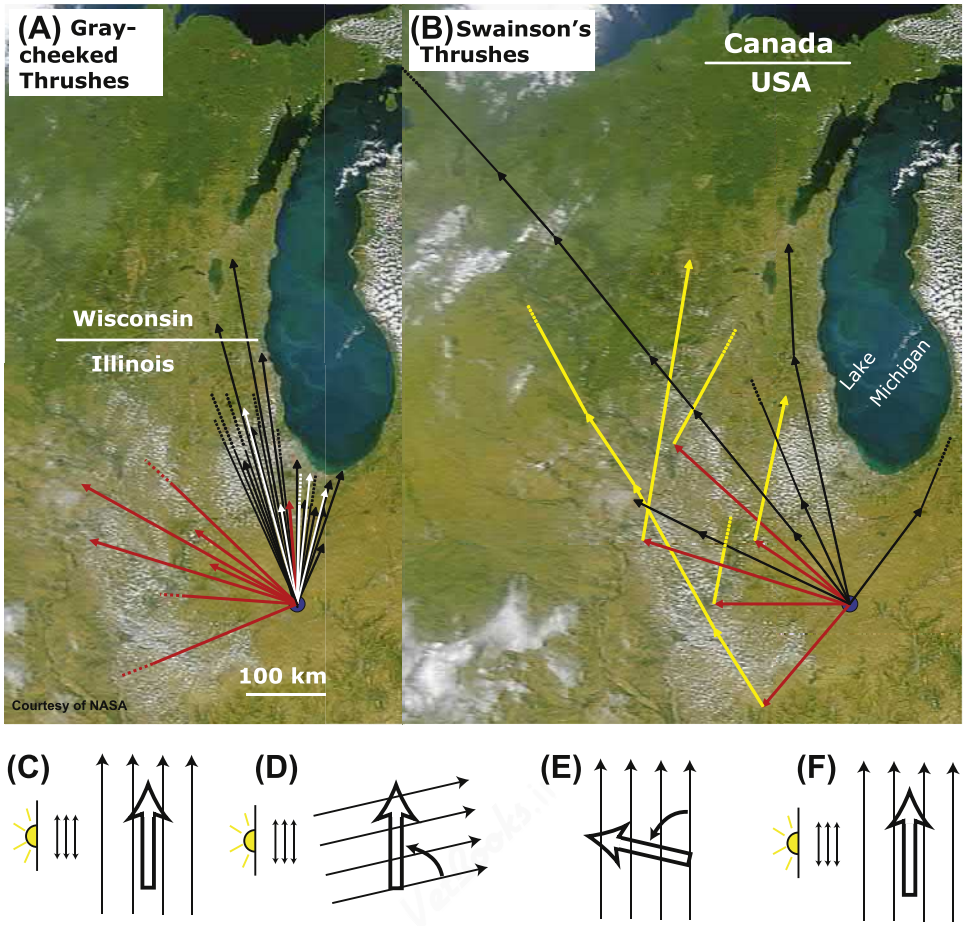

FIGURE 15.6 Some birds calibrate their magnetic compass from celestial cues around sunset. Tracks of free-flying Gray-cheeked Thrushes (A) and Swainson's Thrushes (B) released from Champaign, Illinois are shown. The *arrows* indicate the direction and ground tracks of migratory flights when wind effects were discarded. *Black arrows* indicate migratory flights of nonmanipulated individuals. *Red arrows* indicate migratory flights of experimental birds that had experienced a magnetic field turned to 80 degrees East prior to takeoff, and *yellow arrows* indicate the migratory flights of the experimental birds during subsequent nights. *White arrows* indicate the migratory flight paths of experimental birds that did not migrate on the night of magnetic treatment, but did so 1−6 days later. *Connected arrows* show flights of the same individual during successive nights. Data are depicted differently in (A) and (B) because for Gray-cheeked thrushes, experimental and control birds are different individuals while in Swainson's thrushes, the same experimental individuals were followed for at least two successive nocturnal migrations (due to the large spread in natural headings). *Broken lines* indicate that birds were lost during tracking at the site where the broken lines start. Notice that the birds that experienced a magnetic field turned 80 degrees to the east during sunset and which were released after all light from the sun had disappeared, migrated toward the west when they embarked on migration on the same night. On later nights, they migrated in the appropriate northerly spring migratory direction. These results mean that the birds had calibrated their magnetic compass from their sun compass prior to take-off and that this calibration happens daily. The reasons are illustrated in (C−F). (C) situation for control birds. (D): the turned field is calibrated by the sun during sunset. (E): after release, the birds experience the natural field lines and since all light from the sun had disappeared at time of release, their sunset-calibrated magnetic compass makes them fly wrong for the rest of the first night. (F): on the second night after release, sun and magnetic cues are in agreement and the birds will reorient into their intended migratory direction. The four *thin parallel arrows* (C−F) indicate the horizontal direction of the magnetic field lines experienced by the birds. The *thick arrow* indicates the expected orientation of the birds. The setting sun and the three lines with *double arrowheads* indicate whether sun and polarized light cues were available for calibration. *Figure and parts of the legend from Cochran et al. (2004).*

semicircular canals for induction to work. Thus, for many birds, another mechanism must be responsible for magnetoreception.

15.11 The magnetic-particle−based hypothesis

When human beings want to use the direction of the geomagnetic field for orientation, we use a technical compass based on a needle made of magnetized iron or a magnetic iron compound that moves in the horizontal plane. Therefore, the first suggestion almost any human thinks of when one asks them how birds may detect the geomagnetic field is: "Maybe they have little compass needles in their head." A compass-needle-like structure has been realized inside magnetotactic bacteria, see Fig. 15.7A (Blakemore, 1975; Frankel and Blakemore, 1989). Not surprisingly, this suggestion was also the first suggestion

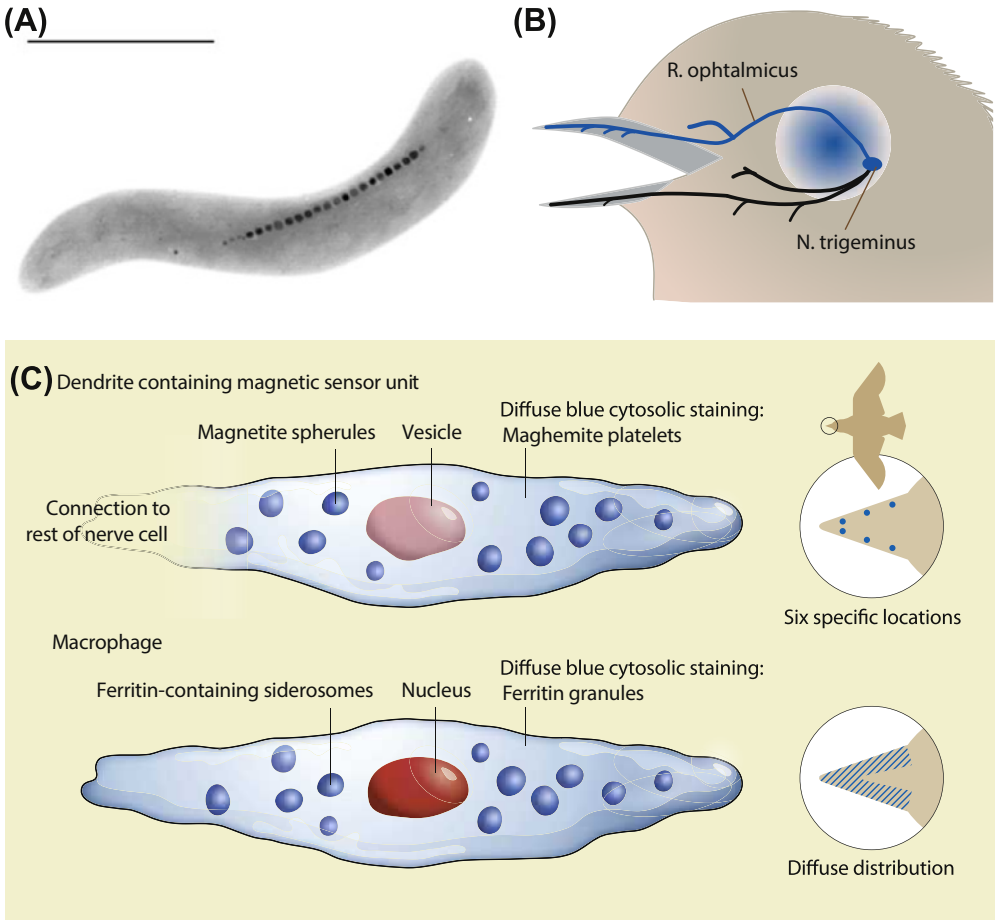

FIGURE 15.7 **Iron-particle structures in birds.** (A) Transmission electron micrograph of the magnetotactic bacteria, *Magnetospirillum magnetotacticum*, showing the magnetosome chain inside the cell. Scale bar: 1 μm. Magnetosomes would be the most straightforward solution for a magnetic field sensor in the nervous system of a bird, but, so far, magnetosomes have not been proven to occur in any bird. (B) Bird head schematically illustrating the anatomical location of the three branches of the trigeminal nerve. (C) Schematic drawing of iron-containing structures in birds' upper beak illustrating the opposing interpretations of Fleissner et al. (2003) and Treiber et al. (2012). *(A) Photograph © Richard B. Frankel. (C) Figure reproduced with permission from Nature: Mouritsen (2012) Nature 484: 320–321. Reproduced from Mouritsen (2013).*

scientists came up with. A chain of single domain magnetite particles (Blakemore, 1975; Frankel and Blakemore, 1989; Kirschvink et al., 2010) or other very similar iron oxides (Falkenberg et al., 2010) would be the easiest realization of a small compass-needle-like structure inside a bird, but other arrangements of iron-based particles could also work as a magnetic field detector (Solov'yov and Greiner, 2009; Kirschvink et al., 2010). Any such magnetic particles are expected to transduce the magnetic signal by opening or closing pressure-sensitive ion channels (Johnsen and Lohmann, 2005; Cadiou and McNaughton, 2010; Shaw et al., 2015).

Many studies have documented the presence of magnetite or other kinds of iron-based compounds in almost any animal, where researchers have seriously looked (e.g., in *Caenorhabditis elegans*, mollusks, insects, crustaceans, and various vertebrates; Mouritsen, 2013, 2018; Shaw et al., 2015). However, the mere existence of iron-containing compounds, particles, or even magnetite does not represent significant evidence by itself that such structures have any relevance to magnetoreception (Mouritsen, 2013, 2018; Malkemper et al., 2019). Iron is an important element required for proper function of most organisms. Consequently, iron homeostasis is important, and iron-containing deposits may just be a way for an organism to get rid of excess iron. Therefore, only if iron-containing particle structures are found at consistent, specific locations and are associated with the nervous system, the iron-containing structures qualify as serious magnetosensory candidates (Mouritsen, 2013, 2018). The existence of magnetite particle chains, which lead to a magnetically oriented swimming behavior in so-called magnetotactic bacteria (Blakemore, 1975; Frankel and Blakemore, 1989; Bazylinski and Frankel, 2004), unequivocally proves that

living cells can, in principle, synthesize magnetite that will align with the geomagnetic field. However, the magnetite particles in these bacteria are not part of an active sensory system, they only lead to passive alignment (Wiltschko and Wiltschko, 1995; Mouritsen, 2013).

For a while, the most promising, active, magnetic-particle–based magnetoreceptor candidate structures in vertebrates were those reported from the olfactory epithelium of fish (Walker et al., 1997; Eder et al., 2012) and in the upper beak of birds (Fleissner et al., 2003; Falkenberg et al., 2010). However, recent findings suggest that these structures were contamination artifacts (Edelman et al., 2015) and macrophages involved in iron homeostasis (Treiber et al., 2012), respectively. Thus, at present, no convincingly documented, magnetic-particle–based, magnetoreceptive candidate structures are known from birds, see Fig. 15.7C (Mouritsen, 2012, 2018).

Conditioning of birds to magnetic stimuli has also proven to be very difficult, and independent replication is rare. It has been reported that homing pigeons, *Colomba livia*, can be conditioned to respond to strong magnetic fields (Mora et al., 2004; Mora and Bingman, 2013). The conditioned response to a very strong magnetic field (around two times the strength of the geomagnetic field) required intact trigeminal nerves (Mora et al., 2004). Consequently, pigeons seem to, in principle, be able to detect strong magnetic field changes via the ophthalmic branch of the trigeminal nerve. However, in order to use geomagnetic information for a map, animals must be sensitive to changes in the geomagnetic field, which are three to five orders of magnitude smaller than the anomalies used in the successful conditioning experiments. Using a very similar paradigm adapted for European robins and using weaker fields resulted in nicely conditioned responses to auditory stimuli but failed to produce a conditioned response to magnetic field stimuli (Kishkinev et al., 2012).

The ophthalmic branch of the trigeminal nerve (see Fig. 15.8) terminates in the principal (PrV) and spinal tract (SpV) nuclei of the trigeminal brainstem complex (Williams and Wild, 2001; Heyers et al., 2010, see Fig. 15.8). Neuronal activation studies show that sub-populations of neurons both in the ventral PrV and in parts of SpV in European robins (*Erithacus rubecula*), Pigeons (*Columba livia*), Northern Wheatears (*Oenanthe oenanthe*), and Eurasian Blackcaps (*Sylvia atricapilla*) are activated by changing magnetic field stimuli, but not by a zero magnetic field (Heyers et al., 2010; Lefeldt et al., 2014; Elbers et al., 2017; Kobylkov et al., 2020a). Furthermore, the activation seen in the changing magnetic field is strongly reduced when the ophthalmic branch of the trigeminal nerve is severed (see Fig. 15.8B and C). Neuronal tracing experiments have shown that SpV projects to PrV (Arends et al., 1984; Faunes and Wild, 2017), and that the magnetically activated ventral part of PrV forms a separate, previously unknown, connection to the ipsilateral trigeminal frontal nidopallium (NFT) in the forebrain that is likely to be a key processing pathway for trigeminally mediated magnetoreception (see Fig. 15.8A; Kobylkov et al., 2020a). These findings suggest that the ophthalmic branches of the trigeminal nerves carry magnetic information in birds (Heyers et al., 2010; Lefeldt et al., 2014; Elbers et al., 2017; Kobylkov et al., 2020a). However, the sensory origin (most

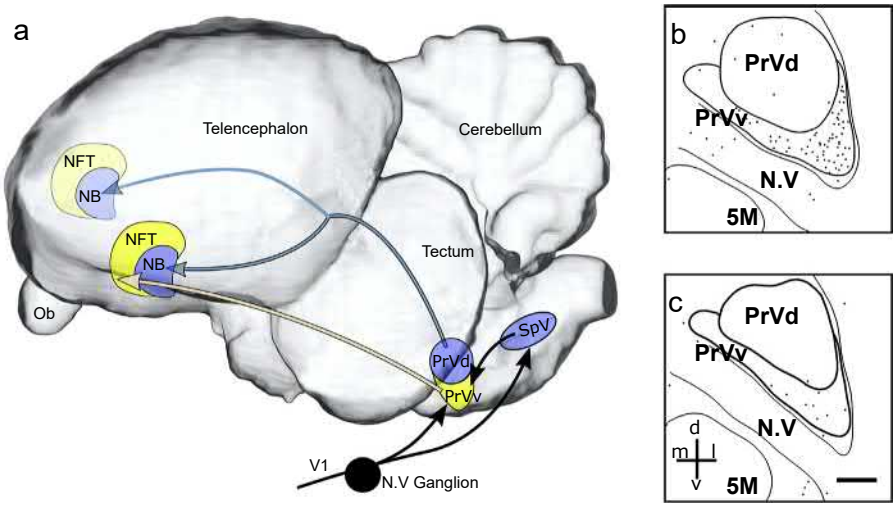

FIGURE 15.8 Magnetically activated neurons in two hindbrain-regions, SpV and ventral PrV, receive sensory input from the ophthalmic branch of the trigeminal nerve (V1) and passes this information onto the NFT in the forebrain of night-migratory birds. (A) schematic drawing of the currently known parts of the pathway processing magnetic information received via the ophthalmic branch of the trigeminal nerve in night-migratory songbirds. (B) Neurons in the ventral part of PrV are activated by magnetic stimuli (activated neurons are indicated by the *black dots* in (B) and (C); after Heyers et al., 2010). (C) The neuronal activation in PrVv significantly drops after bilateral V1 ablation or removal of the magnetic stimuli (after Heyers et al., 2010). *Figure modified after Kobylkov et al. (2020b).*

likely magnetic-particle–based) of the trigeminally mediated magnetic information are unclear at present (see Fig. 15.7C; Mouritsen, 2012).

Information from the ophthalmic branch of the trigeminal nerve is neither required nor sufficient for magnetic compass orientation in several night-migrating songbird species (e.g., Zapka et al., 2009, see Fig. 15.13). Homing experiments with pigeons have shown that pigeons tested around Pisa (Italy) need intact olfactory nerves but not intact trigeminal nerves to home (Gagliardo et al., 2006, 2008, 2009). The most likely function of the trigeminal nerve-related magnetic sense is to detect large-scale changes in magnetic field strength and/or magnetic inclination, which could be used to determine approximate position. Real displacement experiments have shown that Eurasian Reed Warblers, *Acrocephalus Scirpaceus*, are capable of correcting for a 1000 km eastward displacement (Chernetsov et al., 2008), but that this ability disappears when the ophthalmic branch of the trigeminal nerve is cut (Kishkinev et al., 2013, see Fig. 15.3). Eurasian Reed Warblers also correct for virtual magnetic displacements in which all the magnetic field parameters are set to match the real displacement location of previous experiments, but in which the birds were not actually moved (Kishkinev et al., 2015). Because all other cues such as olfactory and celestial cues are identical before and after virtual displacements, virtual magnetic displacement experiments demonstrate that magnetic parameters can play a decisive role in the map sense of long-distance, night-migratory songbirds (Kishkinev et al., 2015; Chernetsov et al., 2017; Pakhomov et al., 2018). Intact ophthalmic branches of the trigeminal nerves are required for these birds' abilities to correct for virtual magnetic displacements (Pakhomov et al., 2018). Furthermore, experiments with night-migratory songbirds exposed to strong magnetic pulses, which are thought to disturb any magnetite-based magnetic sense for days to weeks, but which should not have any effect after the treatment itself on a light-dependent magnetoreception mechanism (see next section), support the idea that the magnetic map or signpost sense could be magnetic-particle–based (Wiltschko et al., 2009; Holland, 2010; Holland and Helm, 2013).

It has also been suggested that the avian lagena (a part of the birds' vestibular system) and/or the semicircular canals play a role in magnetodetection (Wu and Dickman, 2011, 2012; Malkemper et al., 2019; Nimpf et al., 2019). Whether the inner ear provides the primary magnetic information or gravity information to the magnetic sense is not yet clear (Malkemper et al., 2019), but if the electrophysiological data (Wu and Dickman, 2012) can be independently replicated, the role of the lagena in magnetoreception is very significant indeed and the vestibular brainstem nuclei would be a very important processing station for magnetic field information.

15.12 The light-dependent hypothesis

The magnetic compass behavior of newts (Phillips and Borland, 1992) and birds (Wiltschko et al., 1993, 2010b; Muheim et al., 2002) is dependent on the wavelengths of light being available during behavioral tests. Already in the late 1970s, theoretical considerations led Klaus Schulten to suggest that chemical reactions based on radical-pairs in photosensitive molecules could form the basis of a magnetic compass sense (Schulten et al., 1978). An extensive tutorial review on the radical-pair mechanism of magnetoreception can be found in Hore and Mouritsen (2016).

The principles of the suggested light-dependent magnetic sensing mechanism are illustrated in Fig. 15.9. A light-sensitive molecule absorbs light and uses the light energy to transfer an electron within a molecule or between associated molecules. Thereby, a radical pair is produced. If this radical pair is long-lived ($\sim$1–10 μs), it can, depending on the spin of the electrons, exist in one of two states, a singlet state (spins antiparallel) or a triplet state (spins mostly parallel). It is known from chemistry that singlet and triplet states have different chemical properties and thus often result in different chemical end products. Earth-strength magnetic fields can theoretically affect the relative likelihoods of the molecule being in the singlet or triplet states, and thereby modulate a presently unknown biochemical pathway (Schulten et al., 1978; Ritz et al., 2000; Rodgers and Hore, 2009; Hore and Mouritsen, 2016), but see Wu et al. (2020).

How can we imagine that a bird using a light-induced, radical-pair mechanism would detect the magnetic field? It is possible that a virtual visual image would literally enable birds to "see" the direction of the magnetic field lines. Various specific virtual images have been suggested (see e.g., Fig. 15.10; Ritz et al., 2000, 2010; Solov'yov et al., 2010). However, all these images are for illustrative purposes only because we have much too little information available at present to know how an actual magnetically modulated light pattern seen by a bird would look like (Mouritsen, 2013; Hore and Mouritsen, 2016). It is almost certain, however, that the mechanism would require two neighboring sensors oriented in such a way relative to each other that they would calculate out light intensity and light polarization angle (Hore and Mouritsen, 2016; Worster et al., 2017). The outer or inner segments of cone photoreceptor cells, most likely the double cones (Günther et al., 2018, 2021), would be ideal locations for the light-dependent, radical-pair–based, magnetic field sensors (Hore and Mouritsen, 2016; Mouritsen, 2018; Xu et al., 2021).

If the radical-pair mechanism is responsible for magnetoreception, it means that it is based on a quantum mechanical effect (Rodgers and Hore, 2009; Ball, 2011; Hogben et al., 2012; Solov'yov et al., 2014; Hore and

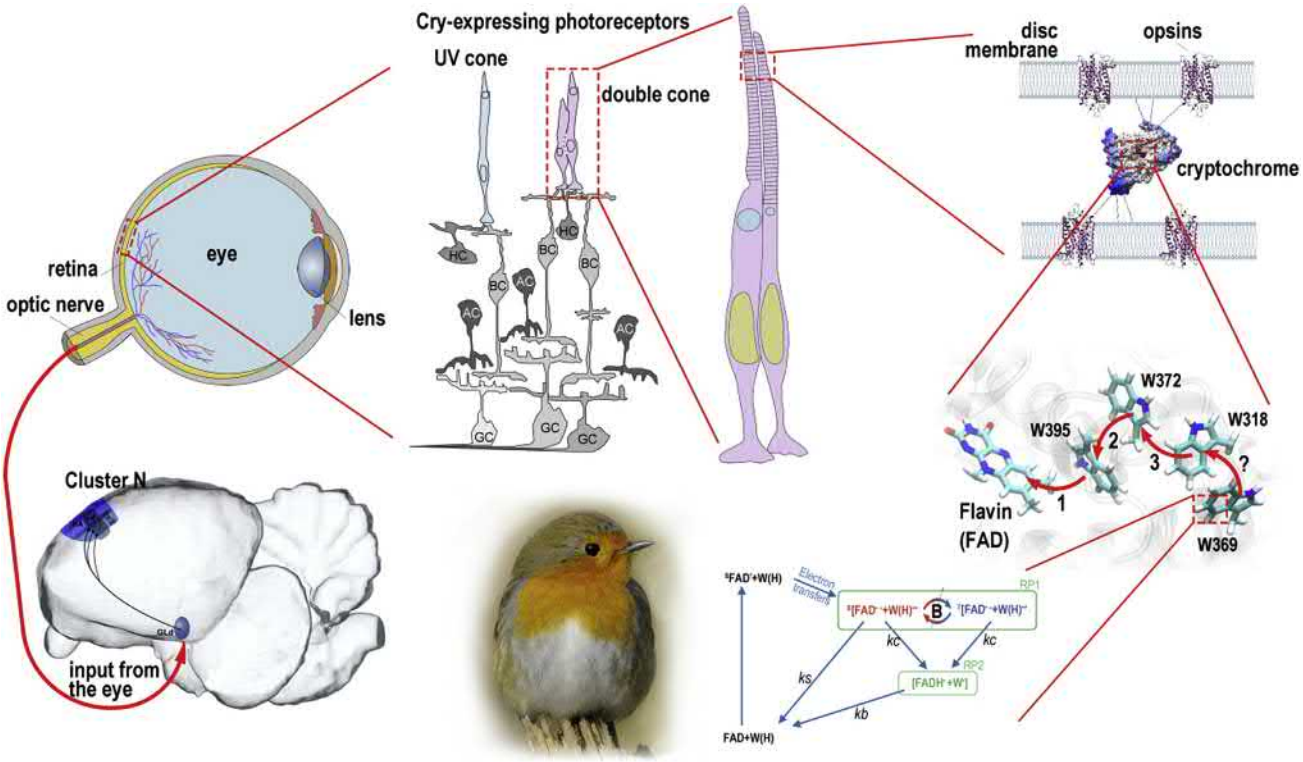

FIGURE 15.9 Summary of the proposed light-dependent magnetic compass sensing hypothesis in birds. Most of the experiments reviewed here were performed on European robins, *Erithacus rubecula*. The reference direction provided by the Earth's magnetic field is detected in the birds' eyes. It is hypothesized that cryptochrome proteins are the light-dependent magnetic sensory molecules. Light absorption is thought to generate long-lived flavin-tryptophan radical pairs generated by sequential electron transfers within cryptochromes in the retina, whose reaction yields are determined by the orientation of the molecule with respect to the magnetic field vector. If the cryptochromes were associated with the membrane disks of the outer segments of the photoreceptors, then an ordered structure could result, and different reaction yields in different parts of the retina or between neighboring cells could be compared to provide a visual impression of the compass bearing (see Fig. 15.10). The most likely magnetoreceptive candidate molecule at present is cryptochrome 4 which is located in the outer segments of the double cones and long-wavelength single cones. Light-dependent magnetic compass information is transmitted from the retina through the optic nerve to the visual thalamus and from there to Cluster N in the forebrain, via the thalamofugal visual pathway (Fig. 15.12). If Cluster N is destroyed, European robins can no longer use their magnetic compass (Fig. 15.13). The illustration of the cryptochromes bound to photoreceptor membranes is modified from Solov'yov et al. (2010). The brain illustration originates from Mouritsen et al. (2016). The compound illustration was created by Ilia Solov'yov. *Photo by Henrik Mouritsen.*

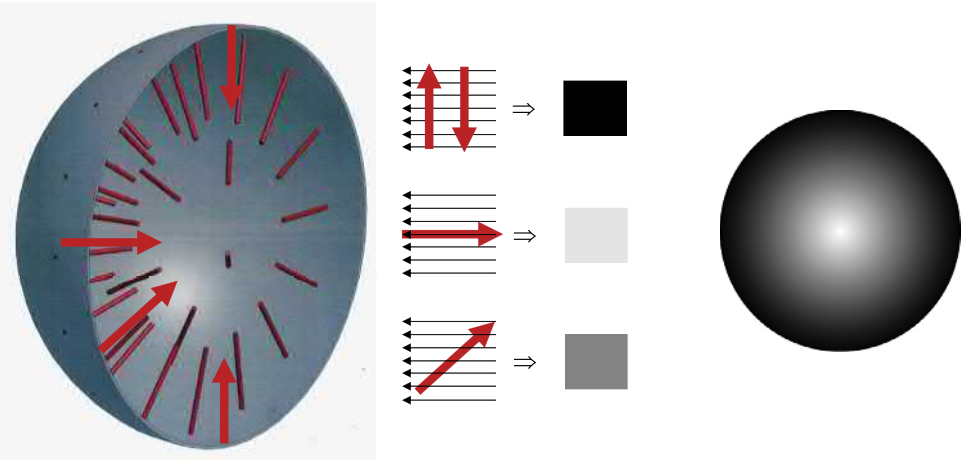

FIGURE 15.10 How the light-dependent, radical-pair–based, magnetic sensing mechanism could lead to perception of a visual image. Principal illustration suggesting how birds could, in principle, convert a magnetic stimulus into a putative visual image. Left: three-dimensional illustration of the half-sphere of an eyeball. Red pins simulate cryptochrome orientation all pointing toward the center of the eyeball. If a bird's eye would be looking in the direction of the magnetic field lines, one could imagine that the birds would see a pattern similar to the one illustrated on the right because the light-sensitivity of one or more cryptochromes would depend on their orientation relative to the axis of the magnetic field lines. *Redrawn after Mouritsen (2013) inspired by Ritz et al. (2000).*

Mouritsen, 2016; Mouritsen, 2018). It might in fact be the only sensory mechanism in biology to be inherently quantum in nature. Critics of the radical-pair mechanism have pointed out that the interaction energy between a geomagnetic field and a radical is typically several orders of magnitude below the background thermal energy, k_BT (e.g., Kirschvink et al., 2010). At first glance, this might seem critical, but because the spins in the relevant radicals are very far from equilibrium this is not a fundamental problem. Very weak magnetic interactions can affect radical pair reactions essentially for three reasons (Hore, 2011; Hore and Mouritsen, 2016). (a) Radical pair chemistry is controlled by the electron spins in the radicals. (b) The electron spins are not at thermal equilibrium. (c) The electron spins behave quantum mechanically. Weak magnetic fields affect the coherent behavior of the electron spins in a fundamentally quantum manner in which k_BT plays no role. Instead of comparing interaction energies to k_BT, one must compare the time required for a magnetic interaction to have an effect with the time required for the system to reach thermal equilibrium, the so-called spin-correlation time (Hore, 2011; Hore and Mouritsen, 2016). If the former is shorter than the latter, then the magnetic field can have an effect (Hore, 2011), and if the spin-correlation time is at least 2−10 μs, a so-called quantum-needle effect appears, which could improve the directional accuracy of a radical-pair–based magnetoreceptor system very substantially (Hiscock et al., 2016). As an excellent analogy (Hore, 2011; Hore and Mouritsen, 2016), one can imagine a fly and a rectangular granite block. If the granite block is standing on one of its sides (conventional physics, equilibrium), the fly has no chance to flip the granite block, but if the granite block is balancing on one of its sharp corners (quantum mechanics, nonequilibrium), depending on where the fly lands, it might flip the granite block to one or the other side (Fig. 15.11).

Which molecule can be responsible for light-dependent magnetoreception? Opsins cannot function as radical-pair–based magnetoreceptors because opsins use the light energy to change a chemical bond, not to transfer an electron. The only currently known photoreceptor molecules found in vertebrates, which can use light energy to form long-lived radical pairs are the cryptochromes (Ahmad and Cashmore, 1993; Cashmore et al., 1999; Ritz et al., 2000, 2010; Giovani et al., 2003; Liedvogel et al., 2007a; Biskup et al., 2009; Rodgers and Hore, 2009; Liedvogel and Mouritsen, 2010; Nießner et al., 2011, 2016, 2018; Bolte et al., 2016; Sheppard et al., 2017; Günther et al., 2018; Zoltowski et al., 2019; Xu et al., 2021). Some cryptochromes are known to be involved in circadian clocks (Cashmore et al., 1999; Sancar, 2003). However, in birds, more cryptochromes than the ones thought to be involved in the clock occur, so it is easy to imagine that they can play a role in other biochemical processes (Liedvogel and Mouritsen, 2010; Günther et al., 2018; Xu et al., 2021). Cryptochromes are related to the DNA repair

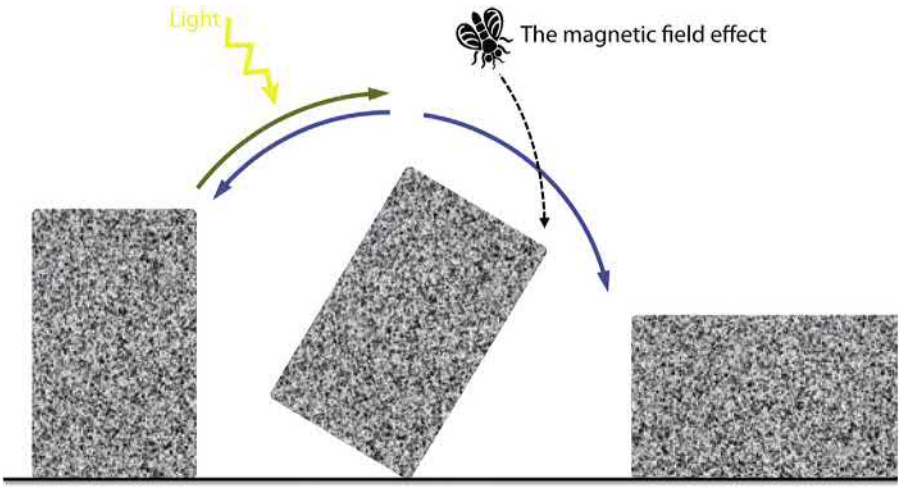

FIGURE 15.11 Granite block analogy of light-dependent magnetoreception. A granite block analogy can help understand how a radical-pair–based mechanism can theoretically be used to sense Earth-strength magnetic fields, even though the energy exerted by the magnetic field on the radical is much lower than thermal energy, k_BT. Imagine a granite block standing on one of its sides (the system is in equilibrium). If a fly lands on the granite block while it is in this position, there is no way the fly can make the granite block flip over. In fact, quite a lot of energy is needed to move the granite block onto one of its sharp corners (a state very far from equilibrium), but once it is on one of its sharp corners, a very small amount of energy can influence which way the granite block falls. Now even a fly landing on the granite block may make it flip over to one or the other side. In the light-dependent, radical-pair–based magnetoreception hypothesis, light has much more energy than the magnetic field. It is the absorption of light that brings a photoreceptor molecule (probably a cryptochrome) into an exited state (moves the granite block onto its sharp corner in the analogy). This excited state is highly sensitive to even very small magnetic field effects (the fly landing onto the granite block in the analogy). *After Hore (2011) and Hore and Mouritsen (2016).*

enzymes called photolyases (Cashmore et al., 1999; Sancar, 2003) and consist of a photolyase homology region and a C-terminal end, which varies greatly between different cryptochromes (Cashmore et al., 1999; Sancar, 2003; Müller and Carell, 2009; Liedvogel and Mouritsen, 2010; Chaves et al., 2011; Ozturk, 2017; Zoltowski et al., 2019). Many cryptochromes, including at least bird cryptochrome 4, noncovalently bind the cofactor flavin (Ozturk et al., 2009; Xu et al., 2021; Zoltowski et al., 2019). The light-induced electron transfer takes place between the flavin and three or four tryptophan residues within the cryptochrome protein (Gindt et al., 1999; Biskup et al., 2009; Rodgers and Hore, 2009; Solov'yov et al., 2012; Maeda et al., 2012; Hore and Mouritsen, 2016; Sheppard et al., 2017; Zoltowski et al., 2019; Xu et al., 2021). Very recently, it was shown that Cryptochrome 4 from night-migratory European robins is very magnetically sensitive in vitro, and more so than cryptochrome 4 from non-migratory pigeons and chickens (Xu et al., 2021).

Cryptochromes are predominantly found within photoreceptor cells and ganglion cells in the eyes of birds (Mouritsen et al., 2004; Möller et al., 2004; Nießner et al., 2011, 2016; Bolte et al., 2016, 2021; Günther et al., 2018). At present, cryptochromes are the only seriously considered candidate molecules for radical-pair–based magnetoreception in birds (Mouritsen and Ritz, 2005; Rodgers and Hore, 2009; Ritz et al., 2010; Hore and Mouritsen, 2016; Mouritsen, 2018), and Earth-strength magnetic fields effects on a radical pair reaction in an artificially produced molecule mimicking the reaction principle thought to take place in cryptochrome have been observed and thus support the theoretical feasibility of the suggested mechanism (Maeda et al., 2008; reviewed in Mouritsen and Hore, 2012).

Following the suggestion of Klaus Schulten et al. (1978), it was shown that the compass orientation behavior of night-migrating songbirds is influenced by the color (i.e., wavelengths) of the light available in the room in which the orientation tests are performed (Wiltschko et al., 1993, 2010b). This wavelength dependence is difficult to explain if the eyes and/or pineal organ are not somehow involved in the magnetic compass. In birds, the pineal organ is not needed for magnetic compass orientation (Schneider et al., 1994), whereas photoreceptor molecules in the pineal organ seem to be essential for magnetic compass orientation in newts (Phillips et al., 2001).

The radical-pair mechanism of magnetoreception should be disturbed by oscillating radio frequency (RF) magnetic fields with frequencies in resonance with one or more of the singlet-triplet oscillation frequencies, which are determined by the possible energy-level splits of the radical pair, because such fields could override the effect of the external magnetic field and thus alter the reaction yield (Henbest et al., 2004). On the contrary, weak RF magnetic fields are both too weak and too fast to interfere with any induction- or magnetite-based magnetoreceptors (Hore and Mouritsen, 2016).

Oscillating, RF magnetic fields in the low MHz range as weak as a few nT (ca. 0.01–0.1% of the geomagnetic field strength) disrupt the magnetic compass orientation capabilities of night-migratory songbirds (Ritz et al., 2004, 2009; Engels et al., 2014; Schwarze et al., 2016; Pakhomov et al., 2017; Kobylkov et al., 2019). At first, it was claimed that only an RF magnetic field at the so-called Larmor frequency could disrupt the orientation of birds (Ritz et al., 2009), but later it was shown that broadband RF fields are much more effective in disrupting the birds' magnetic compass (Engels et al., 2014; Schwarze et al., 2016). Broadband RF effects are much easier to understand than the claimed Larmor frequency-specific effects because any realistic organic radical-pair that could occur inside a bird will have magnetic nuclei such as hydrogens and/or nitrogen near the unpaired electrons, and this leads to multiple energy level splits and thus to a predicted broadband RF effect (for a detailed explanation, see Hore and Mouritsen, 2016). While it can be understood based on quantum mechanical theory why broadband RF fields can affect a radical-pair–based magnetoreception mechanism, it remains a challenge to explain how RF fields as weak as a few nT can have the effects observed in behavioral tests (Hore and Mouritsen, 2016; Hiscock et al., 2017; Mouritsen, 2018).

On the neuroanatomical level, a region named Cluster N (Fig. 15.12) is by far the most active forebrain region when night-migrating birds perform magnetic compass orientation, and this activation disappears when the birds' eyes are covered (Mouritsen et al., 2005; Feenders et al., 2008; Zapka et al., 2010; Hein et al., 2010). Cluster N receives its neuronal input from the eyes via the thalamofugal visual pathway (Heyers et al., 2007; Mouritsen et al., 2016). The presence and activation of Cluster N at night has been independently replicated in other night-migratory songbirds (Rastogi et al., 2011). Could Cluster N be a processing center of light-dependent magnetic compass information?

Double-blind experiments (Fig. 15.13) with European robins have shown that birds with bilateral Cluster N lesions were unable to orient using their magnetic compass (Zapka et al., 2009). In contrast, sham Cluster N lesions or bilateral sections of the ophthalmic branch of the trigeminal nerves did not influence the robins' ability to use their magnetic compass for orientation (Zapka et al., 2009). Cluster N lesions only affect the magnetic compass, since Cluster N lesioned robins orient well using their sun and star compasses (Zapka et al., 2009). These data (a) show that Cluster N is required for magnetic compass orientation in this species; (b) indicate that Cluster N may be specifically involved in processing magnetic compass information; (c) strongly suggest that a vision-mediated mechanism

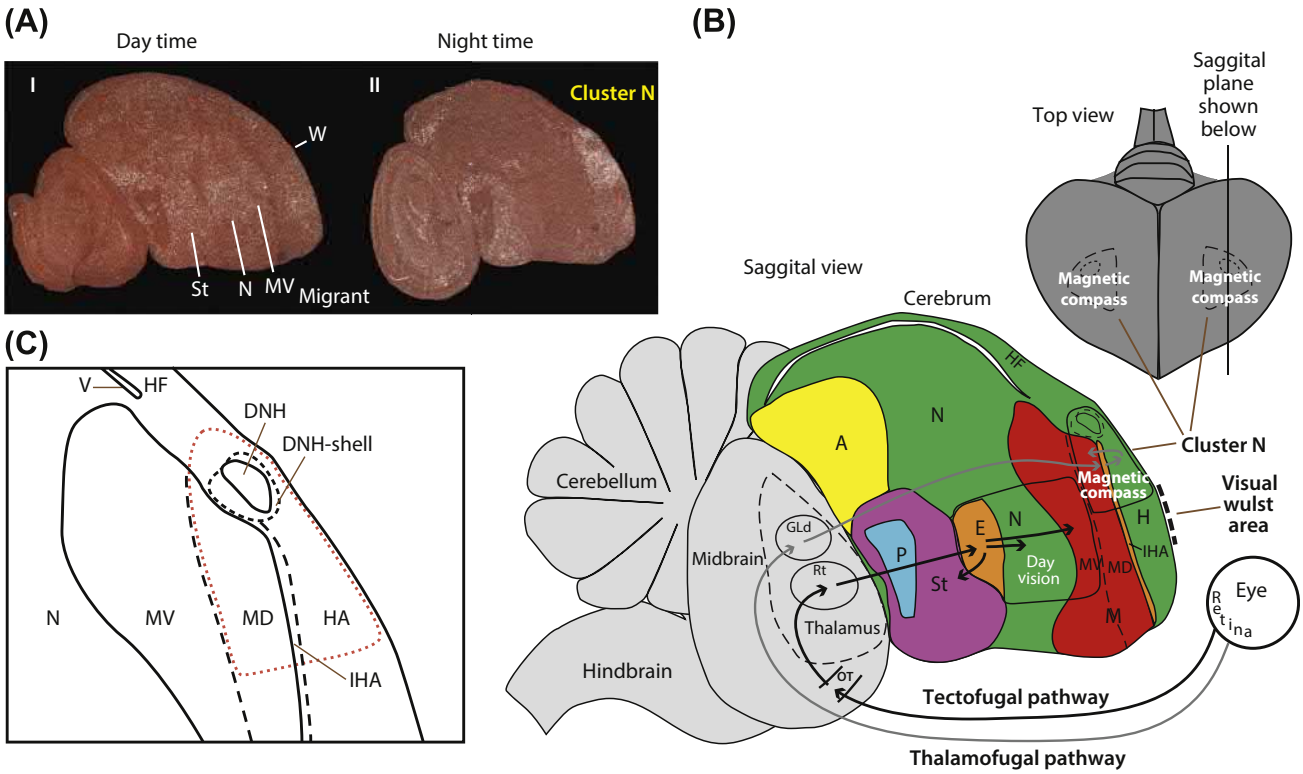

FIGURE 15.12 **Cluster N.** (A) Cluster N is the most active brain area when migratory birds perform magnetic sensing and/or compass orientation at night (white signal in the brain slices indicate activated neurons) and Cluster N is required for magnetic compass orientation (see Fig. 15.13). (B) Cluster N is a part of the visual Wulst and receives input from the eyes via the thalamofugal visual pathway (Heyers et al., 2007). Top view of the brain in gray indicates the medial-lateral and the frontal-caudal extent of Cluster N and the DNH and DNH-shell. (C) Cluster N is a functional unit consisting of a part of the hyperpallium, maybe a part of the dorsal mesopallium (Jarvis et al., 2013), and a nucleus embedded within the hyperpallium named DNH with a shell of cells around the DNH. Anatomy: *A*, arcopallium; *DNH*, dorsal nucleus of the hyperpallium; *DNH-shell*, shell around the DNH; *E*, entopallium; *H*, hyperpallium; *HF*, hippocampal formation; *IHA=HI*, interstitial region of the hyperpallium intercalatum; *LGd*, Lateral geniculate nucleus, dorsal part; *M*, mesopallium; *MD*, mesopallium dorsale; *MV*, mesopallium ventrale; *N*, nidopallium; *OT*, optic tectum; *P*, pallidum; *Rt*, nucleus rotundus; *St*, striatum; *v*, ventricle; *W*, visual Wulst. *From Mouritsen (2013) after Mouritsen et al. (2005).*

underlies the magnetic compass in this migratory songbird; (d) indicate that input from the lagena is not sufficient for magnetic compass orientation in robins; and (e) show that the proposed magnetic input to the brain transmitted via the trigeminal nerve is neither necessary nor sufficient for magnetic compass orientation of European robins tested in an orientation cage (Zapka et al., 2009; Mouritsen, 2013, 2018). The exact role of Cluster N within the magnetic compass information processing circuit has not been determined, but the existing results raise the distinct possibility that this small part of the visual system enables birds to "see" magnetic compass information (Mouritsen, 2013, 2018).

Do these results exclude the possibility that magnetic-particle–based and/or trigeminally mediated and/or lagena-mediated magnetoreception exists? Absolutely not. In birds, magnetic-particle–based magnetoreception may very well exist, and magnetic field–dependent neuronal activation in trigemino-recipient and lagena-recipient regions has been documented (see above). Trigeminally mediated magnetoreception just does not seem to be the primary mechanism for the magnetic compass of night-migratory songbirds (Zapka et al., 2009), but is likely to be a primary source for magnetic positional information (Mora et al., 2004; Kishkinev et al., 2013; Pakhomov et al., 2018). In fact, it is likely that light-mediated, radical-pair–based magnetoreception and magnetic-particle–based magnetoreception mechanisms exist side by side in several animal species and that they may provide the animals with different types of magnetic information (Wiltschko and Wiltschko, 2007; Hore and Mouritsen, 2016; Mouritsen, 2018).

As so often in biology, when there are two hypotheses how something works, it often turns out that both of them are correct to a certain degree. Furthermore, seemingly unnecessary redundancy seems to be a very common occurrence in biology, probably because organisms that can perform an important function in several ways will be more robust to changes and thus be favored by evolution (Mouritsen, 2013).

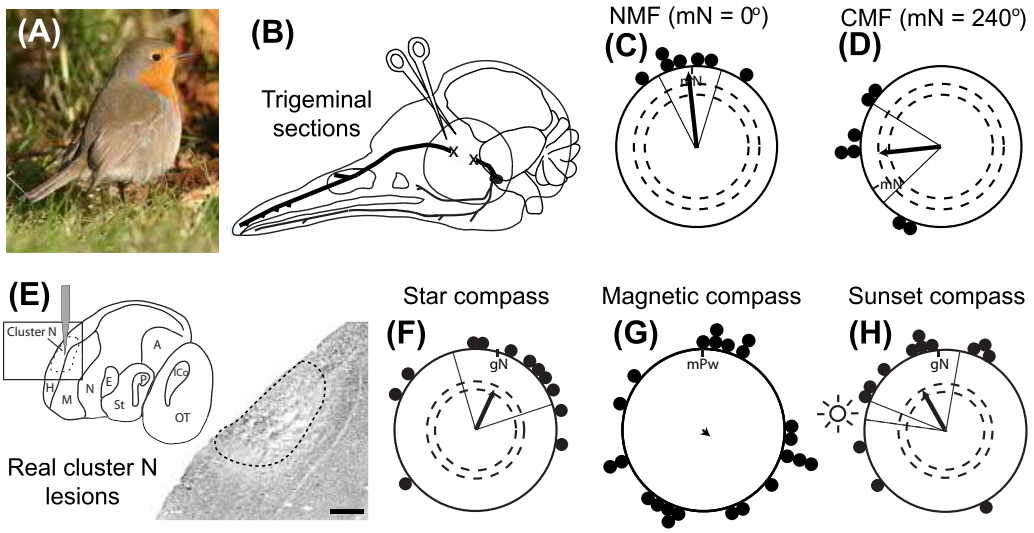

FIGURE 15.13 The brain region Cluster N is necessary for magnetic compass orientation behavior, but not for star and sun compass orientation. The trigeminal nerve is neither necessary nor sufficient for magnetic compass orientation in European Robins. (A) The European Robin. (B–D): Bilateral sectioning of the ophthalmic branch of the trigeminal nerve (B) does not affect the birds' magnetic compass orientation capabilities (C–D; mN = magnetic North). (E–H) Bilateral chemical lesions of Cluster N (E) destroyed the magnetic compass capabilities of the birds (G), whereas star compass orientation in a planetarium (F) and sun compass orientation outdoors with view of the setting sun (H) was unaffected by Cluster N lesions. The circular diagrams are explained in the legend of Fig. 15.3. (E) shows a schematic drawing and an example part of a brain section saggitally cut through the center of Cluster N and stained with a neuronal marker. Scale bar 500 µm. Rostral is left, caudal is right. Note that the tissue where Cluster N should have been in the lesioned bird (E) is destroyed. Anatomy: *A*, arcopallium; *E*, entopallium; *H*, hyperpallium; *ICo*, intercollicular complex; *M*, mesopallium; *MD*, mesopallium dorsale; *MV*, mesopallium ventrale; *N*, nidopallium; *OT*, optic tectum; *P*, pallidum. *(A) Photo © Henrik Mouritsen. 15.13 Irreproducible results and the urgent need for independent replication

Magnetic sense research is strongly influenced by a number of claims, which nobody has ever been able to independently replicate. This is particularly true for electrophysiological evidence (e.g., Semm and Demaine, 1986; Beason and Semm, 1987; Ramirez et al., 2014), but there are also many other examples of contradicting and/or seemingly irreproducible results in the literature including the effects of lidocaine treatment on upper beak receptors (Engels et al., 2018), many claims that humans have a magnetic sense (Westby and Partridge, 1986; Baker, 1989), and the claim that the magnetic compass of birds should only be in the right eye of birds (Wiltschko et al., 2002, 2003; Liedvogel et al., 2007b; Stapput et al., 2010; Hein et al., 2010, 2011; Engels et al., 2012). These problems with reproducibility do not necessarily mean that the original claims were wrong. However, it means that any result in magnetoreception—and in any other field for that matter—should be treated with caution until a given finding has been independently replicated.

This lack of reproducibility in magnetic sense–related research is, unfortunately, accompanied by an almost complete lack of double-blind procedures. Considering this history and the fact that humans have no intuitive feel for magnetic stimuli (and therefore are less likely to detect even obvious artifacts), double-blind procedures should become the standard. Studies representing the first independent, double-blind, replication of key findings in magnetoreception are therefore almost as important as the original finding (Mouritsen, 2013, 2018).

15.14 Where do we go from here?

Even though the magnetic senses are still not completely understood, many studies from different fields support both the magnetic-particle–based and the light-dependent magnetoreception hypotheses. However, fundamental questions remain in all relevant fields.

For instance, functional understanding of any particular magnetic-particle–based structure proven to be involved in an active sensory system is lacking (Mouritsen, 2012, 2018). Likewise, we yet have to understand biophysically how nature designed radical-pair receptors so that they can be sensitive to Earth-strength magnetic fields at physiological temperatures, a feat that has been approximated, but not yet fully accomplished in manmade radical-pair reactions (Maeda et al., 2008; Rodgers and Hore, 2009; Hore and Mouritsen, 2016). Furthermore, studies at the protein level in vitro suggest that cryptochromes from night-migratory songbirds, but seemingly not those from nonmigratory chicken and pigeons, have properties optimal

for magnetic sensing (Xu et al., 2021), but we yet have to demonstrate magnetic field effects on bird cryptochromes in vivo.

On the neuroanatomical level, we have just begun to explore the brain circuits processing magnetic information, but we are still far from understanding how a bird gets from the detection of magnetic information to a directional choice, which is made, based on integration of information from multiple sensory systems (reviewed in Mouritsen et al., 2016). Also, so far, none of the reported responses of single neurons to magnetic stimuli have been independently replicated. Even at the behavioral level, where most studies about magnetic senses have been published, a clear separation of experimental parameters has proven difficult, and many behaviors appear to be multimodal, or at least modulated by other modalities, such as vision and olfaction (Mouritsen, 2013, 2018).

In conclusion, magnetoreception is an important part of life for birds and a wide variety of other animals, and there are still many opportunities to perform new, groundbreaking research on the molecules, cells, and neural processes underlying any kind of magnetoreception.

Chapter 16

The avian subpallium and autonomic nervous system

Wayne J. Kuenzel[1] and Alexander Jurkevich[2]

[1]Poultry Science Center, University of Arkansas, Fayetteville, AR, United States; [2]Advanced Light Microscopy Core, University of Missouri, Columbia, MO, United States

16.1 Introduction

The telencephalon of vertebrates comprises two major formations, the dorsal part or pallium (cortex in mammals) and the basal part or subpallium. The last two decades revolutionized our understanding of the structural organization of these two telencephalic divisions. Discovery of evolutionally conserved homeobox genes, a group of transcription factors regulating the development of the telencephalon, and analysis of their expression patterns provided the conceptual molecular framework for accurate identification of homologs of pallial and subpallial structures in morphologically diverse brains of various classes of vertebrates (Puelles et al., 2007, 2019; Abellán and Medina, 2009, 2010; Medina and Abellán, 2012; Gonzalez et al., 2014; Pauly et al., 2014; Vicario et al., 2017. These findings were complemented with developmental studies of other neurochemical markers (acetylcholinesterase, tyrosine hydroxylase, gamma-aminobutyric acid, substance P (SP), encephalin, CART, and other neuropeptides) that revealed the extent of structural subdivisions of the subpallium (Reiner et al., 1984a,b; Goodson et al., 2004; Bálint et al., 2011; Bruce et al., 2016; Gutierrez-Ibanez et al., 2016).

The subpallium comprises the basal ganglia (BG) and other anatomical components critical to the survival of a particular species. Specifically, it includes structures and pathways that help to regulate movements and complex ingestive, reproductive, and defensive behaviors. Indeed, those functions listed require close coordination with the autonomic nervous system (ANS). Importantly, some neuronal groups residing in the subpallium project directly to central structures that serve as premotor nuclei of the ANS. Therefore the overall purpose of this review is to provide an overview of the structures and functions of the subpallium and indicate how that basal forebrain region connects with components of the ANS. The last section of the chapter includes specific examples and hypotheses about how the subpallial nervous system, ANS, and neuroendocrine systems are interconnected and integrated to regulate the reproductive system, ingestive behavior, stress, and selected ethophysiological events of the annual cycle of birds. By focusing on central neural structures, it is hoped that readers will be directed to brain regions or neural pathways that regulate functions or behaviors of interest and will recognize areas where research is greatly needed due to large gaps in our knowledge.

16.2 Components of the subpallium

The subpallium includes six major components: (1) dorsal somatomotor basal ganglia (DSBG), (2) ventral visceroolimbic basal ganglia (VVBG), (3) extended amygdala, (4) basal telencephalic cholinergic (Ch) and noncholinergic corticopetal system, (5) septum, and (6) preoptic area (POA) (Figure 16.1). Note that since the publication of the previous edition of this chapter (Kuenzel, 2015), an additional component, the POA, has been added to the groups comprising the avian subpallium. The reason for adding the POA is that developmental genes used to compare the mouse and chick forebrains during embryogenesis, showed evidence that the POA displayed markers of subpallial origin. Specifically the POA showed expression of *Dlx-2* and *Nkx-2.1* considered as striatum and pallidum gene markers, respectively, in tissues regarded as subpallial (Rubenstein et al., 1998; Puelles et al., 2000). Additionally, in both editions of the Chick Brain in Stereotaxic Coordinates (Puelles et al., 2007, 2019), it was stated that some structures in the POA should be regarded as subpallial. We concur with this view; however, there are no data indicating what specific structures within that area are subpallial. A major structure that nicely separates the subpallium from the overlying pallium is the

Sturkie's Avian Physiology. https://doi.org/10.1016/B978-0-12-819770-7.00031-1

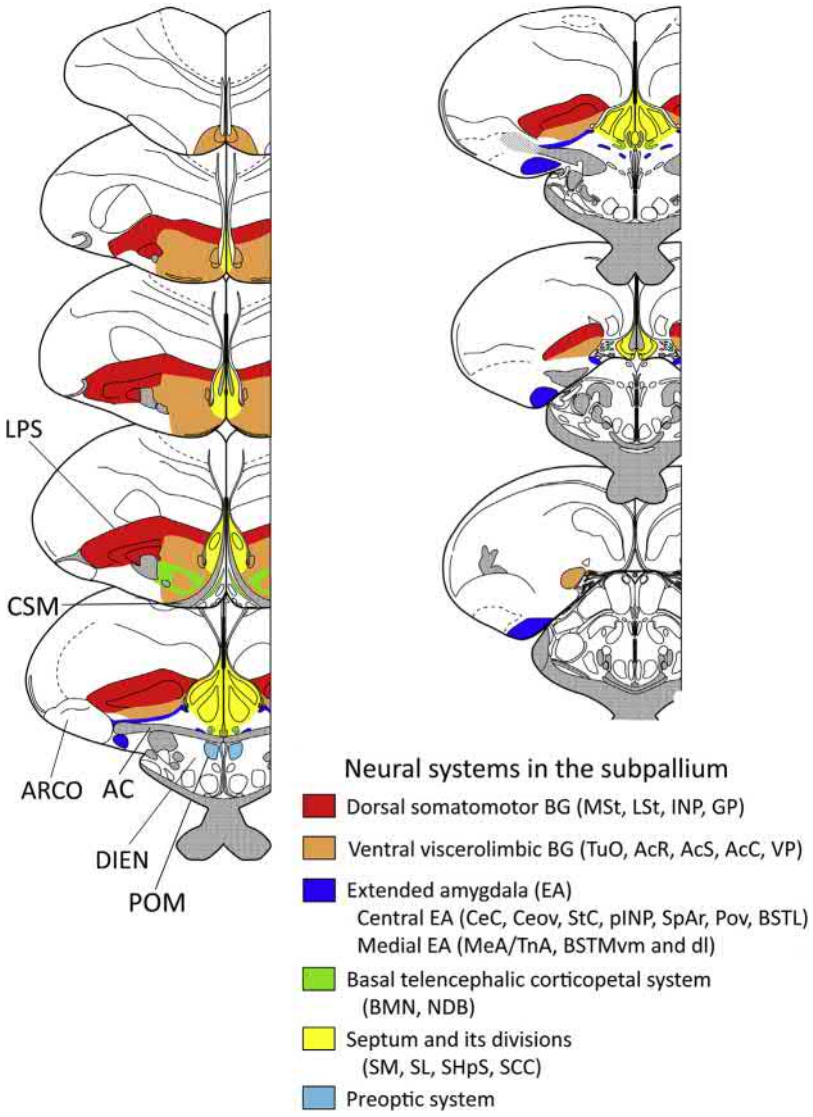

FIGURE 16.1 Six neural components of the avian subpallium. **(1)** Dorsal somatomotor basal ganglia (shown in red) include the medial striatum (MSt), lateral striatum (LSt), intrapeduncular nucleus (INP), and globus pallidus (GP). The pallial-subpallial lamina (LPS) marks the dorsal border of the avian subpallium. **(2)** Ventral viscerolimbic basal ganglia (shown in tan) include the olfactory tubercle (TuO), nucleus accumbens (rostral pole, shell and core, AcR, AcS, and AcC), and ventral pallidum (VP). **(3)** Extended amygdala and bed nuclei of the stria terminalis (shown in dark blue) include the central extended amygdala (Central EA) and medial extended amygdala (Medial EA). The Central EA is composed of the CeC, Ceov, StC, pINP, SpAr, Pov, and BSTL (see also Figure 16.7A). The Medial EA comprises the MeA/TnA and BSTMvm, BSTMdl (see also Figure 16.7B). **(4)** Basal telencephalic corticopetal system (shown in green) includes the basal magnocellular nucleus (BMN) and diagonal band nucleus (NDB). **(5)** Septum and its divisions (shown in yellow) comprise the medial septal, lateral septal, septohippocampal septal (SHpS), and caudocentral septal divisions. **(6)** Preoptic system (shown in light blue) comprises the POM and probably additional, unidentified structures. Abbreviations: *AC*, anterior commissure; *ARCO*, arcopallium; *CSM*, corticoseptomesencephalic tract; *DIEN*, diencephalon; *LPS*, pallial-subpallial lamina; *POM*, medial preoptic nucleus. SL. lateral septum; SM, medial septum. Abbreviations of extended amygdala structures. Central EA: *BSTL*, lateral bed nucleus of the stria terminalis; *CeC*, capsular extended amygdala; *Ceov*, oval central amygdalar nucleus; *pINP*, peri-intrapeduncular nucleus island field; *Pov*, perioval zone; *SpAr*, rostral division of the subpallial amygdala; *StC*, striatal capsule. Medial EA: *MeA*, medial amygdala/TnA, nucleus taeniae amygdala, BSTMvm, dl, ventromedial (vm) and dorsolateral (dL) portions of the medial bed nucleus of the stria terminalis. *Modified from Kuenzel (2015).*

pallial-subpallial lamina (LPS, Figure 16.1). This lamina when visualized in coronal sections in anterior regions of the forebrain clearly defines the subpallium. When coronal sections of an avian brain reach the level of the hypothalamus, as evidenced by the appearance of the anterior commissure (AC), the neural structures ventral and posterior to that fiber tract are regarded as hypothalamic in avian and other vertebrate species. Note that in Figures 14 and 15 of Puelles et al. (2007, 2019), the LPS, abbreviated "psp" in both figures, dips ventrally, below the AC, into both the hypothalamic and POAs. Hence, if the LPS is regarded as an effective, structural marker of the subpallium, then currently a more extensive group of structures within the preoptic and hypothalamic regions have been proposed to be included in the subpallium. Further research will be required to obtain a consensus regarding which preoptic structures should be included in the sixth component of the subpallium.

Significant advances have been made in understanding the embryonic development of the subpallial region of the avian brain from known proliferative zones based upon gene expression and fate mapping data. Details about the histogenetic zones can be obtained in the following references (Puelles et al., 2000, 2007; Cobos et al., 2001a,b; Marín and Rubenstein, 2001; Redies et al., 2001; Flames et al., 2007; Abellán and Medina, 2008; 2009; García-López et al., 2008; Abellán et al., 2010; Kuenzel et al., 2011; Vicario et al., 2017). Each of the six subpallial components in posthatching and adult birds is discussed in the following sections of this chapter.

16.2.1 Dorsal somatomotor basal ganglia

16.2.1.1 Structures

The BG are composed of dorsal somatomotor and ventral viscerolimbic components. Discovery of the abundance of dopamine and acetylcholinesterase in the avian subpallium in the 1960s (Spooner and Winters, 1966; Juorio and Vogt, 1967; Karten, 1969; Nauta and Karten, 1970) showed the avian BG occupied the ventromedial portion of the forebrain (Figure 16.2) and not its extent throughout the entire forebrain as previously thought. The pallial-subpallial lamina (LPS; Figure 16.2C) marks the boundary between the pallium and BG. Importantly the use of immunohistochemistry and an antibody to tyrosine hydroxylase (an indicator of dopamine) and choline acetyltransferase (ChAT) [synthesizes acetylcholine (ACh)] clearly showed how similar the avian BG were to those of mammals regarding their location and relative size compared with the rest of the telencephalon.

Key structures of the DSBG include the dorsal and ventral parts of the medial striatum (MSt), lateral striatum (LSt), nucleus intrapeduncularis (INP), and globus pallidus (GP) (Figure 16.2). Based on gene expression pattern shared with other striatal (st) structures, the INP has been suggested to be renamed the intermediate striatum (Jarvis et al., 2013). In songbirds, the dorsal somatomotor BG include also Area X, a structure involved in the control of vocal motor functions (Gale and Perkel, 2010). The MSt and LSt are generally considered homologous to the mammalian caudate-putamen (Reiner et al., 2004). The MSt (previously called the lobus parolfactorius) and LSt are each further divided into medial and lateral zones. For neurochemical details of comparisons among birds, mammals, reptiles, amphibians, and other vertebrates see Reiner et al. (1998), Smeets et al. (2000), Bruce et al. (2016). Detailed neurochemistry of the BG focusing particularly on neuropeptides and neurotransmitters in specific neuroanatomical regions has been published in birds (Wynne and Güntürkün, 1995; Reiner et al., 1998; Abellán and Medina, 2009; Kuenzel et al., 2011; Bruce et al., 2016).

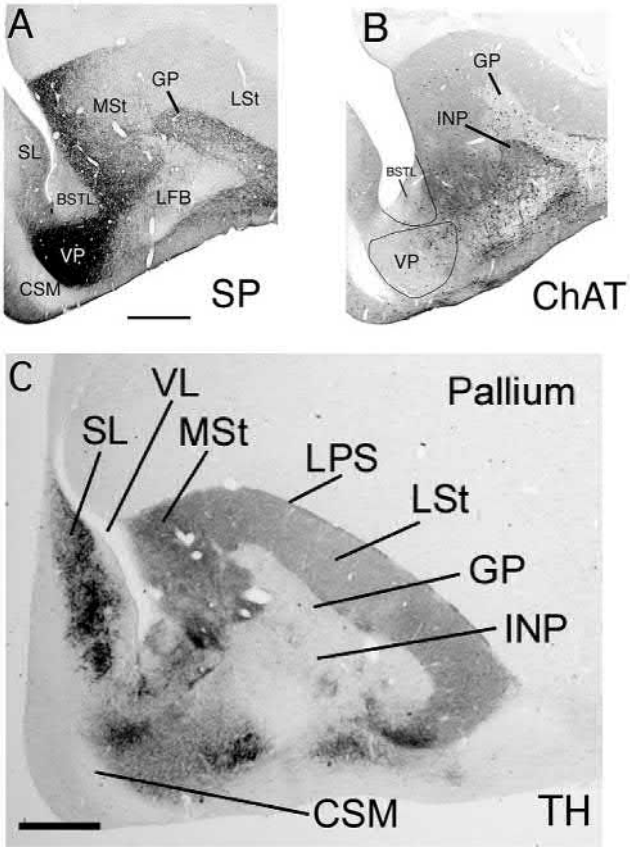

FIGURE 16.2 Components of the dorsal somatomotor basal ganglia. Images of transverse sections of pigeon brain showing immunoreactivity for (A) substance P (SP) and (B) choline acetyltransferase (ChAT). A transverse section of chicken brain shows immunolabeling for (C) tyrosine hydroxylase (TH). The use of TH, an indicator of dopaminergic input, identifies striatal structures of the dorsal somatomotor basal ganglia, particularly the lateral (LSt) and medial striatum (MSt). Note also the increased immunoreactivity of SP fibers in the ventral pallidum (VP) as well as portions of the VP showing increased levels of ChAT neurons and TH fibers. In B, the field of cholinergic neurons spanning the VP and lateral forebrain bundle (LFB) represents the basal magnocellular cholinergic cell group (BMN). There exists a paucity of ChAT neurons and SP immunoreactivity in the lateral bed nucleus of the stria terminalis (BSTL). Other abbreviations: *CSM*, corticoseptomesencephalic tract; *GP*, globus pallidus; *INP*, intrapeduncular nucleus; *LPS*, pallial-subpallial lamina; *SL*, lateral septum; *VL*, lateral ventricle. Scale bar = 1 mm in (A) and (C) (scale bar in A applies to A, B). *Modified from Kuenzel (2015).*

16.2.1.2 Functions

Models of the functional organization of the somatic BG, first developed in mammals, comprised two parallel output circuits that had opposing functions in motor control as well as interactions between them (Albin et al., 1989; DeLong, 1990; Gerfen, 1992). Birds have been shown to have similar direct and indirect pathways (Reiner et al., 1998). A modified representation of the direct and indirect motor pathways involving the avian DSBG is shown in Figure 16.3. The direct pathway (Figure 16.3A) promotes movement of birds (head, wings, legs). Input into the avian striatum (homologous to mammalian caudate-putamen) occurs via the "corticostriatal" projections (from pallium), shown here as glutamatergic excitatory (+) input to the lateral and MSt (Veenman and Reiner, 1996; Csillag et al., 1997; Reiner et al., 2001; Ding et al., 2003; Ding and Perkel, 2004; Farries et al., 2005). Modulatory dopaminergic input to the striatum likewise occurs from the substantia nigra, pars compacta (SNc) [A9 catecholaminergic (CA) cell group], ventral tegmental area (VTA; A10 CA group) and retrorubral field (A8 CA group)

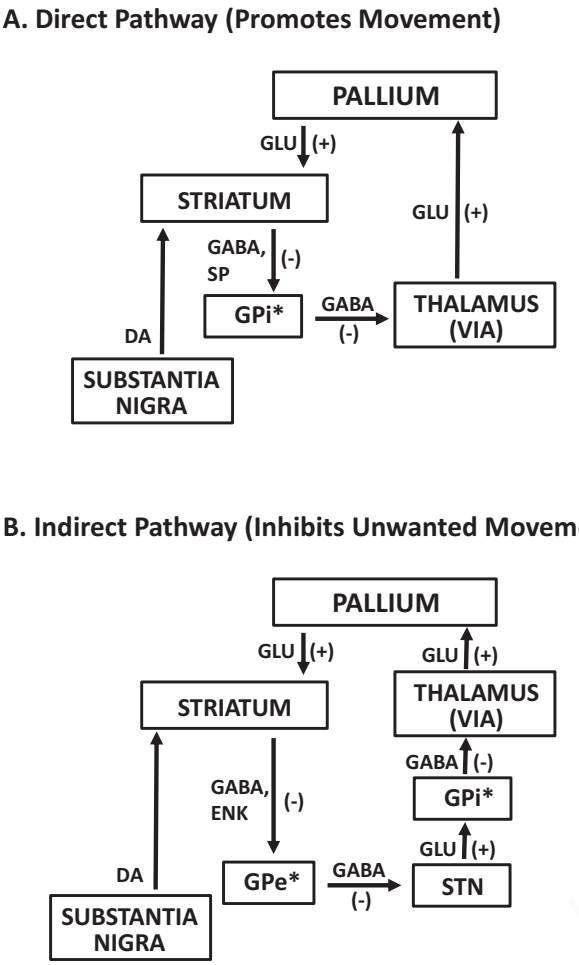

FIGURE 16.3 Schematic diagram showing a direct pathway where excitatory inputs (+) from the pallium and modulatory inputs from the substantia nigra promote skeletal muscle movements in birds. In parallel, an indirect pathway functions to inhibit unwanted movement thereby facilitating the movement initiated by the direct pathway. Abbreviations: *DA*, dopamine; *ENK*, encephalin; *GABA*, gamma-aminobutyric acid; *GLU*, glutamic acid; *GPe*, globus pallidus externa (lateral portion of GP); *GPi*, globus pallidus internus (medial portion of GP); *SP*, substance P; *STN*, subthalamic nucleus; *VIA*, ventrointermediate thalamic area. *From Kuenzel (2015).*

(Brauth et al., 1978; Kitt and Brauth, 1986b; Bailhache and Balthazart, 1993; Moons et al., 1994; Reiner et al., 1994; Wynne and Güntürkün, 1995, Figure 16.4). Both the lateral and MSt receive excitatory inputs from the pallium. The striatum, in turn, projects inhibitory neurons containing both GABA and SP to the medial (interna) region of GP (Figure 16.3A), indicated by globus pallidus internus (GPi) (Anderson and Reiner, 1990, 1991; Reiner, 1986; Reiner and Anderson, 1990; Veenman and Reiner, 1994). The medial area of the GP projects inhibitory GABAergic neurons to a small thalamic region called the ventrointermediate thalamic area (VIA; Karten and Dubbeldam, 1973; Kitt and Brauth, 1982; Medina et al., 1997). The VIA contains glutamatergic neurons which are excitatory and project to the Wulst in the dorsal region of the pallium that appears comparable to the mammalian primary somatosensory/somatomotor cortex (Wild, 1987; Korzeniewska and Güntürkün, 1990; Medina and Reiner, 2000).

In addition to the previously described direct pathway facilitating body movement, there is an antagonistic pathway that inhibits bird movements (Figure 16.3B). This parallel pathway, distinct from the direct pathway, is called the indirect pathway. It originates from the striatum, comprises neurons co-localized with GABA and encephalin (ENK), and functions to inhibit unwanted body movements. Nonetheless it has the same excitatory inputs shown previously for the direct motor pathway (Figure 16.3B). Those striatal (st) projection neurons are inhibitory and innervate the lateral (externa) portion of the globus pallidus (Figure 16.3B; Brauth, 1984; Reiner et al., 1984a,b; Reiner, 1987; Anderson and Reiner, 1990; Veenman and Reiner, 1994; Veenman et al., 1994). Inhibitory GABAergic neurons project to the avian equivalent of the subthalamic nucleus (STN) which contains excitatory glutamatergic neurons that in turn project back to the GP interna (Jiao et al., 2000). The medial GP comprises predominantly GABAergic inhibitory neurons that project to a ventral tier thalamic region called the VIA. The VIA contains excitatory glutamatergic neurons projecting to the pallium (Figure 16.3B). In summary, activation of ENK and GABA containing neurons in the striatum produces inhibition of neurons in the GPe ultimately resulting in release of GABA from the GPi. GABA release inhibits the thalamic VIA thereby decreasing glutamate output into specific pallial projection sites. The overall effect of this pathway is to promote suppression of unwanted movements that potentially would conflict with the movements being promoted by the direct pathway (Figure 16.3A). Behavioral data supporting the function of the indirect pathway were obtained in rats following unilateral lesions to the STN (Kafetzopoulos and Papadopoulos, 1983; Piallat et al., 1996) and later in pigeons following unilateral surgical lesions directed to the anterior nucleus of the ansa lenticularis, the avian homolog of the mammalian STN (Jiao et al., 2000), that produced hyperkinesia and rotation due to blocking glutamatergic input into the internal part of the GPi. Therefore the GPi projection neurons produced little GABA and the VIA released elevated glutamate. The lesioned pigeons showed enhanced motor movements on one side of the body, and thereby rotation movements were observed.

Recently the model of direct and indirect pathways of the BG was re-examined, and subsequently more dynamic interactions between the two pathways have been proposed in mammals (Calabresi et al., 2014). Additional data will need to be obtained in birds to determine if a similar level of plasticity exists in the avian BG.

Other abbreviations: *IP*, interpeduncular nucleus; *N-III*, oculomotor nerve. *From Kuenzel (2015).*

Data obtained in lampreys (jawless vertebrates) have shown that this species likewise contains all the major components of the BG including striatum, GP, and STN suggesting that this phylogenetically old group of vertebrates had similar, functional direct and indirect pathways forming a core network regulating motor function (Stephenson-Jones et al., 2011). Data support the general hypothesis that the BG circuits evolved in vertebrates to support selection of motor actions (Redgrave et al., 1999). Further research has shown the marked conservation of the dual-output pathways throughout vertebrate phylogeny (Stephenson-Jones et al., 2012). Additionally, a neural structure in lampreys found to be homologous to the mammalian pedunculopontine nucleus (PPN), located in the midbrain near the substantia nigra and VTA, has been identified (Stephenson-Jones et al., 2012). The PPN is thought to be involved in the initiation and modulation of gait and other stereotyped movements in mammals (Pahapill and Lozano, 2000). In birds, the ventral mesencephalic profundus nucleus identified in avian brain atlases (Karten and Hodos, 1967; Kuenzel and Masson, 1988) was renamed the pedunculopontine tegmental nucleus (PPT or PPN; Reiner et al., 2004) due to the presence of cholinergic (Ch) neurons and its association with components comprising the BG. The PPN has been proposed to be an extended part of the BG among vertebrates due to its connectivity with BG structures (Mena-Segovia et al., 2004).

16.2.2 Ventral viscerolimbic basal ganglia

16.2.2.1 Structures

The VVBG are organized structurally similar to the DSBG in that it has a dorsal st and a ventral pallidal subdivision. The VVBG comprises the ventral portion of the MSt, nucleus accumbens (core, shell, and rostral pole), olfactory tubercle, and ventral pallidum (VP) (Figure 16.5, 16.6). The st subdivision consists of the ventral portion of the MSt, shell, and core of the nucleus accumbens and superficial part of the olfactory tubercle. Striatal components, particularly nucleus accumbens, receive excitatory pallial inputs, most likely glutamatergic (Veenman and Reiner, 1996; Csillag et al., 1997; Reiner et al., 2001; Ding et al., 2003; Ding and Perkel, 2004; Farries et al., 2005). Pallial inputs to the olfactory tubercle come from the olfactory bulb (Figure 16.5A), piriform cortex (Bingman et al., 1994), and dorsomedial hippocampus (Atoji and Wild, 2004). Dopaminergic st, modulatory input largely originates from the VTA A10 cell group (Figure 16.4B) and also from the substantia nigra (Figure 16.4C; Kitt and Brauth, 1986b; Moons et al., 1994; Panzica et al., 1994, 1996). Striatal structures have been shown to have interneurons containing NADPH-diaphorase and nitric oxide synthase (NOS; Vincent et al., 1983; Brüning, 1993; Brüning et al., 1994; Panzica et al., 1994), as well as calcitonin gene-related peptide fibers (Lanuza et al., 2000; Roberts et al., 2002) and thyroid hormone releasing hormone-containing fibers (Jozsa et al., 1988). As stated previously, the st subdivision of the ventral viscerolimbic BG, regarding its inputs and outputs, is structurally similar to the DSBG as it receives excitatory glutamatergic input from the pallium and modulatory dopaminergic input largely from the VTA or A10 cell group and some input from the SNc. Additionally, the MSt, nucleus accumbens, and olfactory tubercle of the st subdivision, similar to the DSBG, have GABAergic projection neurons co-localized with either SP or ENK. The viscerolimbic pallidal subdivision includes the VP and deep olfactory tubercle (Figure 16.5A and B).

A prominent, major structure of the VVBG is the nucleus accumbens. The mammalian nucleus accumbens (Ac) comprises a central core (AcC) surrounded on its medial, ventral, and lateral sides by a shell (AcS; Herkenham et al., 1984; Záborszky et al., 1985). A third subterritory of the mammalian accumbens has also been identified (Zahm, 2000; Zahm and Brog, 1992; Zahm and Heimer, 1993). Similarly, in avian species, three sub-territories of the Ac have been defined utilizing antibodies to SP, neuropeptide Y (NPY), dopamine and cAMP-regulated phosphoprotein (DARPP-32), calcium-binding proteins, and neurotensin (NT) (Roberts et al., 2002; Bálint and Csillag, 2007; Abellán and Medina, 2009; Bálint et al., 2011, 2016; Husband and Shimizu, 2011). The rostral pole (AcR), core (AcC), and shell (AcS) subdivisions of accumbens in the chick brain have been documented (Balínt and Csillag, 2007; Balínt et al., 2011) and are shown in Figure 16.6 (Balínt et al., 2011). Recently using 12 different antibodies of neuropeptides (calcium-binding proteins or neuromodulator-related enzymes) the AcR, AcC, and AcS and other structures within the BG have been studied in pigeons (right side of Figure 16.6, Bruce et al., 2016), and specific accumbens boundaries of subunits have been shown to differ from previous studies completed in the chicken (Bálint and Csillag, 2007). The AcC and AcS in

Scale bars for 5A-D = 1.0 mm. *Modified from (Kuenzel, 2015).*

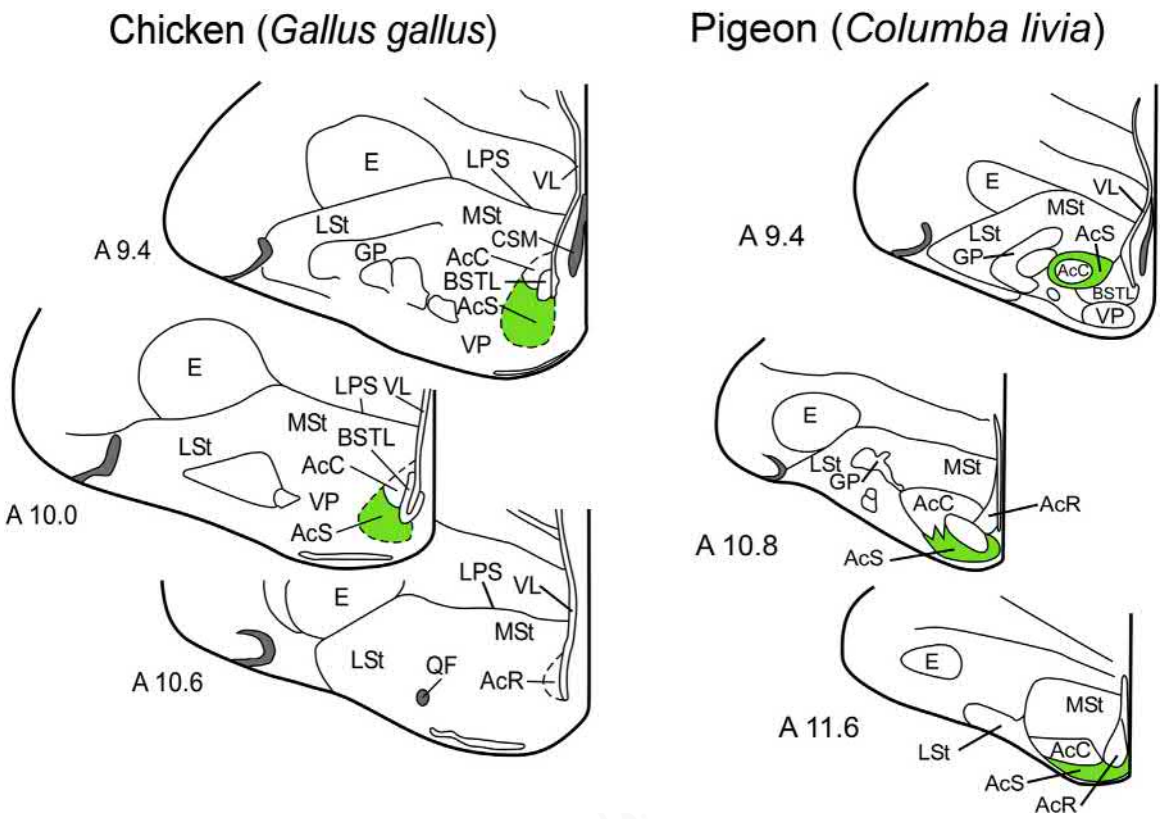

FIGURE 16.6 Comparison of the extent and size of subdivisions of the nucleus accumbens in two avian species. Coronal sections of chick brain showing atlas plate A9.4 (posterior forebrain) to plate A10.6 (more anterior section). Shown is the rostral-caudal extent of subdivisions of the nucleus accumbens (AcR, AcC, and AcS). Modified sections of pigeon brain, mapped on estimated, equivalent locations on chick brain atlas plates in order to compare sizes of accumbens subdivisions (AcR, AcC, and AcS) and their rostral-caudal extent in forebrain. Abbreviations: *AcC, AcR, AcS*, accumbens core, rostral pole, shell, respectively; *BSTL*, lateral bed nucleus of the stria terminalis; *CSM*, corticoseptomesencephalic tract; *E*, entopallium; *GP*, globus pallidus; *LPS*, pallial-subpallial lamina; *LSt*, lateral striatum; *MSt*, medial striatum; *QF*, quintofrontal tract; *VL*, lateral ventricle; *VP*, ventral pallidum. *Modified from Bálint and Csillag (2007) and Bruce et al. (2016). Atlas plates modified from Kuenzel and Masson (1988).*

the pigeon extend to more rostral levels of the forebrain than noted in chickens. Nonetheless, there is overall agreement of the positions of the three components within the BG showing that their subdivisions are somewhat conserved.

The complex accumbens structure is important to understand due to its diverse reciprocal connections with limbic and visceral structures including the hippocampal formation, arcopallium/amygdala, VP, lateral hypothalamus, and VTA and its multiple functions (reviewed in Husband and Shimizu, 2011). It also receives input from central components of the ANS including the lateral hypothalamus (Berk and Hawkin, 1985), lateral bed nucleus of the stria terminalis (BSTL) (Atoji et al., 2006), parabrachial nucleus (Wild et al., 1990), nucleus tractus solitarius (NTs) (Arends et al., 1988; Bálint and Csillag, 2007), and dorsal motor nucleus of the vagus (Arends et al., 1988). As noted previously, st subdivisions have dopaminergic input from the VTA and substantia nigra. In addition, the nucleus accumbens receives dense noradrenergic input from the A6 area (locus coeruleus; Fig. 16.4F and G), particularly in the AcS (Kitt and Brauth, 1986a; von Bartheld and Bothwell, 1992; Bailhache and Balthazart, 1993; Reiner et al., 1994; Moons et al., 1995; Mello et al., 1998). Output of the st accumbens nucleus as well as that from some neurons of the st olfactory tubercle is to the VP. The avian VP in turn projects to several diencephalic sites including the STN, paraventricular nucleus (PVN), lateral hypothalamic area, thalamic reticular nucleus, dorsomedial thalamus, and habenular nucleus (Kitt and Brauth, 1981; Berk and Hawkin, 1985; Veenman et al.,1995; Medina and Reiner, 1997). Additionally, the AcC and AcR subdivisions project via neurotensinergic neurons to the parabrachial nucleus, the NTs, and vagal motor nucleus that are regarded as unique to chickens at this time (Balínt et al., 2016).

16.2.2.2 Functions

The mammalian nucleus accumbens has been described as a limbic-motor integrator because it receives inputs from diverse structures that contribute to an organism's affective and motivational states, including the basolateral amygdala,

hippocampus, prefrontal cortex, and midbrain monoamine and brainstem autonomic systems. Early studies showed that the accumbens is involved in reward-seeking behaviors. A useful definition of reward in animal experiments is a demonstration that an unconditioned stimulus can initiate appetitive behavior and evoke "approach" behavioral effects (Ikemoto and Panksepp, 1999). The extensive data in mammals show that rats will self-administer dopamine, amphetamine, or electrical stimulation (each of these is initially an unconditioned stimulus) in the region of the Ac (Broekkamp et al., 1975; Cador et al., 1991). However, emerging new evidence suggests that the function of the Ac is not limited to "a center of reward" but also includes "action selection" facilitating goal-seeking appetitively or aversively motivated behaviors (Floresco, 2015). Striking differences in afferent and efferent projections of the core and shell subdivisions of Ac (Heimer and Alheid, 1991; Zahm and Brog, 1992; Bálint and Csillag, 2007) imply that they may have different functional roles. The AcC has similarities to the overlying caudate-putamen and therefore more allied with voluntary motor functions. Research by Alheid and Heimer (1988), Heimer and Alheid (1991), and Zahm and Brog (1992) suggested that the AcC mediates appetitive instrumental learning or learning of new motor skills. In contrast, the AcS due to its connections with the extended amygdala (Alheid and Heimer, 1988) is associated with visceral or motivational mechanisms. Specifically, blockade of AMPA/kainite receptors within the AcS, but not the AcC, induced marked and prolonged feeding in satiated rats (Maldonado-Irizarry et al., 1995). Hence the AcS was thought to be responsible for integrating basic drives and visceroendocrine mechanisms. The shell appears to have a role in regulating both appetitive and aversively motivated behavior since expression of Fos in the shell is activated by both stressful and reinforcing stimuli (Kelley, 1999). The Ac, and the shell region in particular, displays significant changes to stress (Kalivas and Duffy, 1995; King et al., 1997). In mammals, the medial shell region of accumbens has shown stress responsivity (Castro and Bruchas, 2019) and modulates social stress behaviors (Russo and Nestled, 2013).

In mammals, reinforcement-based learning involving reward or punishment has been shown to include parts of the dorsal and ventral striatum and other BG nuclei receiving dopaminergic input from the VTA (Graybiel and Grafton, 2015). The ventral striatum appears necessary for initial learning of motivated behaviors that could become habitual (Atallah et al., 2014). It has been suggested that addictive behavior may be an extreme form of habits involving a sequence of motor behaviors developed by trial-and-error learning (Graybiel and Grafton, 2015). Studies with songbirds indicate that the BG, including the ventral viscerolimbic division, may be involved in integration of the three key components of reinforcement learning: motor exploration or variability, error and evaluation signals, and biasing signals to adjust future actions (Gale and Perkel, 2010; Woolley and Kao, 2015; Xiao et al., 2018). In female songbirds, the Ac is involved in discrimination of conspecific courtship vocalization. Importantly, the neural activation of Ac in response to male courtship song appears to be estradiol-dependent (Maney, 2013).

In chicks, the MSt has been suggested to be a storage site for memory traces (Rose, 2000). Chicks that were trained to avoid bitter-tasting beads of particular color in a passive avoidance learning paradigm showed retrograde amnesia following the MSt lesions that also included at least some of the Ac (Gilbert et al., 1991; Patterson and Rose, 1992). Furthermore, passive avoidance training resulted in a series of metabolic and morphological changes in the MSt, such as increased glucose uptake and changing synaptic ultrastructure (Rose and Stewart, 1999). By contrast, other studies employing chemical lesions of the caudal MSt in chicks indicated that this structure is unlikely to be a principal site for permanent storage of memory. In these studies, chicks were trained to discriminate color beads associated with food reward. Posttraining lesion of the caudal MSt impaired subsequent novel learning but did not interfere with memorized association of color (Izawa et al., 2002, 2003; Matsushima et al., 2003). Bilateral electrical lesion of the Ac in chicks resulted in increased vocalization or distressed calls, when placed in an open field environment (Zachar et al., 2017).

16.2.3 Extended amygdaloid complex: central extended amygdala and medial extended amygdala

Heimer and coworkers recognized that the mammalian amygdaloid complex comprised two major groups, each of which had associated neuronal structures that extended from them forming a neuronal corridor. The two corridors were named the extended amygdala, one originating from the central nucleus of the amygdala (CeM) while the second was continuous with the medial amygdaloid nucleus. Both passed through a territory ventral to the GP (anatomically referred to as sublenticular), and the neuronal corridors ended in different components of the bed nuclei of the stria terminalis (Alheid and Heimer, 1988; Alheid et al., 1995). Each corridor possessed similar neurochemical characteristics of the amygdaloid nucleus from which they were confluent. Functionally, the central and medial amygdaloid nuclei and their respective sub-nuclei of the complex bed nuclei of the stria terminalis represent the major output nuclei of the amygdala of mammals (Swanson and Petrovich, 1998; Swanson, 2000; Paré et al., 2004).

Developmental, neurohistochemical, hodological, and behavioral data suggest strongly that comparable structures

forming a subpallial amygdaloid complex exist in birds (Jurkevich et al., 1997, 1999; Aste et al., 1998; Cheng et al., 1999; Panzica et al., 1999; Absil et al., 2002a,b; Roberts et al., 2002; Reiner et al., 2004; Yamamoto et al., 2005; Abellán and Medina, 2009; Xie et al., 2010, 2011; Vicario et al., 2014, 2015, 2017). For clarification of the structures and functions of the subpallial amygdaloid complex, each of its two basic components will be discussed, first in mammals and then in birds.

16.2.3.1 Central extended amygdala

16.2.3.1.1 Structures

The CeM, cells within the corridor of the central extended amygdala, and the lateral BSTL comprise structures of the central extended amygdaloid complex in mammals. Associated with the CeM are groups of intercalated cells positioned between the lateral amygdala and the CeM (Paré et al., 2004). The major group of neurons projecting from the central extended amygdaloid complex is GABAergic, similar to the dorsal somatomotor and VVBG discussed previously. A difference is that the GABAergic neurons are typically enriched with one of several neuropeptides including corticotropin-releasing hormone (CRH), NT, somatostatin, or ENK (Moga and Gray, 1985; Swanson and Petrovich, 1998; Paré and Smith, 1994; Alheid et al., 1995; Poulin and Timofeeva, 2008; Panguluri et al., 2009). The major descending projections of the central extended amygdaloid complex are to the lateral hypothalamus, central gray (GCt), parabrachial nucleus, and nucleus of the solitary tract, all of which are structures in the diencephalon and brainstem associated with of the ANS. Functionally the structures and their connections to the ANS regulate physiological processes and behaviors related to ingestion, and fear/anxiety/stress (Alheid and Heimer, 1988; Alheid et al., 1995; Swanson, 2000; de Olmos et al., 2004).

In birds, a major component of the central extended amygdaloid complex, positioned directly below the GP, was previously termed the subpallial amygdaloid area (SpA; Reiner et al., 2004). Thereafter, it was proposed that the SpA and its lateral continuation directly ventral to the LSt be renamed the central extended amygdala (EAce, Figure 16.7A, Abellán and Medina, 2009; Vicario et al., 2014). It was also suggested that part of the caudolateral striatum and lateral continuation of the SpA may be the avian structure homologous to the mammalian CeM (Abellán and Medina, 2009). Another avian structure that has been suggested to be homologous to the mammalian central amygdaloid nucleus is the compact division of the posterior pallial amygdaloid nucleus (Atoji and Wild, 2006). A structure, recently termed the st capsule (StC) (composed of a thin group of subpallial neurons) located between the nidopallium and LSt (Puelles et al., 2007), has been proposed to be comparable to the intercalated cell masses of the mammalian amygdala (Abellán and Medina, 2009) that occur juxtapositioned to central amygdaloid

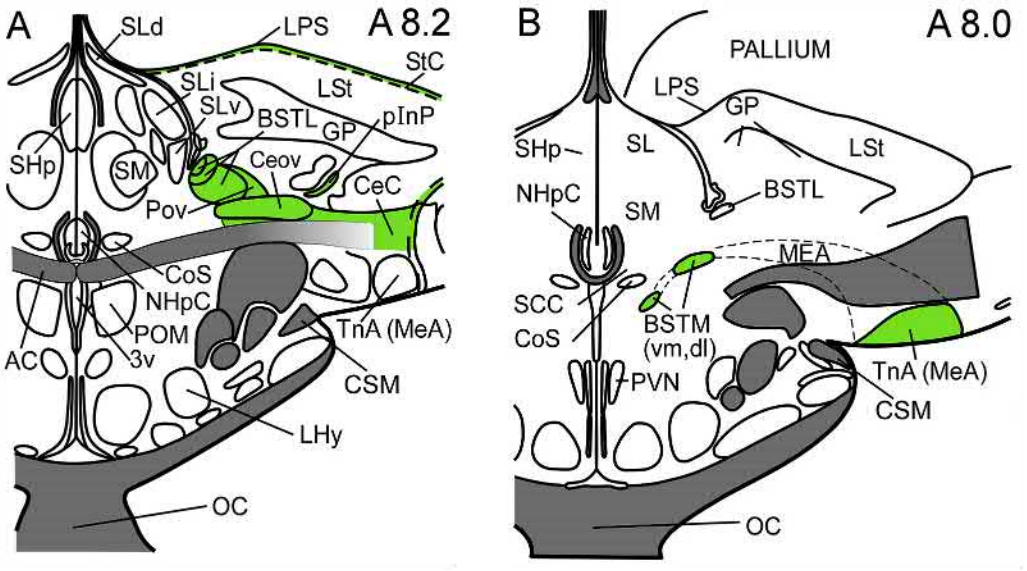

FIGURE 16.7 Central and medial extended amygdala in the chicken brain. The central extended amygdaloid complex is shown in green (A) and comprises the CeC, StC, pInP, SpAr (not shown), Ceov, Pov, and BSTL. The medial extended amygdaloid complex, shown in green (B) consists of the TnA/(MeA), BSTMvm, and BSTMdl (refer to Fig. 16.1 for names of abbreviations). Other abbreviations: *AC*, anterior commissure; *CoS*, commissural septal nucleus; *CSM*, corticoseptomesencephalic tract; *GP*, globus pallidus; *LHy*, lateral hypothalamic nu.; *LPS*, pallial-subpallial lamina; *LSt*, lateral striatum, *NHpC*, nucleus of hippocampal commissure; *OC*, optic chiasma; *POM*, medial preoptic nucleus; *PVN*, paraventricular nucleus; *SCC*, caudo-central septum; *SHp*, septohippocampal septum; *SLd*, dorsal lateral septal nucleus; *SLi*, intermediate lateral septal nucleus; *SLv*, ventral lateral septal nucleus; *SM*, medial septal nucleus; *3v*, third ventricle. *Modified from Abellán and Medina (2009) and Vicario et al. (2014).*

nucleus of mammals (Paré et al., 2004). An important component of the central extended amygdaloid complex is the lateral BSTL (Figure 16.7A) that is regarded as comparable to the mammalian BSTL due to the presence of CRH (Panzica et al., 1986; Ball et al., 1989; Richard et al., 2004), neurotensinergic (Reiner and Carraway, 1987; Atoji et al., 1996; Reiner et al., 2004) and enkephalinergic (Molnar et al., 1994) neurons. The avian BSTL has been shown to have direct connections to components of the ANS including hypothalamic structures, parabrachial nucleus, nucleus of the solitary tract, and dorsal motor nucleus of the vagus (Berk, 1987; Arends et al., 1988; Wild et al., 1990; Atoji et al., 2006; Bálint et al., 2011). In summary, the structures that comprise the avian EAce along primarily a sublenticular corridor include the following: (1) capsular central amygdala, (2) StC, (3) peri-intrapeduncular nuclear island field, (4) oval central amygdalar nucleus (Ceov), (5) rostral division of the subpallial amygdala, (6) perioval zone, and (7) dorsal part of the lateral BSTL (Figure 16.7A, Abellán and Medina, 2009; Vicario et al., 2014).

16.2.3.1.2 Functions

In mammals, the central extended amygdaloid complex is thought to be involved in food intake and fear/anxiety/stress behavior due to its connectivity to central components of the ANS located in the hypothalamus and caudal brainstem (van der Kooy et al., 1984; Luiten et al., 1987; Paré et al., 2004). In particular, CRH neurons in the BSTL can affect the regulation of appetite (Heimer and Alheid, 1991; Clark and Kaiyala, 2003; Gallagher et al., 2008; Krogh et al., 2008). The stria terminalis is known to have connections with the lateral hypothalamic area, parabrachial nucleus, nucleus of the solitary tract, and dorsal motor nucleus of the vagus, all of the previously listed structures have connectivity to the ANS. In birds, similar central connections with the ANS have been demonstrated showing that neural pathways regulating ingestive behavior in mammals and birds are conserved (reviewed in Kuenzel and Blähser, 1993; Kuenzel, 1994, 2000; Kuenzel et al., 2011). Furthermore, CRH has been shown to be an important regulator of stress and anxiety in mammals (Paré et al., 2004) and causes distress vocalizations in chicks (Zhang et al., 2004).

16.2.3.2 Medial extended amygdala

16.2.3.2.1 Structures

The medial extended amygdaloid complex in mammals comprises the medial amygdala (MeA), the neuronal corridor emerging from the MeA, and the medial nuclear complex of the BSTL. The main input to the MeA originates in the olfactory bulb as well as in the accessory olfactory system and its vomeronasal organ. It is rich in gonadal steroid receptors and projects to various hypothalamic structures involved with reproductive behavior, aggression, and defense (Alheid et al., 1994; Swanson, 2000). Similar to other projection neurons comprising the subpallial structures, the medial extended amygdala (MEA) has predominantly GABAergic neurons (Alheid et al., 1994, 1995; Swanson, 2000). Glutamatergic neurons have also been identified (Choi et al., 2005).

The composition of the MEA in birds was established relatively recently. The nucleus taeniae was proposed for some time to be comparable to the mammalian MeA (Cheng et al., 1999) and was renamed the nucleus taeniae of the amygdala (Reiner et al., 2004). Controversy persists, however, and recently it was proposed that the name nucleus taeniae of the amygdala be changed to medial ventral arcopallium due to several, diverse in situ hybridization results in the zebra finch showing that the songbird arcopallium is primarily pallial (Mello et al., 2019). Nonetheless, over the years, data in other avian species have supported the concept that birds have a MeA and an extended amygdala (Yamamoto et al., 2005). Birds also have the medial BSTL (Figure 16.7B, Jurkevich et al., 1997, 1999; Aste et al., 1998). In addition to arginine vasotocin (AVT), neurons of the BSTM of chickens contain galanin (Klein et al., 2006). Embryological studies showed that birds have a subpallial MeA with a corridor of neurons that extends to the BSTM, and therefore it was proposed that birds have a MEA (Figure 16.7B) complex (Abellán and Medina, 2009). Recently binding site densities of 11 receptors were studied to map their distribution in specific subregions of the arcopallium/amygdaloid complex of pigeons in order to compare their subregions with mammalian counterparts (Herold et al., 2018). In addition to GABAergic and glutamatergic neurons, the MEA complex likewise has nitrergic neurons (Panzica et al., 1994; Balthazart et al., 2003) resembling comparable findings of GABAergic and nitrergic neurons in the mammalian medial amygdalar nucleus (Tanaka et al., 1997; Swanson, 2000). In addition to inputs from the olfactory bulbs, the avian subpallial amygdala receives projections from the piriform cortex (Bingman et al., 1994; Veenman et al., 1995). Vasotocin neurons of the BSTM component of the medial extended amygdaloid complex project to the medial preoptic nucleus (POM) (Absil et al., 2002a). The avian MeA is reciprocally connected to the hippocampal formation (Atoji et al., 2002; Atoji and Wild, 2004). A detailed account of transcription factors that have played a role in the development of the MEA in zebra finches has recently been published (Vicario et al., 2017). Importantly, the medial extended amygdaloid complex contains high concentrations of androgen and estrogen receptors as well as the enzyme aromatase which converts testosterone to estradiol (Balthazart et al., 1998b; Foidart et al., 1999). The

abundance of sex steroid receptors is greater in males in this region (Watson and Adkins-Regan, 1989). A more detailed account of aromatase and steroid receptors is reviewed under the subheading *Septal and preoptic neuroendocrine systems.*

16.2.3.2.2 Functions

As stated previously, in mammals, the medial extended amygdaloid complex plays a key role in mating, sexual, defensive, and aggressive behaviors. Olfactory inputs from the main and accessory olfactory systems are important signals to the complex (Swanson, 2000; Choi et al., 2005). Hodological and behavioral data suggest that the BSTM and MeA play a similar role in birds (Panzica et al., 1998; Thompson et al., 1998; Absil et al., 2002a; Abellán and Medina, 2009; Xie et al., 2010, 2011; Vicario et al., 2017). Due to a lack of a defined accessory olfactory system and small olfactory bulbs in most avian species, it has been thought that pheromones and odors do not serve a critical function in this vertebrate class. Nonetheless, it has been shown that chemosensory communication plays a role in avian social and sexual behavior (Balthazart and Schoffeniels, 1979; Caro et al., 2015) and navigation in homing pigeons (Wiltschko and Wiltschko, 2017). A tract-tracing study in pigeons revealed bilateral projections from the olfactory bulbs to the nucleus of the taeniae of the amygdala and ipsilateral projections to the medial septum suggesting that olfactory cues in birds can be relayed to the limbic system (Patzke et al., 2011). Furthermore, electrophysiological responses in the avian olfactory bulb to odorants are comparable to those in mammals (McKeegan, 2002). Importantly, structures in the medial extended amygdaloid complex have been shown to be sexually dimorphic in avian species. Specifically, the BSTM has been shown to be larger in males, is steroid-responsive and plays a role in copulatory behavior in mammals (Del Abril et al., 1987; Guillamón and Segovia, 1997) and birds (Kiss et al., 1987; Voorhuis et al., 1988; Panzica et al., 1998; Viglietti-Panzica et al., 1992; Aste et al., 1998; Jurkevich et al., 1999). A subnucleus of the BSTM in chickens, the BSTM2 (ventromedial BSTM) functions in male appetitive sexual behavior (Xie et al., 2010, 2011).

16.2.4 Basal telencephalic cholinergic and noncholinergic corticopetal system

16.2.4.1 Structures

The basal corticopetal system, sets of neurons at the base of the forebrain that project to the cortex in mammals, or pallium in birds and other vertebrates, is composed mostly of Ch neurons that in mammals are found overlapping other neuronal types located in the GP and VP of the BG and medial septum-diagonal band nuclei. Specifically Ch neurons are located in three main areas: anteromedial (medial septal nucleus or Ch1), intermediate [vertical and horizontal limbs of the diagonal band nuclei (NDBv and NDBh, respectively) or Ch2/Ch3], and caudolateral [nucleus basalis of Meynert (NBM) or Ch4] (Mesulam et al., 1984; Mesulam, 1990). In birds, three nuclei have been grouped together that comprise this telencephalic corticopetal system: basal magnocellular nucleus (BMN), nuclei of the diagonal band, vertical limb (NDBv), and horizontal limb (NDBh) (Figure 16.1). All three avian nuclei have in common the presence of Ch neurons (Reiner et al., 2004). In the first nucleus listed, the NBM, the Ch neurons are found in and about the ventral GP, VP (Figure 16.2B), intrapeduncular nucleus and in and about the lateral and medial forebrain bundle (MFB) (Medina and Reiner, 1994; Reiner et al., 2004). The darkly stained circular dots scattered between the VP and GP structures on Figure 16.2B are cell bodies of Ch neurons immunolabeled with an antibody to ChAT. Of interest is that the avian NBM is considered equivalent to the mammalian nucleus basalis of Meynert which contains Ch neurons that project to neocortex, hippocampus, and amygdala (Záborsky et al., 1999). In birds, the NBM receives input from the VVBG, including the nucleus accumbens, as well as the subpallial amygdaloid complex including the arcopallium (Veenman et al., 1995; Medina and Reiner, 1997). Another two avian Ch nuclei, the NDBv and NDBh, are comparable to groups of Ch neurons located in the nucleus of the diagonal band in the mammalian basal forebrain region (Woolf, 1991). The avian NDB projects heavily to the hippocampal and parahippocampal areas (Benowitz and Karten, 1976; Casini et al., 1986; Atoji et al., 2002; Montagnese et al., 2004).

16.2.4.2 Functions

In mammals, the basal forebrain, particularly the nucleus basalis of Meynert, has been implicated in learning and memory. Evidence from clinical geriatric studies resulted in the "Ch hypothesis" that memory dysfunction was the result of pathological changes to Ch neurons (Bartus et al., 1982). Specifically, corticopetal Ch neurons have been shown to play a role in modulating cortical activity and in attentional and arousal processes (Zaborszky et al., 1999) that affect learning and memory (Mesulam and Geula, 1988; Metherate et al., 1988, 1992; Cape and Jones, 2000; Cape et al., 2000). There exists a high correlation between the loss of memory and loss of Ch neurons in humans, e.g., Alzheimer's disease (Auld et al., 2002). It has been hypothesized that a different pattern of neuronal loss occurs within the nucleus basalis of Meynert (NBM) in different neuronal diseases and that understanding the functional significance of subregions of the NBM would prove

important in elucidating the pathogenesis of dementia in other neuropsychiatric disorders such as Parkinson's disease (Liu et al., 2015).

Little is known about the role of basal forebrain Ch neurons in cognitive processes in birds. Nonetheless pharmacological blockage of muscarinic Ch receptors results in impaired learning and memory in diverse avian species (Patterson et al., 1990; Mineau et al., 1994; Savage et al., 1994; Kohler et al., 1996; Zhao et al., 1997). Additionally, beta-amyloid toxicity, known to damage the basal forebrain Ch system in mammals, impairs memory in chicks (Gibbs et al., 2010). Of interest, previous studies in mammals have reported basal forebrain Ch neurons originate from the subpallium (Marin et al., 2000; Xu et al., 2008), however more recently, it has been suggested that they originate from the pallium (Pombero et al., 2011). Pombero et al. (2011) analyzed pallial implants in mice just caudal and ventral to the olfactory bulb. The cells migrated caudally and ventrally into the subpallium and were detected in the basal forebrain region. The original pallial cells that reached the ventral forebrain were shown to express choline acetyltransferease therefore differentiated into Ch neurons. Olfactory alterations have been identified as a risk factor and an early marker of neurodegenerative diseases, such as Alzheimer's disease. Hence this long-distance migration from the caudal region of the olfactory bulbs to the basal forebrain may be one reason for the cause of some neurodegenerative diseases affecting cognitive function (Pombero et al., 2011). It would be of interest to determine whether the origin of Ch cells in the basal forebrain of chick embryos likewise occurs in the anterior pallial region.

16.2.5 Septum and septal neuroendocrine systems

16.2.5.1 Divisions and structures

The avian septum lies dorsal and anterior to the diencephalon and comprises all neural structures medial to the ventral horns of the lateral ventricle (Figures 16.1 and 16.7). It first appears in rostral coronal sections of forebrain as the ventral horns of the lateral ventricle begin to move apart laterally from midline. The corticoseptomesencephalic tract (CSM, Figure 16.1), previously called the tractus septopalliomesencephalicus begins to descend from the hippocampal region into the septum (Figure 16.1, vertical set of images #3 & 4 in left column). The CSM comprises two parallel symmetrical tracts descending at midline, one on each side of the brain. Each tract gradually moves away from midline as it descends to the base of the brain. The brain region medial to the CSM contains preoptic structures (Figure 16.1, fourth vertical image from the top, white area) while the territory lateral to the CSM on both sides of the brain and extending to the lateral, descending horns of the lateral ventricle is the septal region (Figure 16.1, yellow in color). Posteriorly, the AC delineates the ventral boundary of the septal region (AC, Figure 16.1). Structures ventral to the AC are regarded as preoptic or hypothalamic (Figure 16.1). Moving caudally beyond the AC, the top of the third ventricle (3V) marks the floor of the septum (Figure 16.7B). Posteriorly, the septum gradually decreases in size, but before the septum disappears, the corticohabenular and corticoseptal tract becomes one of the last visible traces of the septum.

The septum of mammals has been parcellated into numerous chemoarchitectonic zones that can be grouped into four major divisions (Jakab and Leranth, 1995; Risold and Swanson, 1997a,b). A comparative study was completed using a variety of songbird species and antibodies against 10 neuropeptides and enzymes in order to develop a nomenclature and framework to establish homologous septal zones among tetrapods (Goodson et al., 2004). Results suggested that the avian septum is comparable to the mammalian structure and can be divided into four major divisions: lateral septum (SL), medial septum (SM), septohippocampal septum (SHpS), and caudocentral septum (SCC). Coupled with recent developmental (Puelles et al., 2007; Abellán and Medina, 2009; Abellán et al., 2010) and hodological (Atoji and Wild, 2004; Montagnese et al., 2004, 2008) studies, homologous divisions and structures have been proposed which will be detailed below.

16.2.5.1.1 Lateral septal division

The developing avian lateral septum (SL, Figure 16.7A) comprises three nuclei, the dorsal (SLd) and intermediate are st derivatives based upon expression of Pax6 and LIM-only gene *Lmo4,* while the ventral one is a pallidal derivative due to expression of the *Nkx2.1* gene (Garcia-López et al., 2008; Abellán and Medina, 2009; Medina and Abellán, 2009). In roosters, a suggested location of the three SL structures using AVT and CRH immunostaining is shown in Figure 16.8. Hodological studies have shown four major inputs to the lateral septum including the hippocampal formation, arcopallium/amygdala, diencephalon, and brainstem. Different hippocampal domains project preferentially to different SL regions of birds (Atoji and Wild, 2004; Montagnese et al., 2004, 2008) as well as mammals (Risold and Swanson, 1997b). In addition, in mammals, major glutamatergic inputs to the SL have been documented from pyramidal neurons in the hippocampus (Jakab and Leranth, 1995; Risold and Swanson, 1997b). The caudal intermediate arcopallium and nucleus taeniae of the amygdala (MeA) have been shown to project to the avian SL (Atoji and Wild, 2004; Montagnese et al., 2004, 2008). The mammalian MeA, proposed to be homologous to the avian nucleus taeniae of

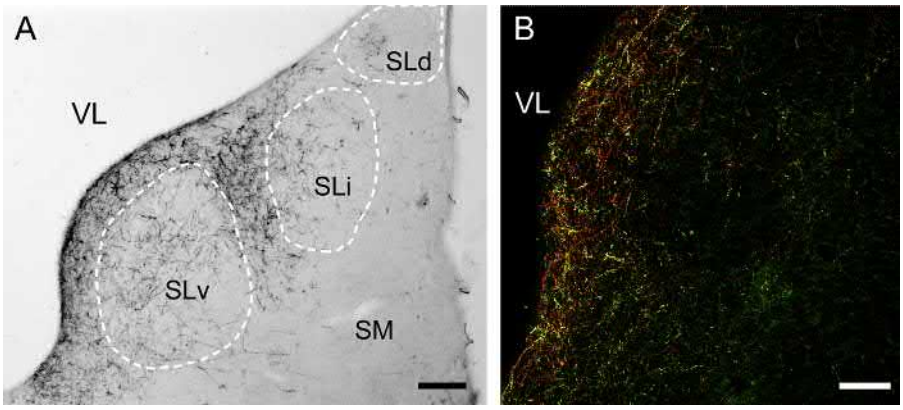

FIGURE 16.8 The septum of the chicken. (A) Coronal section of the septal area of a rooster brain showing immunoreactivity for arginine vasotocin with outlined proposed locations of three structures in the lateral area of the lateral septal division. (B) Coronal section of the septal area of a rooster showing arginine vasotocin (red) and corticotropin releasing hormone (green) innervation. Scale bar for 16,8A = 200 μm, 16,8B = 100 μm. Abbreviations: *SLd, SLi, SLv*, dorsal, intermediate and ventral nuclei of lateral septum; *SM*, medial septum; *VL*, lateral ventricle.

the amygdala (Thompson et al., 1998; Cheng et al., 1999; Yamamoto et al., 2005), sends projections to the SL (Canteras et al., 1995). Extensive input to the SL originates from the rostral-caudal extent of the ventral diencephalon including the POA (POM) (Berk and Butler, 1981; Panzica et al., 1992; Balthazart et al., 1994; Balthazart and Absil, 1997; Atoji and Wild, 2004; Montagnese et al., 2008), hypothalamus (anterior and lateral hypothalamic area), tuberal and mammillary region (Atoji and Wild, 2004, 2006). Similar projections have been demonstrated in the rat (Canteras et al., 1992, 1994; Risold and Swanson, 1997b). A major output from the mammalian SL descends via the MFB and innervates the medial septal nucleus, nucleus of the diagonal band, lateral hypothalamic area, medial preoptic, anterior hypothalamic, ventral premammillary, and mammillary nuclei (Risold and Swanson, 1997b). The avian SL sends similar projections to the POM, anterior and ventromedial hypothalamic nucleus, lateral hypothalamic area, and lateral mammillary nucleus (Atoji and Wild, 2004) thereby showing numerous reciprocal projections between hypothalamic nuclei and SL in birds and mammals. Finally, a fourth, extensive set of projections to the mammalian and avian SL originate from the brainstem, specifically from the VTA (Kitt and Brauth, 1986b), locus coeruleus (Kitt and Brauth, 1986a), and nucleus raphe/linear caudalis (Cozzi et al., 1991; Atoji and Wild, 2004). Those projections to the SL have been reported to be dopaminergic (Bailhache and Balthazart, 1993; Bottjer, 1993; Moons et al., 1994; Wynne and Güntürkün, 1995), noradrenergic (Bailhache and Balthazart, 1993; Moons et al., 1995; Mello et al., 1998), and serotonergic (Challet et al., 1996), respectively.

Additional chemoarchitectonic studies have shown dense neural terminals containing AVT and its mammalian homolog vasopressin in the caudal and ventrolateral region of the SL among various vertebrate taxa (De Vries and Panzica, 2006). The density of these projections in vertebrates is testosterone-dependent and sexually dimorphic (Moore and Lowry, 1998; Goodson and Bass, 2001). The sexual dimorphic expression has been demonstrated in several avian species (Voorhuis et al., 1988; Viglietti-Panzica et al., 1992; Jurkevich et al., 1997; Panzica et al., 1999). The SL is also rich in androgen-concentrating cells (Arnold et al., 1976; Barfield et al., 1978) and in estrogen receptors (Panzica et al., 2001). Other chemoarchitectonic studies have shown that galanin fibers occur in the lateral wall of the septum in Japanese quail (Azumaya and Tsutsui, 1996), collared dove (Dubbeldam et al., 1999), songbirds (Goodson et al., 2004), chickens (Klein et al., 2006), anuran amphibians (Lazar et al., 1991), and mammals (Melander et al., 1986; Risold and Swanson, 1997a; Chaillou et al., 1999). Of interest is that the distribution of galanin fibers in the lateral septum and perikarya in the medial BSTL have been shown to be sexually dimorphic in chickens (Klein et al., 2006) as previously demonstrated for AVT. Both the SL and SM of chickens contain numerous CRH-immunoreactive terminals. Interestingly, the density of these terminals increases in adult chickens (Richard et al., 2004).

16.2.5.1.2 Medial septal division

The medial septal division in the developing mouse and chicken expresses Tbr1 (Puelles et al., 2000), Lhx6, Lhx7/8, GAD67, and VGLUT2 (Flames et al., 2007; Abellán and Medina, 2009; Abellán et al., 2010) and consists of glutamatergic, GABAergic, Ch neurons, and some neurons from pallial septal and pallido-preoptic subdivisions, the latter in the ventral region of the SM expresses some GABAergic neurons (Abellán et al., 2010). Similar to the lateral septum, the SM (Figure 16.7) has inputs from the hippocampal complex, entire rostral-caudal extent of the ventral diencephalon including nuclei from the preoptic, anterior hypothalamus, mammillary, and tuberal regions as well as

receives projections from the VTA, locus coeruleus, and linear caudalis (Kitt and Brauth, 1986a,b; Atoji and Wild, 2004; Montagnese et al., 2008). Other inputs documented include the nucleus of the diagonal band (Atoji and Wild, 2004; Montagnese et al., 2008), medial division of the BSTL (Montagnese et al., 2008), and the dorsal lateral nucleus of the anterior, medial thalamus (Atoji and Wild, 2004). The SM sends projections to the hippocampal complex (Atoji and Wild, 2004), olfactory tubercle, VP, lateral septum, nucleus of the diagonal band, and commissural septal nucleus (Atoji and Wild, 2004; Montagnese et al., 2008). Chemoarchitectonic studies show that most peptidergic and aminergic neurons and fibers show less immunoreactivity (ir) compared to the SL. The one exception appears to be the presence of Ch neurons which show their greatest concentration in the medial septum, particularly at caudal levels not only in a variety of bird species but also the ventromedial septum of most tetrapod groups (Goodson et al., 2004). Refer to the previous Section 16.2.4 covering the "Basal telencephalic cholinergic and noncholinergic corticopetal system."

16.2.5.1.3 Septohippocampal septal division

A septohippocampal nucleus occurs in mammals (Jakab and Leranth, 1995; Risold and Swanson, 1997a,b) and a similar nucleus, the SHpS (Figure 16.7A), has been proposed to exist in birds comprising a small, thin vertical area located above the AC and extending to the dorsal region of the septum (Goodson et al., 2004). Developmental studies utilizing the pallial marker Emx-1 initially suggested that a discrete, dorsal area of the SHpS was pallial (Puelles et al., 2007). More recent data using a gene *Lhx5* encoding a transcription factor showed that the entire medial portion of the septohippocampal division from its most dorsal extent ventral to the nucleus of the hippocampal commissure comprises a pallial portion of the septum (Abellán et al., 2010). Chemoarchitectonic data displayed VGLUT2 transporter surrounding the nucleus of the hippocampal commissure suggesting that the neurons were glutamatergic providing additional support that the SHpS is a pallial derivative (Abellán et al., 2010). Another source of evidence for its pallial origin comes from the well-known migration of gonadotropin-releasing hormone, type one (GnRH-1) neurons from the embryonic olfactory placode into the pallium behind the olfactory bulb and their subsequent migration toward the preoptic, hypothalamic, and septal regions (Figure 16.9A). The unusual neuronal migration has been demonstrated in amphibians (Muske and Moore, 1988), mammals (Schwanzel-Fukuda and Pfaff, 1989; Wray et al., 1989) and birds (Murakami et al., 1991; Norgren and Lehman, 1991). Of interest is that for mammalian species, a major portion of the GnRH-1 neurons finally reside in the POA and arcuate nucleus of the hypothalamus (Silverman et al., 1994) while in the avian brain such as the chick, 73% of the total GnRH-1 neurons remain in the septum between the medial and lateral septal divisions and surrounding the nucleus of the hippocampal commissure (NHpC, Figure 16.9B, Kuenzel and Golden, 2006). Within the core region of the nucleus of the hippocampal commissure are dense plexuses of galanin (Figure 16.9C, Klein et al., 2006) and CRH fibers (Richard et al., 2004). Recent studies revealed a large group of CRH neurons in the NHpC (Figure 16.9D–F, Nagarajan et al., 2014) and demonstrated that they are involved in the neuroendocrine regulation of stress (Nagarajan et al., 2017a,b; Kadhim et al., 2019). The avian SHpS is also characterized by SP, NPY, and vasoactive intestinal peptide (VIP) fibers (Goodson et al., 2004). The latter two peptides (NPY and VIP) are associated with reproductive function. Similarly, the septohippocampal nucleus of rats has been shown to express NPY mRNA in cell perikarya and SP in fibers (Risold and Swanson, 1997a).

16.2.5.1.4 Caudocentral septal division

The fourth major septal area of mammals is the posterior septum which contains the septofimbrial and triangular nuclei (Jakab and Laranth, 1995; Risold and Swanson, 1997a,b). It has been proposed that birds have a caudocentral septal division that is topographically comparable to the mammalian septofimbrial nucleus and appears to be a caudal expansion of the ventrolateral SL (Goodson et al., 2004). The most posterior aspect of the caudocentral septum contains the corticohabenularis and corticoseptal tract. In the rat, a similarly located fiber tract is termed the fimbria of hippocampus and connects the septofibrial nucleus with the hippocampus (Risold and Swanson, 1997b). It has therefore been proposed that the corticohabenularis and corticoseptal tract be renamed the fimbria of hippocampus (Goodson et al., 2004; Puelles et al., 2007, 2019). In the ventral region of the avian caudocentral septal division occur GnRH-1 neurons that are a continuation of the major group of GnRH-1 found in and about the nucleus of the hippocampal commissure (Kuenzel and Golden, 2006). On the ventral side of the NHpC displaying a projection into the 3V (Figure 16.9E) is the subseptal organ (SSO) homologous to the mammalian subfornical organ (SFO) that plays a role in the regulation of water intake.

16.2.5.2 Functions

16.2.5.2.1 Septal-hypothalamic-pituitary-gonadal neuroendocrine system

As previously stated, during embryonic development, GnRH-1 neurons migrate into the brain just behind the olfactory bulbs and migrate from the pallium to the septal and diencephalic regions. In chicks, most of the GnRH-1

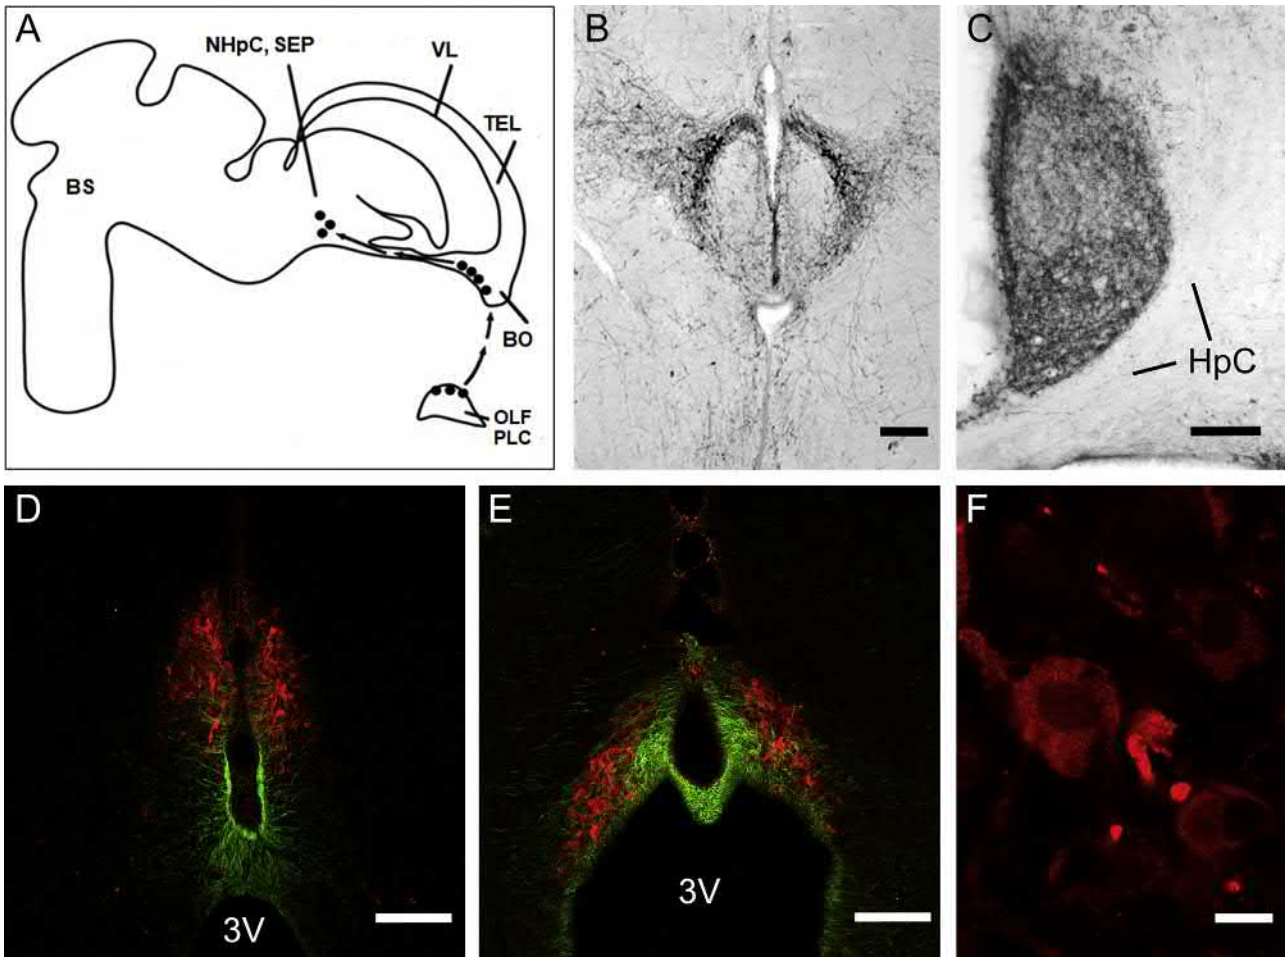

FIGURE 16.9 Neuroendocrine neurons in and around the nucleus of the hippocampal commissure. (A) GnRH-1 neurons originate outside the brain in the olfactory placode (OLF PLC) and migrate into the brain. (B) A septal area surrounding the nucleus of the hippocampal commissure (NHpC) receives a major, migrating group of GnRH-1 neurons. (C) Galanin fibers within the NHpC are surrounded by the (HpC). (D) and (E) show anterior and posterior images of the NHpC immunostained for corticotropin releasing hormone (red) and the avian vasotocin 1a receptor (V1aR, green). (F) High magnification image of CRH neurons within the NHpC. Scale bar for 16,9B = 300 μm, scale bars for 16.9C, D, and E = 100 μm, and 16,9F = 10 μm. neurons reside in the septum, particularly around the periphery of the NHpC. We have proposed to name the region, the belt (b) of the NHpC (NHpCb, Figure 16.9B). The NHpC extends a significant rostral-caudal distance thereby residing within three divisions of the septum, the medial septum (SM), SHpS, and caudocentral septum (SCC). Moreover, the NHpC is located in a close apposition to four circumventricular organs (CVOs) making this nucleus an important hub for neuroendocrine communication between the septum and the rest of the brain via the cerebrospinal fluid.

What are CVOs? CVOs are found in the brain of all vertebrate classes. As the name implies, they occur adjacent to the ventricles of the brain in specific regions. Four CVOs are associated with the avian septum including the lateral septal organ (LSO), organum vasculosum of the lamina terminalis (OVLT), SSO, and choroid plexus (ChP). There are general characteristics that many CVOs possess including specialized ependymal cells, a vascular area that lacks a blood-brain barrier and cerebrospinal fluid-contacting neurons (Vigh, 1971). Due to their known neuroendocrine function for sustained and integrated activities of vital importance to the survival of a given vertebrate species (Weindl, 1973), four CVOs that border the avian septum will be briefly discussed, beginning with the LSO.

The avian LSO was named and shown located at the base of each lateral ventricle in chickens (Kuenzel and van Tienhoven, 1982) and later characterized as comprising two components, a lateral and medial part (Kuenzel and Blähser, 1994; Kuenzel et al., 1997). The medial LSO (LSOm) is located at the base of the lateral ventricle in the

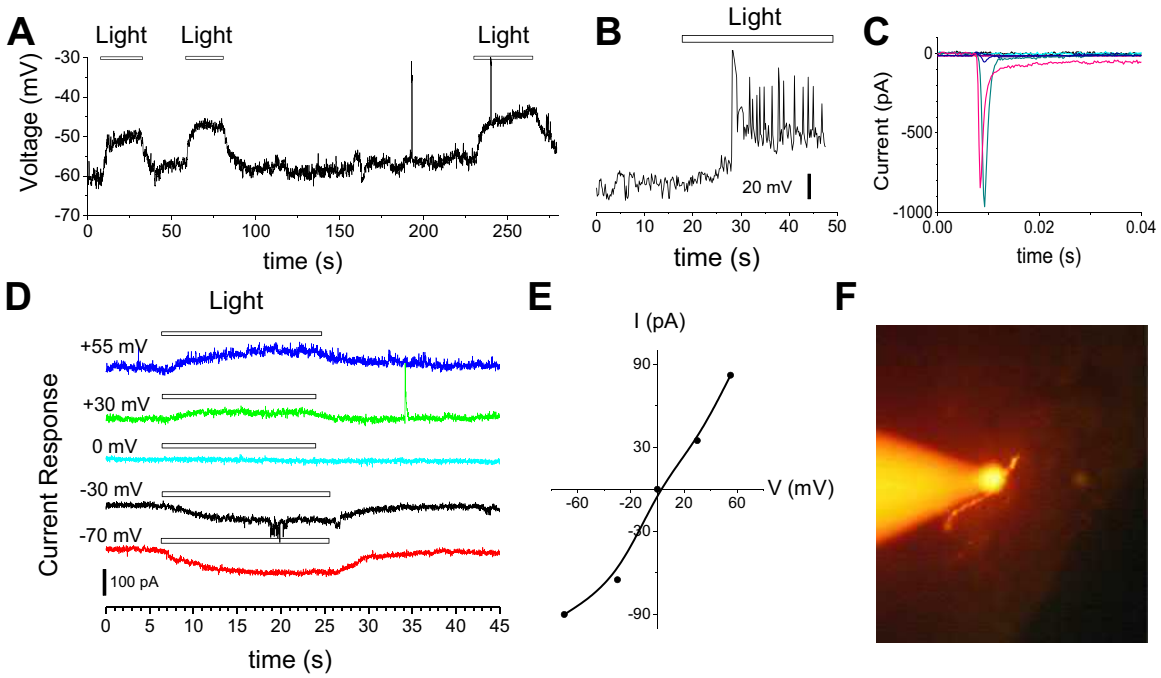

FIGURE 16.10 (A) Light-evoked responses from a neuron in the lateral septal organ, showing slowly rising subthreshold depolarization under current clamp. (B) Light-evoked response from another cell under current clamp, showing a light-evoked slow depolarization, which led to delayed suprathreshold spikes. (C) Voltage-gated Na currents (shown after leak subtraction) from the same cell as in B, in response to a series of depolarizing voltage steps of increasing amplitude from a holding potential of −70mV. (D). Light-evoked current responses recorded at various holding potentials under voltage clamp, showing a reversal potential near 0 mV. (E) Current:voltage (I−V) relation of light-evoked currents in (D). (F) Digital image of an Alexa Fluor 594-filled neuron near the ventricular surface of a septal slice under whole-cell patch showing a bipolar morphology. The intensity of full-field light stimulation was 0.04 nW/μm^2. *From Kuenzel et al. (2015).*

ventral portion of the lateral septum. It has cerebrospinal fluid-contacting neurons that contain and synthesize vasoactive intestinal peptide (VIP) as well as other neurochemical types, and specialized ependyma. The lateral component of LSO occupies a location at the base of the lateral ventricle in the st brain region and therefore is currently referred to as the st part of the LSO (LSOst, Figure 16.5D). The LSOst has layers of highly modified ependymal cells, VIP receptors, and lacks a complete blood-brain barrier (Kuenzel and Blähser, 1994; Kuenzel et al., 1997). VIP containing neurons in the avian (Silver et al., 1988; Wada et al., 2000) and reptilian (Foster et al., 1994; Foster and Soni, 1998) lateral septum have also been shown to contain opsin-like compounds suggesting that those neurons or others in that organ may serve as deep brain photoreceptors involved in monitoring seasonal time by sensing exposure to daylight. Our laboratory was the first to record currents from LSO neurons that responded to light using the patch-clamp technique. Results showed light-evoked responses from bipolar neurons in the LSOm displaying slowly rising subthreshold depolarization under current clamp (Kuenzel et al., 2015). When recorded under voltage clamp at various holding potentials, these cells responded to light with slowly developing current responses that reversed direction at approximately 0 mV (Figure 16.10D), suggesting that they were mediated by nonselective cation channels. The electrophysiological data, notably the slowness, 5 s in rise time (Figure 16.10A) following light stimulation, and most interestingly, its polarity, depolarization (Figures 16.10A and B) rather than the characteristic hyperpolarization found in rods and cones, and the cation-selective nature of the underlying ion channels all share a remarkable similarity with the intrinsically photosensitive (ip) retinal ganglion cells (RGCs) examined in the mammalian retina (Berson et al., 2002; Berson, 2003). The seminal data of Berson et al. (2002) have shown that the mammalian ipRGC is a primitive form of photoreceptor and has been proposed to use an invertebrate-like phototransduction cascade (Qiu et al., 2005). Data suggest that neurons in the LSO of chicks contain photoreceptors with similar electrophysiological responses to light as found in the mammalian ipRGC. Unknown is what photopigment is contained in the light responsive bipolar cells within the avian LSOm. Recent data have shown that dissected brain areas containing the LSOm show significantly increased gene expression of both opsin 4 (melanopsin) and opsin 5 (neuropsin). Birds were sampled at both three and seven days following exposure to long-day photostimulation. Data suggest that neurons within the dissected area contain one or both opsin-

type receptor neurons and display increased photopigment gene expression that persists through at least seven days following long-day photoperiods (Kang and Kuenzel, 2015). Notably, gonadal development in birds subjected to an increase in photoperiod was significantly attenuated by bilateral lesions directed to the LSO suggesting that this structure could be a functional site of deep brain photoreceptors (Rathinam and Kuenzel, 2005). In agreement with these findings, VIP within the septal region showed significant gene activation following photostimulation (Li and Kuenzel, 2008) and an opsin-containing neuron located in the avian lateral septum was shown at the light and electron microscopic level to innervate dendrites of a GnRH neuron (Saldanha et al., 2001). Nonetheless, all data to date have not provided direct evidence that the LSO contains a key group of deep brain photoreceptors.

The other three CVOs that contact the NHpC include two residing in the 3V, the OVLT, and SSO, homologous to the mammalian SFO, and ChP located primarily in the terminal region of the NHpC where the two lateral ventricles join the dorsal 3V. The avian OVLT first appears near the rostral wall of the 3V, termed the lamina terminalis where the POA begins. At this location, the OVLT is a highly vascular structure on both sides of the 3V. In rodents, the OVLT is restricted to the anterior, ventral preoptic/hypothalamic region, and it is found near the suprachiasmatic nucleus (Duvernoy and Risold, 2007). In contrast, the OVLT of birds is more extensive and comprises a prechiasmatic segment located between the anterior part of the optic chiasma and base of the brain. The vascular OVLT extends dorsally on both sides of the anterior region of the 3V, continues as a subcommissural segment and passes in front of and dorsal to the AC to form a precommissural and supracommissural segment, respectively (Dellmann, 1964; Mikami, 1976). The avian OVLT therefore occupies a strategic position between the anterior roof of the diencephalon and floor of the septum along midline. In mammals, GnRH neurons are found in the preoptic region adjacent to the OVLT, and GnRH fibers are found in and about the OVLT (Foster and Younglai, 1991; Silverman et al., 1994). In the chick, a terminal field of GnRH-1 neurons has been observed throughout the entire extent of the OVLT (shown in red in Fig. 5 of Kuenzel, 2018) and continues along midline to become another CVO, the SSO (shown in green in Fig. 5 of Kuenzel (2018) (Figure 16.9E). Anatomical data suggest a large terminal field of GnRH-1 neurons occurs along the midline floor of the septal region where GnRH-1 hormone can be secreted into the cerebrospinal fluid of the 3V and/or into the capillaries of the CVOs (Kuenzel, 2018). The final CVO associated with the NHpC is the ChP, an extensive capillary complex, which surrounds the caudal terminal end of the septum. Hence, the septal complex of GnRH-1 neurons has the capability of sending well-known projections to the median eminence above the anterior pituitary (APit), but also secreting GnRH-1 within the dorsal region of ventricular system into cerebrospinal fluid.

16.2.5.2.2 Septal-hypothalamic-pituitary-adrenal neuroendocrine system

The core of the NHpC contains CRH neurons (Figure 16.9D–F) and appears to be involved in the regulation of stress in birds (Nagarajan et al., 2014, 2017b; Kadhim et al., 2019). The major, evolutionally conserved group of CRH neurons regulating stress is localized in the hypothalamic PVN of birds and mammals. It is of particular interest to understand how these two groups of CRH neurons contribute to the avian stress response. Recent work provided some insights into the time course of neuronal activation in the NHpC and PVN following exposure to a stressor, food deprivation. It appeared that in response to food deprivation the earliest increase in CRH gene expression occurred in the NHpC followed by an increase in CRH gene expression in the PVN (Nagarajan et al., 2017b). Another study using the same stressor showed that both the NHpC and PVN displayed an increase in CRH gene expression at the first sampling time, 2 h (hr.) after stress, however, the rate of increase in the NHpC was 70% from non-stressed controls, while in the PVN the CRH gene expression showed a modest 33% increase. Importantly, the expression of the CRH gene in the NHpC matched the output of the pituitary stress hormone POMC. Specifically, both the CRH gene expression in the NHpC and the expression of the POMC gene in the APit peaked at 2 h following exposure to stress. Moreover, the levels of CRH mRNA in the NHpC and POMC mRNA in the APit returned to control values at 8 h after beginning of food deprivation. In contrast, the CRH gene expression in the PVN showed a slow but steady increase that peaked at 8 h, maintaining the stress response (Kadhim et al., 2019). Results suggested that CRH mRNA produced by the NHpC was a significant contributor, and appeared to be the earliest one that influenced APit production of POMC resulting in a significant increase of the stress hormone CORT (Kadhim et al., 2019).

Food deprivation used in the previous, cited studies is a gradual stressor that increases in time due to the intensity of hunger. Immobilization or restraint is another common experimental model to study stress-related mechanisms. In contrast to food deprivation, immobilization stress is immediately perceived by a bird that is restricted to move and spread its wings. Therefore a different stressor of this type could test whether an early response of CRH neurons in the NHpC was stressor specific or a general avian response to stress. Immobilization induced a significant increase in CRH gene expression in the NHpC and PVN at 15 min, the first sampling point. Of interest, the pattern of

response was the same as in the study with food deprivation. A more than 100% increase in gene expression by CRH mRNA transcripts in the NHpC occurred compared to a 30% increase in gene expression of CRH mRNA transcripts within the PVN at the 15 min sampling point (Kadhim et al., 2021). Similarly, the pattern of APit POMC gene expression also peaked at the 15 min sampling point matching closely the previous experiment using food deprivation stress.

To determine more directly whether the NHpC and its CRH neurons are truly early responders to stress and contribute to the traditional hypothalamic HPA axis, an experiment was designed to surgically implant an electrode into the septum using a stereotaxic instrument to target the NHpC and produce a small electrolytic lesion to down regulate the structure. A group with lesions directed to the NHpC and control birds were subjected to food deprivation stress and sampled at the 2 h sampling point previously shown to be the peak response of the NHpC from that stressor. Results showed a significant reduction in CRH gene expression in the NHpC, significant reduction in APit POMC and plasma CORT (Kidd et al., 2019). Results suggest that the NHpC appears to function in the traditional HPA axis of poultry and appears to be an early responder to stressors. Perhaps a comparable neural structure exits in other vertebrate species as well.

16.2.5.2.3 Other functions related to structures within the septum

The septum has major connections with the hippocampus, amygdala, diencephalon, and brainstem. Functions attributed to this brain subpallial region include ingestive, defensive, and reproductive behaviors that are fundamental to sustainability of vertebrate species (Swanson, 2000). With respect to inputs from the hippocampus, food caching has been associated with the septum. Specifically, black-capped chickadees are known to display food-storing behavior, a seasonally related activity. A significant increase in septal as well as hippocampal volume occurred during the time of year storing behavior was at its peak (Shiflett et al., 2002). Another seasonal activity displayed by birds is reproductive behavior that usually occurs in the spring when day length increases. The septum plays a major role in courtship and aggressive behavior in a variety of avian species (Ramirez et al., 1988; Goodson, 1998; Goodson and Adkins-Regan, 1999; Panzica et al., 2001). Lesions of the septal region produced a facilitation of male courtship behavior and vocalization in ring doves (Cooper and Erickson, 1976) and facilitated both overt aggression and the number of simple, multipurpose songs in territorial field sparrows (Goodson et al., 1999). When brain sections are immunostained for AVT, the lateral septum of male Japanese quail when compared with females shows significantly greater immunostaining of AVT fibers (Panzica et al., 2001). Similarly, AVT and galanin fibers in male chickens (Jurkevich et al., 1997; Klein et al., 2006) display increased density within the lateral septum. During both courtship and mating behavior between roosters and hens as well as agonistic behavior between two males, significantly greater amounts of Fos protein produced by the immediate early gene *c-fos* occurred in the lateral septum of males (Xie et al., 2010). Increased expression of the gene *c-fos* in neurons is a marker of activation of those cells.

Hodological studies in birds involving the septum have shown that not only is there a descending neuroendocrine system affecting hypothalamic function but also ascending pathways from key diencephalic structures back to the septum suggesting that the downstream motor pathways have a number of feedback loops (Berk and Butler, 1981; Berk and Finkelstein, 1983; Atoji and Wild, 2004; Montagnese et al., 2004, 2008). Several hypothalamic structures with direct connections to the septum have been shown in previous studies to be involved with food intake and the regulation of the ANS. The reciprocal connections of the septum to hypothalamic structures as well as the presence of the SSO at the floor of the septum shown to contain angiotensin II receptors, provides evidence that the septum is involved in the regulation of food and water intake, respectively. Chicks subjected to osmotic stress showed increased avian V1aR, angiotensin II type 1 receptor, and transient receptor potential vanilloid receptor 1 (TRPV1) mRNA levels in the SSO/SFO (Aman et al., 2016) located in the ventral portion of the NHpC. The avian V1aR is found in abundance in the OVLT and SSO as well as other CVOs (Selvam et al., 2015). When the Manning compound (SR-49,059), a specific blocker of the avian V1aR is applied intracerebroventricularly prior to the injection of NPY, food intake was significantly increased compared to a treatment group with NPY alone. Results showed that the V1aR functions in appetite regulation by mediating an anorexigenic effect (Kuenzel et al., 2016). There exists structural and functional evidence that the septum possesses a descending neuroendocrine and integration system involved with basic social and ingestive behaviors and functions.

16.2.6 Preoptic area

16.2.6.1 Structures

There was a long-standing tradition among neuroanatomists of attributing the POA to the hypothalamus. Introduction of genetic molecular markers and developmental analysis of subpallial *Nkx-2.1* and *Shh* gene expression patterns demonstrated striking similarity between the POA and the adjacent subpallial telencephalic areas of the

chicken, zebra finch, and mouse suggesting that the POA has to be considered as a part of the subpallium (Rubenstein et al., 1998; Puelles et al., 2007; Abellan and Medina, 2009; Shimogori et al., 2010; Medina and Abellan, 2012; Vicario et al., 2014, 2017; Puelles and Rubenstein, 2015). In the developing mouse, a narrow dorsoventral belt of Shh-expressing cells forms a clear molecular boundary between the POA and the neighboring paraventricular area of the hypothalamus (Shimogori et al., 2010; Puelles and Rubenstein, 2015). Additional analysis of gene expression patterns revealed two subdivision of the POA—the commissural preoptic area (POC) and the basal preoptic are (POB). In birds, the POC is characterized by strong expression of *Lhx7/8* and *Shh* genes and lack of the pro-*ENK* gene expression, while the POB shows strong expression of the pro-*ENK* and *Shh* genes and lacks the *Lhx7/8* expression in most of its cells (Abellan and Medina, 2009; Vicario et al., 2017). In the mouse and birds, the POC bends around the ventral surface of the AC and includes at least one nucleus, the median preoptic nucleus (MnPO, Medina and Abellan, 2012); however, in birds the boundaries and function/s of this nucleus remain unclear. The POB appears to occupy the ventral portion of the POA and includes the POM and probably some other neural cell groups that have not been defined. Due to insufficient data and lack of consensus regarding localization and functions of neuronal groups within POA subdivisions of the avian brain, only the POM will be discussed here.

The POM is currently the most prominent structure within the POC of birds. Neurons in the POM produce aromatase, a testosterone-converting enzyme, and therefore aromatase immunoreactivity serves as a neurochemical marker of this nucleus (Figure 16.11) (Balthazart et al., 1990; Riters et al., 2000; Xie et al., 2011). Japanese quail males have larger volumes of the POM than females, and this sex difference is testosterone-dependent. Reduction of testosterone levels by castration or by transitioning birds to short daylength results in gonadal regression and a decrease in POM volume in males (Balthazart and Ball, 2007). In male starlings, the size of the POM is largest during the spring breeding season when testosterone concentration peaks and shows a significant reduction during the following nonbreading period (Riters et al., 2000).

The POM of quail receives projections from a component of the medial extended amygdala, namely the BSTM, PVN, and supraoptic nucleus. Specifically, sexually dimorphic vasotocinergic innervation of the POM in males originates from the BSTM (Absil et al., 2002a). More recent neuroanatomical studies in male quail have identified a presumptive polysynaptic pathway from the POM down to the cloacal muscle involved in copulatory behavior. The pathway includes a projection from the POM to the intercollicular complex (ICo; Wild and Balthazart, 2013). Within the ICo was found a distinct, elongated nucleus, the

FIGURE 16.11 Coronal brain section showing the medial preoptic nucleus (POM) immunoreactive for aromatase located directly ventral to the AC. Abbreviations: *AC*, anterior commissure; *OC*, optic chiasma; *3V*, third ventricle. Scale Bar = 500 μm.

dorsomedial nucleus (DM). The DM was shown to project to the caudal brainstem nucleus called the nucleus retroambigualis (RAm; Wild et al., 1997; Wild and Balthazart, 2013). Anterograde tracing from the RAm showed a continuous projection from that caudal brainstem nucleus through the entire length of the spinal cord to the sacral region of spinal cord. The motor neurons in the ventral horn at that spinal cord level innervate the large cloacal sphincter muscle (mSC; Wild and Balthazart, 2013).

16.2.6.2 Functions

The POM is a member of the social behavior network and a pathway from that structure to the lumbar region of the ANS has been mapped showing its involvement in consummatory, sexual behavior.

A social behavior network was proposed to exist in mammals that functioned to regulate male reproductive behavior (Newman, 1999). Birds likewise were shown to have a neuroendocrine social behavior network (Goodson, 2005). The social behavior network comprises six nodes: (1) POA, (2) lateral septum (SL), (3) extended MeA and medial bed nucleus of stria terminalis BSTM, (4) anterior hypothalamus (AHy), (5) ventromedial hypothalamus (VMN), and (6) midbrain [periaqueductal gray (PAG), also known as central gray (GCt)]. Each node binds sex steroid hormones and has been implicated in control of social behavior, particularly appetitive/consummatory reproductive and aggressive behavior (Newman, 1999; Goodson, 2005). Interestingly, using FOS ir (immediate, early gene data), each behavioral context is associated with a distinct *pattern* of activation across nodes (Goodson, 2005). The POA is more responsive in males, particularly the POM and

shows differentially regulated subregions of the POM for appetitive and consummatory sexual behavior in Japanese quail (Balthazart et al., 1998a). The POM was found to be sexually dimorphic (Viglietti-Panzica et al., 1986; Adkins-Regin and Watson, 1990). As mentioned previously under subheading (C. Extended Amygdaloid Complex, MEA, 2. Functions), the MeA projects to the BSTM complex, and the BSTM has been shown to be sexually dimorphic, larger in males, steroid-responsive and affects copulatory behavior in birds (Kiss et al., 1987; Voorhuis et al., 1988; Panzica et al., 1998; Viglietti-Panzica et al., 1992; Aste et al., 1998; Jurkevich et al., 1999). The rooster ventromedial BSTM functions in appetitive sexual behavior (Xie et al., 2010, 2011). Importantly, vasotocin neurons in the BSTM project to the POM (Absil et al., 2002b).

The avian POM is one of the largest and best-documented group of neurons expressing aromatase (Figure 16.11). Estrogen synthesis by the enzyme aromatase within the POM has been known for some time to activate male sexual behavior (Panzica et al., 1996; Balthazart et al., 2004) and interestingly, rapid changes in aromatase within the POM have been documented within minutes following a sexual interaction with a female (de Bournonville et al., 2013).

Using FOS-immunoreactivity (FOS-ir) as an indicator on neuronal activation, Xie et al. (2010) have observed a prominent increase of FOS-ir cell number in the POM of chicken males following copulation with a female. Curiously, a similar increase in FOS-ir cell number was observed in the POM of males that interacted with another male. These data confirmed previous observations regarding a key role of the POM in controlling male copulatory behavior in many vertebrate species (Crews, 2005; Balthazart and Ball, 2007), and also extended the function of POM to the regulation of male aggression. Several previous studies revealed differential FOS expression in the avian rostral and caudal POM following appetitive (courtship) or consummatory (copulation) sexual behavior (Riters et al., 2004; Balthazart and Ball, 2007). The caudal POM in quail sends sexually dimorphic descending projections to the midbrain PAG forming a pathway controlling male copulatory reflexes (Absil et al., 2002b). It could explain the induction of FOS expression in the caudal POM following copulation observed in the chicken. In contrast to the well-documented function of POM in sexual behavior, the role of this structure in agonistic behavior of avian males has received less attention (Barfield, 1971; Schlinger and Callard, 1990). An induction of IEGs in the POM after male−male interactions was observed in songbirds during the breeding season (Goodson et al., 2005). The latter studies support observations showing an increase in FOS expression in the POM following intermale interactions and suggest that the POM may play a more complex role in social encounters than just controlling consummatory copulation.

16.3 Components of the autonomic nervous system

The avian ANS, characteristic of all vertebrate systems, comprises two basic arms: (1) the sympathetic nervous system (SNS) and (2) parasympathetic nervous systems (PNS). Structural components of the SNS and PNS along with targets of their projections are schematically presented (Figure 16.12). The following short review focuses on the main structures of the ANS and a few key central neuronal structures that serve as components of the central nervous system providing connectivity from subpallial structures to the ANS for its continuous functional regulation. Overall, the ANS is responsible for motor functions and secretions that occur automatically on a daily, seasonal, and annual basis. It involves the integration of sensory information such that smooth muscle, cardiac muscle, and secretory cells located in visceral organs provide the appropriate output to maintain homeostasis of bodily functions such as heart and lungs to regulate blood pressure and respiratory rate thereby affecting osmotic and pH balance, body temperature (particularly in homoiotherms), gastrointestinal movements, reproductive processes, circadian rhythms, and other essential circannual rhythmic functions that are continuously regulated. To balance the regulatory output, two antagonistic systems are in place—the sympathetic and parasympathetic arms of the ANS. More detailed information is available in a number of reviews (Akester, 1979; Bubien-Waluszewska, 1981; Kuenzel, 2000; Yasuda, 2002; Nilsson, 2011).

16.3.1 Sympathetic nervous system

Similar to mammals, a chain of ganglia exists on both sides of the vertebral column in the thoracolumbar region of the spinal cord of birds (Figure 16.12). A marked difference, however, exists in avian species. Most of the vertebrae are fused, due to the function of flight requiring a stable, solid structure to protect the spinal cord during rapid initiation of flight and particularly during landing. Due to the extensive fusion of bones, it requires considerable skills to dissect the entire spinal cord, spinal nerves, and ganglia associated with each segment of the spinal cord. More than one system of numbering the spinal nerves and ganglia exists due to the variable number of vertebrae occurring among various avian species. Additionally, two different methods have been developed which either number the spinal segments and nerves sequentially beginning with the cervical region and ending with the last coccygeal vertebra (Dubbeldam, 1993; Yasuda, 2002) or number the vertebrae, spinal segments, and their associated spinal nerves, dorsal root

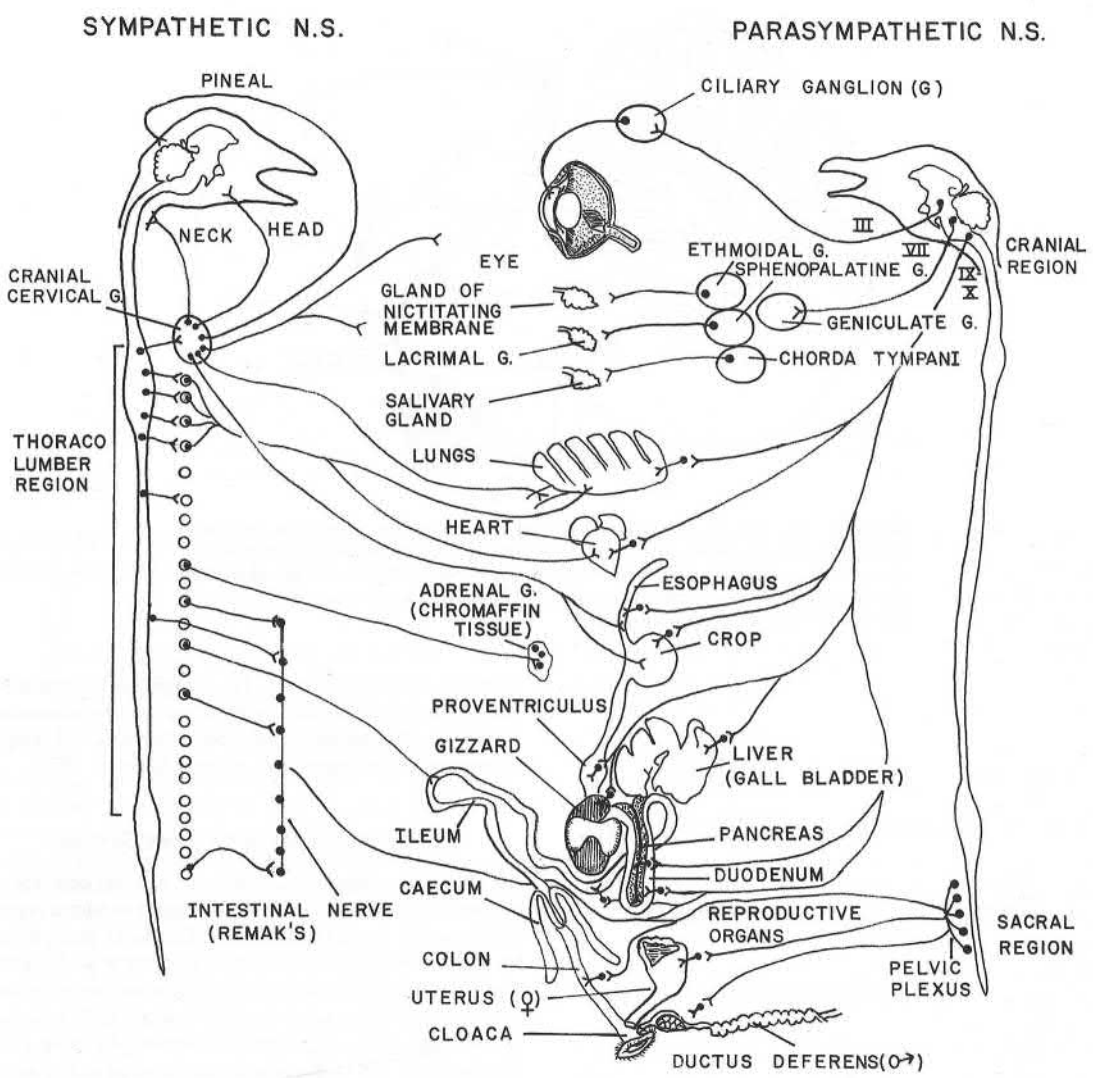

FIGURE 16.12 The motor component of the avian autonomic nervous system (ANS). The sympathetic and parasympathetic arms of the ANS are shown on the left and right sides, respectively.

ganglia, and the chain of autonomic ganglia to a regional group of vertebrae (Nickel et al., 1977; Landmesser, 1978). The usual, traditional regional terms cervical, thoracic, lumbar, and sacral (or synsacral and coccygeal) nerves (and ganglia) have been utilized, but the transitional zones may be problematic to ascribe a ganglion or spinal nerve to the appropriate region when the synsacral bone is dissected to reveal the caudal spinal cord (Dubbeldam, 1993). Therefore, documentation with images is most helpful for each species, particularly when referencing a specific segment, ganglion, or spinal nerve in a study.

Within each segment of the thoracolumbar region of the spinal cord is a nucleus that identifies the central nervous system origin of the SNS. The intermediomedial nucleus, previously termed the column of Terni, contains the preganglionic motor neurons of the SNS. The nucleus is located at midline of a cross-section of spinal cord, directly dorsal to the central canal (see Figure 16.5 in Kuenzel, 2000). The axonal processes of the neurons move laterally a short distance and innervate one of the autonomic ganglia. A major neurotransmitter released is ACh that binds to nicotinic receptors present on postganglionic neurons. The long postganglionic axons project to specific visceral organs and release primarily the neurotransmitter norepinephrine which binds to subtypes of alpha or beta adrenergic receptors.

An autonomic, ganglionated nerve unique to birds is Remak's nerve (Figure 16.12). It appears at the end of the duodenum, running parallel to the intestinal tract and ending at the cloaca. Remak's nerve plays a role in the regulation of gut motility (Hodgkiss, 1984a,b). Microinjections of a neurotracer into individual neurons within

ganglia of Remak's nerve in the chicken revealed four distinct morphological types of neurons. The function of each neuronal type remains unknown (Lunam and Smith, 1996). Previous research into gastrointestinal motility by the late Dr. Gary Duke's laboratory discovered that sections of the avian gastrointestinal tract showed clear antiperistalsis or reversed peristalsis, that is smooth muscle movement resulting in a sequential movement of food or "owl pellets" in an adoral direction (Duke et al., 1977; Lai and Duke, 1978). His research and videos clearly show retro- and/or antiperistalsis which is a characteristic of avian species. The research from the lab of Hodgkiss does not cite any of Duke's publications, where Hodgkiss has suggested that Remak's nerve may function in gut antiperistalsis (Hodgkiss, 1984a,b). It is a pity their two labs did not interact as this area appears to be a fertile area of investigation for determining the mechanism of antiperistalsis in birds.

16.3.2 Parasympathetic nervous system

The PNS has a system divided into two sets of preganglionic neurons, one originating in the brain and a second set located in the sacral region of the spinal cord (Figure 16.12). Preganglionic neurons in the brain are found in motor nuclei of the oculomotor (III), facial (VII), glossopharyngeal (IX), and vagus (X) nerves (Akester, 1979; Dubbeldam, 1993). The cranial nerve that has a major impact on a diverse number of visceral organs regarding parasympathetic regulation of function is the vagus. Those in the sacral region have processes that form a pelvic plexus. In contrast to the SNS, the preganglionic neurons of the PNS project long processes to specific ganglia located within or adjacent to visceral organs or tissues regulated by the preganglionic neurons. Similar to the SNS, the preganglionic neurons secrete the neurotransmitter ACh. Nicotinic receptors on postganglionic neurons bind ACh and, in turn, the major neurotransmitter released from postganglionic neurons is ACh which binds to muscarinic receptors found within the targeted visceral organ.

16.4 Integration of the subpallium and ANS in complex neural circuits in birds: two examples involving vasoactive intestinal polypeptide as a regulator

16.4.1 The social behavior network

Newman (1999) proposed that three subpallial structures, the POA, the lateral septum (LS), and the medial extended amygdala (MeA and BSTM); along with the anterior hypothalamus, ventromedial hypothalamic area, and the periaqueductal gray of the midbrain are implicated in the control of various forms of social behavior in mammals. These six regions or "nodes" were grouped together based on their properties to be involved in modulation of several social behaviors, their interconnectivity, and their sensitivity to steroid hormones. It was suggested that social behaviors emerge from complex, dynamic temporary patterns of activity generated by all components of the SBN. Different social contexts result in unique patterns of activation producing different behavioral outcomes. A similar six-node SBN was shown to occur neuroanatomically and functionally in fish and birds (Goodson, 2005), and subsequent studies suggested an evolutionally conserved nature of the SBN (O'Connell and Hofmann, 2012). Recent findings revealed vasoactive intestinal polypeptide (VIP) and VIP receptors throughout the SNB of songbirds (Kingsbury and Wilson, 2016). Functionally, VIP has been shown to be the major neuroendocrine releaser of prolactin from the APit in birds (Macnamee et al., 1986; Opel and Proudman, 1988; Mauro et al., 1989). In ring doves, VIP initiated parental feeding (Buntin et al., 1991) and initiation of egg incubation in bantam hens (Sharp et al., 1989) and turkeys (El Halawani et al., 1996). Utilizing a number of songbird species, VIP neural "hotspots" were described in the SBN where VIP signaling appears to contribute to regulating a given social behavior. VIP and its receptors within the LS and BSTM appeared to play important roles in social affiliation and gregariousness (Kingsbury and Wilson, 2016). Interestingly, the study examined two species, field sparrow (*Spizella pusilla)* and dark-eyed junco (*Junco hyemalis*) showing a territorial phenotype during the breeding season and a flocking phenotype in winter compared to two species not displaying winter flocking. Interestingly, more robust VIP ir of the BSTM was reported in the two species that flock during the winter compared to the two not displaying seasonal wintering flocking. Results suggested that greater VIP-ir fiber density is associated with a winter flocking phenotype (Kingsbury and Wilson, 2016). Based upon their results in variation of VIP fiber and receptor density in three subpallial structures—LS, BSTM, and MeA, it was proposed that species differences in grouping behavior is modulated by VIP signaling throughout the SNB and the three nodes are regarded as hotspots for the regulation of avian affiliative behavior.

In contrast, VIP signaling in the anterior hypothalamus (AHy) and caudal septum, specifically the caudocentral septum (CcS) mediated aggression. Infusions of VIP targeting the caudal septum significantly increased aggressive behavior (Goodson, 1998). The avian septum receives projections from the AHy (Atoji and Wild, 2004), a hypothalamic area in mammals that mediates agonistic behavior (Nelson and Trainor, 2007). The avian AHy has been shown to contain VIP neurons and knockdown of the

VIP peptide using antisense oligonucleotides significantly decreased nest defense aggressive behavior in zebra finches (Goodson et al., 2012).

16.4.2 Poikilostasis or shifts in homeostasis: an hypothesis involving the visceral forebrain system

16.4.2.1 Regulation of annual cycles of avian species

Essentially all previously stated functions of the subpallium and ANS—regulation of bodily movement, reward, reproductive, social and related behaviors, memory, neuroendocrine and autonomic function—are developed to achieve one outcome, homeostasis, not only on a daily basis but also throughout the year to regulate the entire annual cycle of vertebrates. An hypothesis was introduced nearly 30 years ago that appears relevant to both wild and domestic avian species (Kuenzel and Blähser, 1993). It was based upon the neuropeptide distribution and gene expression of VIP mapped throughout the chick brain (Kuenzel and Blähser, 1994; Kuenzel et al., 1997). The unique VIP distribution identified an avian CVO (the LSO), subpallial structures, and central components of the ANS, a majority of which were previously grouped together and proposed to function as a visceral forebrain system in mammals (van der Kooy et al., 1984). The mammalian visceral forebrain system comprised the medial and lateral prefrontal cortex, paraventricular, arcuate and posterolateral hypothalamic nuclei, BSTL, central nucleus of the amygdalal, and nucleus tractus solitarius (NTs). It was hypothesized that the system influenced autonomic functions and could override brainstem homeostatic mechanisms during periods of stress or emotional activity (van der Kooy et al., 1984). A key structure within the visceral forebrain system was the NTs. The NTs immunostains intensely with an antibody to VIP and is a key brainstem structure connected to the parasympathetic arm of the ANS. Some birds display dramatic physiological and behavioral changes throughout their annual cycle, therefore the term poikilostasis, meaning shifts in homeostasis (Kuenzel et al., 1997; Kuenzel, 2000) could explain the remarkable seasonal behaviors displayed by migratory birds. In other words, poikilostasis means that the set point for homeostatsis or the balance between the SNS and PNS does not stay constant, rather the set point shifts either in favor of the PNS or SNS dependent upon the season throughout the year.

Migratory birds, particularly those in temperate zones that migrate north each spring generally forage in flocks prior to migration and need to shift to an anabolic state where rapid body weight gains are essential in order to deposit the necessary fat reserves to make the demanding migratory journey to the breeding grounds. Upon arrival, there occurs a shift to a catabolic state as birds enter a new phase of their annual cycle. Birds become territorial and aggressive in order to defend their selected space, attract and find a mate, and build a nest during the breeding season. The physiological and behavioral processes required for successful reproduction, incubation behavior, and the rearing of young are metabolically demanding. Thereafter birds undergo a major molt that continues their catabolic state resulting in the utilization of considerable lipid reserves. A shift to an anabolic state then follows, resulting in increased food intake to prepare birds for a rigorous return migratory flight to the wintering grounds. Due to the marked changes in metabolic states that birds undergo coupled with short time periods for each particular phase of their annual cycles, birds would unlikely be able to complete their seasonal life history requirements if set points for energy homeostasis were fixed throughout the year. Hence shifts in homeostasis (poikilostasis) would allow the PNS to dominate when anabolic processes were critical for rapid body weight gains and conversely, a shift to greater activity of the sympathetic arm of the ANS could occur when energy demands were high and sustained. The hypothesis of poikilostasis suggests that there exists in birds, and perhaps other vertebrate species, the capacity for dynamic shifts in the balance or set points of the ANS in order to successfully complete their annual cycles. A key neuropeptide, VIP and its receptors appear to play a role in changing the behavior, neuroendocrine regulation, and balance of the ANS to shift the birds from one phase to the sequential one in their annual cycle. The recent molecular models involving neural pathways, energy sensors, and the ability to integrate nutrient and hormonal signaling at the level of the hypothalamus may provide additional key markers for testing the validity of this hypothesis by focusing upon signals and processes associated with shifts in the balance of the ANS.

16.4.2.2 Some current metabolic and behavioral issues with breeding stock of broilers and turkeys

With the continued use of genetic selection programs in broilers as well as turkeys for increased growth rate and better feed conversion, the result has been a modern bird showing a high efficiency for the conversion of feed to a quality meat product. A cost, however, for managers of broiler and turkey breeders has been a feed restriction program that requires careful monitoring throughout the life span of birds in order to insure that parent stock remain healthy and continue to produce an acceptable rate of fertilized eggs (Richards et al., 2010). Data over many years have shown that broilers compared to layers display increased food intake, less overall activity, and a lower

basal metabolic rate. Data suggest an imbalance of the ANS, pointing to a physiological system with high parasympathetic and low sympathetic activity in current meat-type birds. It would be worthwhile to examine VIP and its receptors in combination with the advances in the understanding of the neural regulation of food intake, metabolic signals, energy homeostasis, and genes involved (Richards and Proszkowiec-Weglarz, 2007; Byerly et al., 2009; Yuan et al., 2009). The time may be appropriate to examine gene expression of VIP, its receptors, and related genes affecting subpallial function and ANS in order to develop an objective PNS/SNS ratio indicative of an effective balance between acceptable growth rate, lifetime welfare, and sustained reproductive output for birds selected as parent stock.

16.5 Summary and conclusions

Neural structures that comprise six distinct regions in the subpallium of the avian forebrain (Figure 16.1) as well as the basic components of the ANS were reviewed. Noteworthy is the evidence that the regions are evolutionarily conserved among vertebrates. Therefore data obtained in mammalian and other vertebrate classes can be cautiously utilized to help understand the function of systems that have not been examined extensively in birds. Subpallial structures are important as several have been shown to have connectivity to pallial (cortical-like) brain regions as well as to key hypothalamic and brainstem structures that are part of the cognitive, neuroendocrine, and ANSs. Importantly, the latter two systems involve the production of hormones that can modulate the physiology and behavior of organisms for hours, days, and even weeks indicating processes regulating seasonal activities of birds.

Some of the functions associated with subpallial and ANS components include the neural regulation of feeding, reproductive, voluntary movement, affiliative, agonistic, and stress behaviors. Additional functions associated with the subpallium and ANS include reward, memory, and learning. It is hoped that the review will stimulate further reading and expand discussion of structural and functional aspects of the avian subpallium, as well as help suggest future research that can advance the understanding of the avian central nervous system, its neural pathways, and functions among various wild and domestic avian species.

Acknowledgments

Supported in part by NSF Grant #IOS-0842937, a grant from the Arkansas Biosciences Institute (ABI), the Arkansas Division of Agriculture, and USDA/NIFA Sustainable Agricultural Systems #2019-69012-29905. We wish to thank John Wray for completing Figures 16.6 and 16.7 in the chapter.

Chapter 17

Blood

Colin G. Scanes
Center of Excellence for Poultry Science, University of Arkansas, Fayetteville, AR, United States

17.1 Introduction

Blood consists of the following components:

- Plasma
- Formed elements or cells containing nuclei and mitochondria.
  - Erythrocytes (red blood cells)
  - Leukocytes (white blood cells)
  - Thrombocytes (equivalent to platelets in mammals).

Blood is critically important to the physiology of birds. The functions of blood include the following:

- Transportation of the following:
  - Respiratory gases (oxygen and carbon dioxide)
  - Electrolytes (e.g., Na^+, K^+, Ca^{2+}, Mg^{2+}, PO_4^{3-})
  - Nutrients (e.g., glucose, fatty acids, amino acids)
  - Metabolites (e.g., lactate)
  - Waste compounds (urate, urea)
  - Hormones
  - Heat
- Protection via antibodies, leukocytes, and thrombocytes
- Water, glucose, and electrolyte homeostasis
- Clotting in the event of injury of blood vessels.

Blood also carries pathogens and toxicants.

Blood is more viscous than water. The viscosity of chicken blood is calculated as 27.6×10^{-4} Pa s or 3.1-fold that of water while the viscosity of blood from domestic ducks and geese is 4.2-fold that of water (reviewed Sturkie, 1986). While blood viscosity is increased in broiler chickens with ascites, plasma viscosity was reduced (Maxwell et al., 1992a; Fedde and Wideman, 1996).

17.2 Plasma

Table 17.1 summarizes mean concentrations of the constituents of plasma of birds while Table 17.2 compares the plasma volume with the volumes of other fluids in the body of birds. The osmotic pressure of avian plasma comes the following (Peltonen and Sankarri, 2011):

- Electrolytes: 95% (see Table 17.1)
- Glucose, amino acids, urea, and other organic molecules: 5%
- Proteins: 0.5% of colloidal osmotic pressure.

Plasma is 40% more viscous than water (chickens, ostriches, domestic ducks, geese—reviewed Sturkie, 1986).

The circulating concentrations of electrolytes vary with physiological state. Venous plasma concentrations of sodium and plasma osmolarity are elevated by either dehydration or hyperthermia (chickens: Arad et al., 1983). Hyperthermia also results in elevated concentrations of chloride ions, blood urea nitrogen, and uric acid (chickens: Arad et al., 1983).

17.2.1 Circulating electrolytes

The concentrations of individual electrolytes are maintained within strict limits in view of their critical role in blood osmotic pressure and polarization/depolarization of nerves and muscles. The mean circulating concentrations of electrolytes such as sodium, potassium, and chloride across a large number of avian species are summarized in Table 17.1. There are shifts in the circulating concentration of electrolytes with physiological state. For instance, acute heat stress is followed by decreases in the plasma concentrations of sodium and potassium ions (chickens: Borges et al., 2004). Moreover, plasma concentrations of sodium are reduced with fasting and the concomitant reduction in metabolism (Christensen et al., 2012). There are differences in venous plasma concentrations of sodium and chloride between migratory and nonmigratory species of passeriform birds (Heatley et al., 2013).

Circulating concentrations of bicarbonate changes with pCO_2 (see Section 17.4). For instance, there are decreases in the plasma concentrations of bicarbonate ions due to

Sturkie's Avian Physiology. https://doi.org/10.1016/B978-0-12-819770-7.00044-X

TABLE 17.1 Mean concentrations of constituents of plasma in birds.

Parameter	Number of species	Plasma concentration +SEM	Units
Protein	100	39.6 ± 0.74	g/L
Albumen	63	15.9 ± 0.55	g/L
Globulin	55	18.8 ± 0.96	g/L
Glucose	139	15.4 ± 0.32	mM or mmol./L
Sodium	47	152.5 ± 1.13	mequiv./L
Chloride	43	112.6 ± 1.28	mequiv./L
Calcium	49	2.56 ± 0.10	mequiv./L
Potassium	46	3.21 ± 0.19	mequiv./L
Uric acid	60	0.50 ± 0.04	mM or mmol./L
Blood urea nitrogen	43	1.11 ± 0.09	mM or mmol./L

For details of circulating concentrations of serum/plasma constituents in individual avian species, see Table 1 in the companion website.

TABLE 17.2 Blood and other fluid components of birds.

	Volume as a % of body weight	
	Mallard ducks	Chickens (laying hen)
Plasma[a]	4.3	4.6
Interstitial fluid[a]	15.7	21.7
Intracellular fluid	43.6	31.1
Reference	Ruch and Hughes (1975), Keijer and Butler (1982)	Medway and Kare (1959a,b)

[a] *Plasma + Interstitial fluid = extracellular fluid.*

panting associated with acute heat stress (chickens: Borges et al., 2004) and with the hyperventilation of exercise (chickens: Gleeson and Brackenberry, 1984). Differences have been reported for venous plasma concentrations of bicarbonate between migratory and nonmigratory species of passeriform birds (Heatley et al., 2013).

17.2.2 Circulating nutrients and other small organic molecules

The mean circulating concentrations of glucose, uric acid, and urea across a large number of wild bird species are summarized in Table 17.1.

17.2.2.1 Plasma concentrations of glucose

The plasma concentrations of glucose are more than double those in mammals (Table 17.1). In chickens, plasma concentrations of glucose are relatively refractory to physiological changes such as insulin administration or fasting (see Chapter 25). In contrast in wild birds, there are shifts in plasma concentrations of glucose. Plasma concentrations of glucose are depressed after flight (American robins: Gerson and Guglielmo, 2013) but elevated during captivity (rufous-collared sparrow: Ruiz et al., 2009).

17.2.2.2 Plasma concentrations of fatty acids

At times of starvation and other times when additional energy is required, adipose triglyceride is hydrolyzed to fatty acids and glycerol in the process of lipolysis. The fatty acids transit into the plasma and provide an energy source for tissues such as skeletal muscle (see Chapter 23). Plasma concentrations of nonesterified fatty acids (NEFAs) are increased following fasting (chicken: Lepkovsky et al., 1967; Langlow et al., 1970; Serr et al., 2009). In a concomitant manner, plasma concentrations of NEFA are reduced following feeding (chicken: Sato et al., 2008). In contrast, plasma concentrations of NEFA were unaffected by fasting in white-throated sparrow (Smith et al., 2007). In addition, plasma concentrations of NEFA are increased following flying (American robin: Gerson and Guglielmo, 2013).

Plasma concentrations of NEFA are influenced by endocrine status. In chickens, there are increases following insulin challenge (Lepkovsky et al., 1967; Langlow et al., 1970), goitrogen administration causing hypothyroidism

(Hamano, 2012), glucagon administration (Langlow et al., 1970), and the synthetic glucocorticoid, dexamethasone (Serr et al., 2011). Similarly, plasma concentrations of NEFA were elevated following glucagon administration in emperor penguins (Groscolas and Bézard, 1977). In contrast, plasma concentrations of NEFA are decreased by neuropeptide Y (chicken: Liu et al., 2017).

17.2.2.3 Plasma concentrations of lactate

Anaerobic metabolism generates lactic acid. It is, therefore, no surprising that plasma concentrations of lactate are increased during exercise in birds. For example, increased plasma concentrations of lactate have been reported from chickens on a treadmill (from 2.1 to 8.4 mMoles/L in Gleeson and Brackenberry, 1984), within 2 min of flight in captive peregrine falcons and brown goshawks (Holz et al., 2006) and in free-flying migrating northern bald ibis (Bairlein et al., 2015).

17.2.2.4 Uric acid and urea

Nitrogenous waste is carried in the circulation in birds as uric acid and urea (see Chapter 27). Plasma concentrations of uric acid and urea in birds are summarized in Table 17.1. It is assumed that the circulating concentrations of uric acid and urea are very similar in birds (Sturkie, 1986). However, this is only the case when expressed as mg/dL but not on a millimolar (mmole/L) basis. Circulating concentrations of nitrogenous waste are influenced by physiological state. For example, heat stress reduces circulating concentrations of urate (chickens: Lin et al., 2006). Moreover, plasma concentrations of urate increase in a linear with duration of flight (American robin: Gerson and Guglielmo, 2013). This may reflect nitrogen from deamination of amino acids and gluconeogenic production of glucose. Similarly, circulating concentrations of urate are greater in birds consuming an insect diet (high protein) than a grain diet (white-throated sparrow: Smith et al., 2007).

17.2.2.5 Circulating antioxidants

Antioxidants have a protective role, reducing damage from free radicals and the immune-related respiratory burst. The major antioxidant in the plasma is uric acid with vitamin E and four carotenoids together with vitamin C and malondialdehyde also being antioxidants. There are changes in the circulating antioxidant capacity with stress and diet (Cohen et al., 2007, 2009). Moreover, there are decreases in the blood concentration of vitamin A, carotene, malondialdehyde, and vitamin C in chickens challenged with *Eimeria acervulina* (Koinarski et al., 2005). Moreover, enzymes including peroxide dismutase and catalase acts effectively as antioxidants; their activities are depressed in broiler chickens infected with *Eimeria acervuline* (Koinarski et al., 2005).

17.2.2.6 Carotenoids

Carotenoids (e.g., lutein and zeaxanthin) are transported in the blood to tissues near the surface of birds requiring coloration. The dietary hydroxycarotenoids per se provide yellow coloration while red color is the result of biotransformation to ketocarotenoids. This has been studied in the red-legged partridge with their red ornamentation of the legs, eye rings, and bill (García-de Blas et al., 2016).

17.2.3 Plasma proteins

The mean circulating concentrations of protein, albumen, and globulin across a large number of avian species are summarized in Table 17.1. The mean circulating concentrations of protein, albumin, and globulin across a large number of avian species (Table 1: Appendix 1) are the following:

- Protein 36.2 g/L
- Albumin 13.4 g/L
- Globulin 13.9 g/L.

The colloidal osmotic pressure due to plasma proteins is much lower than that exerted by electrolytes and small organic molecules, such as glucose, and lower than that in mammals (Peltonen and Sankari, 2011). Based on electrophoretic analysis, the major proteins in serum are the following:

- Prealbumin (with transthyretin binding thyroid hormones)
- Albumen (binding fatty acids, lipophilic hormones, etc.)
- Globulins (α, β, and γ).

In the reproductively active female birds, there are high concentrations of yolk precursors. In the avian embryo, the major plasma protein is α-fetoprotein. This binds metals. The α-fetoprotein has been isolated from chick embryos but does not appear to bind steroid hormones, unlike its mammalian counterpart (Ido and Matsuno, 1982).

17.2.3.1 Extracellular fluid

Extracellular fluid is comprised of plasma and interstitial fluid. The volume of interstitial fluid is marked greater quantitatively than plasma (Table 17.2). Based on studies with suction blister fluids, the concentrations of proteins in interstitial fluid (extracellular fluid excluding plasma) are about half those in plasma (Peltonen and Sankari, 2011).

17.2.3.2 Albumin

Serum albumin is synthesized in the liver (chicken: Fujii et al., 1996). The functions of albumin include providing a colloidal osmotic effect and facilitating transport of nutrients and lipophilic hormones. For instance, albumin binds to, transports, and distributes lipids, including fatty acids.

In the presence of albumin, there is increased update of saturated fatty acids, such as palmitate, by chick embryo cardiac cells (Paris et al., 1978).

There are changes in the plasma concentrations of albumen during development with increases during late embryonic development and early chick life (Grieninger et al., 1986). Moreover, there are some changes in the plasma concentrations of albumin with physiological state. For instance, induction of early molt by reduced photoperiod and feed withdrawal for 48 h results in reductions in albumin concentrations in the plasma (chickens: Gildersleeve et al., 1983a). There are marked diurnal changes in plasma concentrations of albumin (chickens: Gildersleeve et al., 1983a). Moreover, plasma concentrations of albumin are decreased in laying females (Morgan, 1975). Administration of turpentine evokes an acute phase response with decreased plasma concentrations of albumin (chicken: Grieninger et al., 1986).

17.2.3.3 Globulins

There are multiple proteins in the globulin groupings. Broadly, globulins can be divided into three categories based on electrophoretic mobility:

- Alpha-globulins
  - α_1-globulin, including apolipoprotein A-1, which binds lipids (chickens: Roman et al., 2009), transcortin, and retinol binding protein
  - α_2-globulin including angiotensin (precursor of angiotensin I and II) and ceruloplasmin.
- Beta-globulins
  - β_1-globulin
  - β_1-globulin, including transferrin in mammals but not in birds.
- Gamma-globulin
  - Nonimmunoglobulin fraction containing transferrin in at least some birds (Torres-Medina et al., 1971). Fujii et al. (1996) and McKnight et al. (1980) reported that transferrin is expressed in the liver and oviduct, and it is secreted into the blood.
  - Immunoglobulins (Igs):
    - IgA
    - IgM
    - IgY (equivalent to IgG in mammals).

The structures of plasma proteins from avian species have been predicted from mRNA and cDNA sequencing including the following:

- Albumin [chicken (*Gallus gallus*): NCBI Reference Sequence: NM_205261.1]
- Alpha fetoprotein (chicken: NCBI Reference Sequence: XM_003641200.1)
- Ceruloplasmin [chicken: NCBI Reference Sequence: XM_001235148.2; turkey (*Meleagris gallopavo*): NCBI Reference Sequence: XM_003209288.1; zebra finch (*Taeniopygia guttata*): NCBI Reference Sequence: XM_002188284.2].
- Transferrin receptors (chicken: NCBI Reference Sequence: NM_205256.1).

Globulin concentrations are influenced by physiological state. For instance, induction of early molting, by reduced photoperiod and feed withdrawal, is followed by increases in the circulating concentrations of total globulin (chickens: Gildersleeve et al., 1983a). Serum concentrations of α_1-globulin decline during growth in male chickens (Peltonin and Sankari, 2011).

17.2.3.4 Specific proteins including vitamin and cation binding proteins

17.2.3.4.1 Ceruloplasmin

The principal circulating transporter protein that binds copper ions is ceruloplasmin. This glycoprotein is produced by the liver. Avian ceruloplasmin has been purified and partially characterized (chicken: Calabrese et al., 1988; Disilvestro and Harris, 1985; Hilewicz-Grabska et al., 1988). Chicken ceruloplasmin binds five atoms of copper per molecule (Calabrese et al., 1988).

Plasma concentrations of ceruloplasmin are influenced by physiological and nutritional status. Concentrations of ceruloplasmin are affected by copper status being depressed by copper deficiency (chicken: Baumgartner et al., 1978; Kaya et al., 2006) and elevated by dietary copper supplementation (chicken: Koh et al., 1996; Jarosz et al., 2018). Plasma concentrations of ceruloplasmin are also elevated acutely following injection of *Escherichia coli* endotoxin/lipopolysaccharide (LPS) (chicken: Curtis and Butler, 1980; Lin et al., 2006; Wang et al., 2016) and by glucocorticoids (chicken: Lin et al., 2004). Circulating concentrations of ceruloplasmin are depressed in birds receiving dietary supplementation with 5-aminolevulinic acid, a precursor for porphyrin and then heme (chicken: Sato et al., 2012).

17.2.3.4.2 Retinol-binding protein

Vitamin A is transported bound to retinol-binding protein (RBP) which can complex with prealbumin (chicken: Abe, 1975). The only circulating RBP is RBP 4 in birds (Yin et al., 2013). Avian RBP has been purified and its crystal structure characterized (chicken: Zanotti et al., 2001). Transthyretin also binds RBP (Eguchi et al., 2008).

The liver has the highest expression of RBP 4, but it is also expressed in the small intestine, ovary, kidney, and heart (chicken: Yin et al., 2013). Synthesis of RBP 4 by the liver is inhibited in vivo by vitamin E in the feed or in vitro by α-tocopherol in the incubation media (chicken: Zhou et al., 2012).

17.2.3.4.3 Transferrin

Transferrin transports iron (two molecules of iron for each molecule of transferrin) in the blood (reviewed Lambert et al., 2005) with, in turn, there being at least some of the transferrin bound to transferrin receptor. The circulating concentrations of iron are reported as ~2 μg/mL (Morgan, 1975). Iron bound to transferrin can be transferred to the other major iron-binding protein, the yolk precursor phosvitin (Morgan, 1975).

The structure of avian transferrin has been reported (chicken: Guha Thakurta et al., 2003; Lambert et al., 2005). In addition to transporting iron, transferrin facilitates the uptake of ferrous iron during development of erythrocytes (chick embryo blood cells: van Bockxmeer and Morgan, 1982). Transferrin also binds a circulating enzyme, butyrylcholinesterase (chicken: Weitnauer et al., 1999).

Transferrin is synthesized by liver and secreted into the blood (chicken: Fujii et al., 1996). In birds, expression of the transferrin gene is restricted to the liver and oviduct (McKnight et al., 1980). The chicken transferrin receptor has been characterized based on the cDNA (chicken: Gerhardt et al., 1991). The transferrin receptor can induce programmed cell death or apoptosis (chicken: Ohno et al., 2008).

The circulating concentrations of transferrin and the transferrin receptor are reported as respectively 2.4 mg/mL (Morgan, 1975) and 1.2 μg/mL (chicken: Wiwanitkit et al., 2007). Plasma transferrin receptor concentrations reflect erythropoietic activity.

There are effects of physiology on circulating concentrations of transferrin. Circulating concentrations of transferrin are elevated by either estrogen or iron deficiency (chicken: McKnight et al., 1980). Hepatic expression of transferrin increased by estrogen and glucocorticoids (chicken: McKnight et al., 1980). Plasma concentrations of transferrin are also increased in chickens with a *Staphylococcus aureus* infection (Chamanza et al., 1999). Similarly, there is a strong tendency for plasma concentrations of transferrin receptor to be increased in birds infected with *Plasmodium gallinaceum*, the protozoan that causes malaria in poultry (chicken: Wiwanitkit et al., 2007).

17.2.3.4.4 Proteins protecting against tissue damage from hemoglobin

When erythrocytes are lysed or the cell membrane is destablized, hemoglobin is released. In the absence of defense mechanisms, there is oxidation of lipids and proteins by the hemoglobin. The hemoglobin binding protein, haptoglobin, is part of the defensive mechanism in mammals and some avian species. Haptoglobin is absent from chickens where there is an alternative hemoglobin binding protein, PIT54 (Wicher and Fries, 2006). The structure of haptoglobin has been deduced from cDNA from multiple avian species [Infraclass: *Palaeognathae* e.g., emu (*Dromaius novaehollandiae*) XM_026104274; Infraclass: *Neognathae* Superorder *Neoaves* e.g., Anna's hummingbird (*Calypte anna*) Genbank Accession number XM_030458019.1; golden-collared manakin (*Manacus vitellinus*) XM_008927555.2; willow flycatcher (*Empidonax traillii*) XM_027904202; peregrine falcon (*Falco peregrinus*) XM_005235439; rock pigeon (*Columba livia*) XM_005504706 and Adelie penguin (*Pygoscelis adeliae*) XM_009335253].

In contrast, the haptoglobin gene appears to be missing in the Superorder *Galloanserae* (ducks, geese, chickens, turkeys, etc.). Haptoglobin like activity, as determined by its ability to prevent hemoglobin peroxidase activity, is increased in chickens challenged with infectious bronchitis virus infection as part of the acute phase response (Asasi et al., 2013). Another protective protein is hemopexin, an α_1-globulin and hemoglobin-binding protein (chicken: Grieninger et al., 1986). There is a 1000-fold increase in plasma concentrations of hemopexin beginning day 21 of embryonic development rising rapidly during early chick life (Grieninger et al., 1986). Moreover, administration of turpentine evokes an acute phase response with increased plasma concentrations of hemopexin.

17.2.3.4.5 Hormone binding proteins

Lipophilic hormones including the steroid hormones are transported in the plasma bound to proteins including albumin and specific binding proteins. The rationale for lipophilic hormones having binding proteins in the circulation is to facilitate the distribution of the hormones throughout their target organ(s) (Richardson et al., 2005).

17.2.3.4.6 Sex hormone–binding protein

While sex steroid–binding globulin is present in mammals [e.g., from Genbank: rat (*Rattus norvegicus*) NM_012650] and reptiles [e.g., from Genbank: Chinese alligator (*Alligator sinensis*) XM_025195189.1; green anole (*Anolis carolinensis*) XM_016998039], it is not present in birds (Wingfield et al., 1984; Breuner and Orchinik, 2009; Malisch and Breuner, 2010) with none recorded in Genbank.

17.2.3.4.7 Thyroid hormones/transthyretin

Homologs of mammalian thyroxine-binding globulin are not present in birds (Schreiber and Richardson, 1997). Thyroid hormones bind to both albumin (Schreiber and Richardson, 1997) and transthyretin in birds as in all other vertebrate classes (Schreiber and Richardson, 1997; Richardson et al., 2005). Avian transthyretin has been purified as a 15 KDa protein (chicken: Eguchi et al., 2008). In contrast with the situation with mammalian transthyretin, there is greater binding of T_3 than T_4 to avian transthyretin

[chicken: Duan et al., 1991; glaucous gull (*Larus hyperboreus*) and herring gull (*Larus argentatus*): Ucán-Marin et al., 2009, 2010]. Transthyretin also binds retinol binding protein (Eguchi et al., 2008).

17.2.3.4.8 Transcortin (corticosteroid bonding globulin)

Birds have a corticosteroid-binding globulin (CBG) or transcortin. This α1 globulin binds and transports corticosterone in the plasma, for example, in the American kestrel (Whitman et al., 2011), chicken (Murakami, 1991), white crowned sparrow (Breuner and Orchinik, 2009), and zebra finch (Schmidt et al., 2010). CBG has been characterized in birds (chicken and zebra finch: Vashchenko et al., 2016). Not only does CBG bind corticosterone, cortisol, and progesterone but also multiple androgens (dark-eyed juncos: Deviche et al., 2001; chicken and zebra finch: Vashchenko et al., 2016). Circulating concentrations of CBG are influenced by reproductive state (e.g., either testosterone treatment or breeding season in male dark-eyed juncos: Deviche et al., 2001) and stress (American kestrel: Whitman et al., 2011).

17.2.3.5 Gamma globulins

Gamma globulins include IgA, IgM, and IgY (equivalent to IgE and IgG in mammals). In growing chickens, the concentrations of Igs are the following:

- Immunoglobulin A (IgA): 0.3 g/L
- Immunoglobulin M (IgM): 2.7 g/L
- Immunoglobulin Y (IgY): 5.5 g/L

(based on Klasing 1998). The concentrations of IgY are markedly lower in laying hens (0.8 g/L) (Cetin et al., 2010) probably reflecting transfer into the yolk-filled oocyte.

In birds, there is transfer of Ig into eggs with, for instance, amounts being 99% of IgY in the yolk and less than 1% in the egg white (see Table 17.3) (chicken: Hamal et al., 2006). Yolk concentrations of IgY are 36% of those of plasma. In contrast, IgA and IgM are only about 5% of plasma concentrations. Chick embryos take up IgY via the yolk sac (see Table 17.3) (chicken: Hamal et al., 2006). This provides passive or maternal immunity. The hatched chicks have maternal antibodies in their circulation as is evident for the decline in plasma concentrations of IgY but not IgA or IgM in posthatching development (see Table 17.3) (chicken: Hamal et al., 2006). Moreover, vaccination of the dam results in important passive immunity to pathogens in the first weeks of life (e.g., Maas et al., 2011; Lardinois et al., 2014). Similarly, transfer of antibodies has been demonstrated in zebra finches (Martyka et al., 2011).

17.2.3.6 Enzymes

There are multiple enzymes in the plasmas of birds including the following: alkaline phosphatase, glutamic oxaloacetic transaminase (GOT), and lactic acid dehydrogenase (LDH) (also see above). The activities of aspartate aminotransferase and creatine phosphotransferase are most frequently determined in hematological studies. Circulating antioxidant enzymes include superoxide dismutase, catalase, and glutathione peroxidase.

The activity of enzymes is reported to be influenced by both physiology and the external environment. For instance, alanine transferase activity in venous plasma is elevated by either dehydration or hyperthermia (Arad et al., 1983). Histidine supplementation increased the activity of the antioxidant enzyme, glutathione peroxidase but decreased reactivity of superoxide dismutase in plasma (turkeys: Kopec et al., 2016). Induction of an early molt by

TABLE 17.3 Demonstration of transfer of maternal IgY but not IgA or IgM via the yolk.

	IgY	IgA	IgM
Plasma concentration (dam[a]) mg mL^{-1}	4.64	0.32	0.92
Egg total in mg (mg mL^{-1})			
Yolk	33.2 (1.70)	0.37 (0.02)	0.40 (0.02)
White	0.24 (0.01)	0.37 (0.01)	0.23 (0.01)
Chick plasma mg mL^{-1}			
Three days	1.25	0.00	0.01
Seven days	0.74	0.02	0.11
14 days	0.59	0.15	0.14
21 days	0.69	0.19	0.22

[a]*Broiler breeder hens.*
Calculated from Hamal et al. (2006).

reduced photoperiod and withdrawing feed results in changes in plasma activities of the following: glutamic pyruvic transaminase (decreased), alkaline phosphatase, LDH, and GOT (increased) (chickens: Gildersleeve et al., 1983a). Moreover, depressed plasma cholinesterase activity has been used as a biomarker for exposure to organophosphate pesticides (Santos et al., 2012). However, it is critically important to have a baseline for cholinesterase activity in plasma of the specific species (Santos et al., 2012).

17.2.3.7 Yolk precursors

The major yolk precursors are transported in the blood of the laying female bird and are the following:

- Vitellogenin
- Very low-density lipoprotein (VLDL).

Both vitellogenin and VLDL are synthesized in the liver with synthesis induced by estrogen (Deeley et al., 1975). In the circulation, VLDL has the following characteristics:

- Globular micelle-like
- Nonpolar core of triglycerides and cholesterol esters
- Coated with amphiphilic mix of phospholipid, free cholesterol, and apolipoprotein.

(reviewed Loh et al., 2011).

Vitellogenin and VLDL are transported across the oocyte cell membrane by a receptor-mediated process (chickens: Stifani et al., 1990). The half-life of VLDL in female turkeys is 5.05 h (Bacon, 1981). There is little variation in the circulating concentration of vitellogenin during the ovulation cycle of the hen (calculated from Redshaw and Follett, 1976). Within the oocyte, vitellogenin is cleaved to lipovitellin and phosvitin (Deeley et al., 1975).

17.3 Erythrocytes

Table 17.4 summarizes multiple erythrocyte characteristics including number, hematocrit, and erythrocyte size in wild birds and adult poultry. The percentage of plasma trapped in formed elements in hematocrit is estimates as 1.7% (Brahm and Wieth, 1977).

17.3.1 Structure of the erythrocyte

Unlike mammalian erythrocytes, avian erythrocytes have nuclei and other intracellular organelles such as mitochondria (e.g., Stier et al., 2013, 2014). Avian erythrocytes exhibit lower permeability to urea than mammalian erythrocytes (Brahm and Wieth, 1977).

Avian erythrocytes are ovoid cells (Figure 17.1) with an average volume of 145 fL across multiple avian species with consistent sizes (Scanes, 2015) (Table 17.4):

- Long diameter: ~ 12.5 μm
- Short diameter: 6.8 μm
- Thickness: 3.2 μm.

The volume of erythrocytes declines during the development from 170 fL at day 10−140 fL at day 18 (chicken: Tazawa et al., 2011). There is marked asymmetry, with a ratio of erythrocyte length to width of 1.7 in chickens and 1.8 in wild birds. The surface area of chicken erythrocytes was reported as 149 μm^2 (Bulliman and Kuchel, 1988).

TABLE 17.4 Characteristics of erythrocytes in wild birds (excluding poultry species) and chickens.

Parameter	Wild birds		Chickens[a]	Units
	Number of species	Data		
PCV[b]/Hematocrit	158	44.0	44.0	%
Hemoglobin	134	14.5	10.1	%
Erythrocytes				
Concentration	164	3.33	3.2	$10^6\ \mu L^{-1}$ or $10^6\ mm^{-3}$
Volume	81	149.6	149.4	fL
Length	364	12.5	12.2	μM
Width	362	6.8	7.1	μM
Ratio of length to width	362	1.844	1.718	
Cross-sectional area[c]	362	68.3	68.0	μM[b]
Hemoglobin amount	23	50.8	32.0	fg

(B) Electron microscopy of chicken bone marrow cells showing developing erythrocytes with electron dense hemoglobin (bar 5 μm). *Reproduced from Shini et al. (2008).*

17.3.1.1 Nucleus

There is a centrally located nucleus (long diameter ~6.5 μm, short diameter ~2.8 μm). The avian erythrocyte differs from that in mammals by the presence of a nucleus and mitochondria and by being larger. The most abundant protein is hemoglobin (Figure 17.1). Nuclear abnormalities such as micronuclei, nuclear buds, notched nuclei, binucleated cells, nuclear tails, and nucleoplasmic bridges are observed in avian erythrocytes (Quero et al., 2016). Erythrocytes of wild birds contain more hemoglobin than those of chickens (Table 17.4). The nuclei of avian erythrocytes contain hemoglobin (Davis, 1961). This is contiguous with cytoplasmic hemoglobin via pores in the nucleus membrane (Davis, 1961).

17.3.1.2 Plasma and nuclear membranes

There is a similar surface area for the plasma and nuclear membranes per cell (Zentgraf et al., 1971). The structures of the plasma and nuclear membranes of chicken erythrocytes have been investigated. Water permeability of avian erythrocytes was reported as 1.35 cm/s (Brahm and Wieth, 1977).

17.3.1.2.1 Lipid composition

Plasma and nuclear membranes differ in composition (see Table 17.5). The fatty acid composition of the cell membrane of avian erythrocytes is modified in the diet (e.g., cockatiel—Heinze et al., 2012). The plasma membrane contains ATPase (Zentgraf et al., 1971) including Na^+/K^+ ATPase (Watts and Wheeler, 1978) and Ca^{2+}-ATPase (Alves-Ferreira et al., 1999; Li et al., 2011) while the nuclear membrane contains lamin B receptor (Simos et al., 1996). The osmotic fragility of avian erythrocytes is reduced by the flavonoid, fisetin (Ogbuagu et al., 2018).

17.3.1.2.2 Carbohydrates in the erythrocyte plasma membrane

N-glycans on the surface of avian erythrocytes have been characterized (chicken: Aich et al., 2011).

17.3.1.2.3 Proteins in the erythrocyte plasma membrane

There are multiple proteins in the plasma membrane of birds including class I molecules. Expression of class I molecules varies markedly in chicken erythrocytes by different chicken MHC haplotypes (Tregaskes et al., 2016). There are also receptors in the erythrocyte plasma membrane. Peptides representing variants of a putative hemagglutination motif bind to a sialylated receptors on avian erythrocytes plasma membranes (chicken: May et al., 2014). Desialylated erythrocyte membranes show much reduced binding of these peptides (May et al., 2014).

17.3.1.3 Microtubules

Microtubules stabilize the asymmetric structure of erythrocytes (Winckler and Solomon, 1991). They are composed of tubulin, with 95% of the tubulin from chicken erythrocytes being tubulin-βVI (Sharma et al., 2010). The erythrocyte anion transport protein (erythrocyte band 3) is the major transport protein in the erythrocyte. It has two functions:

- An anchor for the intracellular cytoskeleton
- The key anion transporter exchanging bicarbonate (HCO_3^-) for chloride (Cl^-) ions.

TABLE 17.5 Lipid composition of cell membranes of avian erythrocytes.

Lipids[a]	Lipid composition of chicken (pigeon) erythrocyte membranes	
	Plasma membrane	Nuclear membrane
Cholesterol	1.04	0.42
Cholesterol esters	0.02	0.11
Phospholipids	1.00	1.00
• Phosphatidylcholine	0.30 (0.33)	0.53
• Phosphatidylethanolamine	0.31 (0.30)	0.26
• Sphingomyelin	… 0.31 (0.19)	0.13
• Phosphatidylinositol	0.04 (0.04)	0.07

[a]*Data are expressed as a molar ratio relative to total phospholipids.*
Data from Kleinig et al. (1971), Watts and Wheeler (1978).

17.3.1.4 Mitochondria

Mitochondria have been demonstrated to be present in erythrocytes by transmission electron microscopy (e.g., zebra finch: Stier et al., 2013, 2014). The mitochondria are functional producing the reactive oxygen species (ROS) and mitochondrial superoxide (zebra finch: Stier et al., 2013).

17.3.2 Erythrocyte chromatin and transcription

Chromatin is composed of DNA with associated proteins. The chromatin structure is critical in the control of DNA replication, repair, and transcription. It is reasonable to conclude that the chromatin is in a decondensed state (Morera et al., 2011). The 30-nm fiber is the "first hierarchical level of chromatin folding" allows transcription and access by regulatory factors but not DNA replication in chicken erythrocytes (Scheffer et al., 2011). There are also strong associations between linker histones and chromatin in chicken erythrocyte nuclei (Koutzamani et al., 2002). The histones associated with the DNA in the nuclei within avian erythrocytes can undergo post-translational modification including acetylation, formylation, phosphorylation, and oxidation (Sarg et al., 2015; Jahan et al., 2016). This influences expression of specific genes.

17.3.2.1 Transcription and translation

There is both transcription and translation in avian erythrocytes (e.g., chicken: Morera et al., 2011; St. Paul et al., 2013). The ratio of RNA to hemoglobin decreases rapidly in a linear manner from about 240 μg per mg on day 3−35 μg per mg at day 6 (chicken: Baumann et al., 2003). Subsequently, the ratio of RNA to hemoglobin declines at a much slower rate to less than 10 μg per mg at day 17 (chicken: Baumann et al., 2003). There are large reductions in the erythrocyte ATP content decreasing from a molar ratio of RNA to Hb from 6.8 (day 3) to 0.5 (day 17) (chicken: Baumann et al., 2003).

Avian erythrocytes have also been demonstrated to express innate immune system genes including toll-like receptor (TLR) 2, 3, 4, 5, 9, and 21 together with type 1 interferon (IFN), myxovirus resistance 1, and interleukin (IL)-8 (Morera et al., 2011; St. Paul et al., 2013). Expression in antimicrobials influenced after infection with Marek's disease virus (AvBD2, 4, 7 ↑; AvBD1, 6, 9 ↓) (Niu et al., 2018). Selenium deficiency influenced the expression of 24 selenoproteins and 10 cytokines (chicken: Luan et al., 2016).

17.3.2.2 Stress and erythrocyte DNA

Stress increases DNA damage in avian erythrocytes with this correlating with both plasma concentrations of corticosterone (captivity in house sparrows: Gormally et al., 2019). Oxidative damage to DNA is reported in erythrocytes from birds (European starling Nettle et al., 2017). Stress has also been reported to influence both methylation and hydroxymethylation of specific genes in the avian erythrocytes (Pértille et al., 2017).

17.3.2.3 Telomeres

Telomeres protect the ends of chromosomes. The length of telomeres decreases with age in multiple species with telomere rate of change being a predictor of lifespan (Tricola et al., 2018). There are exceptions with the decrease in telomere with age not being seen in all birds, e.g., great spotted cuckoos (Soler et al., 2015).

17.3.3 Metabolism of erythrocytes

Surprisingly, metabolism and expression of metabolic enzymes in avian erythrocyte has received relatively little attention. It has been assumed that glucose is the major substrate for energy needs of the erythrocyte. However, glucose failed to maintain erythrocyte ATP in vitro (chicken: Mathew et al., 1993). In contrast, glutamine was effective (chicken: Mathew et al., 1993). Moreover, chicken erythrocytes can employ glycine as a substrate (Dajani and Orten, 1959).

There is evidence that the avian erythrocyte employs the citric acid cycle based on older literature (chicken: Dajani and Orten, 1958). However, there was no detectable activity of TCA cycle enzymes in the pigeon erythrocyte (Kalomenopoulou and Beis, 1990). Metabolic enzymes activities (including the following hexokinase, phosphofructokinase, and pyruvate kinase) are reported in pigeon erythrocytes (Kalomenopoulou and Beis, 1990). High activities for the following enzymes have been reported for erythrocytes from the little penguin (*Eudyptula minor*): triphosphate isomerase, lactate dehydrogenase, glyceraldehyde phosphate dehydrogenase, and phosphoglycerate kinase (Nicol et al., 1988). In the little penguin (*Eudyptula minor*) erythrocytes, about half glucose is metabolized to lactate (Nicol et al., 1988).

Erythrocytes have a high concentration of ATP in early embryonic development e.g., 15 mmol per liter at day three of incubation (chicken: Baumann et al., 2003). Erythrocytes from chick embryos also have significant levels of CTP and UTP (chicken: Baumann et al., 2003). In addition, erythrocytes from chick embryos contain another high-energy compound, 2,3-bisphosphoglycerate (2,3-BPG) (chicken: Baumann et al., 2003). In vitro, ATP concentrations are depressed by hypoxia in erythrocytes from 10-day embryos (chicken: Baumann et al., 2003).

17.3.3.1 Mitochondrial functioning in avian erythrocytes

Mitochondria are not only present in erythrocytes (e.g., zebra finch: Stier et al., 2013) but also exhibit both oxygen consumption together with both basal production of superoxide and elevated superoxide production in the presence of antimycin (Stier et al., 2013).

The important mitochondrial inner membrane phospholipid, cardiolipin, is found in erythrocytes from 21 species of birds from the orders *Accipriformes*, *Anseriformes*, *Columbiformes*, *Faconiformes*, *Galliformes*, *Passeriformes*, and *Strigiformes* (Delhaye et al., 2016). Interestingly, longevity of avian species was reported to be related to both production of ROS by erythrocyte mitochondria and to mitochondrial cardiolipin content (Montgomery et al., 2012; Delhaye et al., 2016).

17.3.3.2 Enzymes in erythrocytes

Antioxidant enzymes are present in erythrocytes. Histidine supplementation decreased the activity of the antioxidant enzyme, superoxide dismutase in erythrocytes (turkeys: Kopec et al., 2016).

17.3.4 Number of avian erythrocytes and packed cell volume

There are physiological effects on both hematocrit and erythrocyte concentrations. These are, for instance, reduced from prior to breeding to egg production (zebra finches: Wagner et al., 2008). Cobalt increases erythrocyte numbers and can cause polycythemia (Diaz et al., 1994). Fair et al. (2007) concluded that hematocrits were greater in adult than immature or nestling birds. In contrast, there was no difference in the hematocrit between males and female birds based on a meta-analysis of 36 studies of wild bird species (Fair et al., 2007). Erythrocyte numbers were greater in January in Belize prior to migration than in summer in Connecticut (gray catbirds: Booth and Elliott, 2003). Similarly, hematocrit was greater in migratory than sedentary Passerine species (Pistone et al., 2017).

Table 17.4 summarizes the mean packed cell volume (hematocrit) and erythrocyte concentrations across multiple avian species and a comparison with earlier data in chickens. Across avian species, hematocrit is inversely proportional to $\log_{10}$ body weight declining from 52% on average in birds at 10 g to 40% in birds at 1 kg (Bishop and Butler, 1995). When erythrocytes are removed, the hematocrit declines as the plasma volume is more rapidly restored. Following removal of 30% of the blood, there is an almost immediate decrease in hematocrit and erythrocyte concentration (Japanese quail: Schindler et al., 1987).

When oxygen partial pressure is low, there is an increase in erythrocyte concentrations and hematocrit. For instance, hypoxia increases hematocrit (Japanese quail: Rosse and Waldmann, 1966; chickens: Maxwell et al., 1987). Similarly following removal of 30% of the blood and the immediate decrease in erythrocyte concentration, there is then a rapid recovery with 72 h (Japanese quail: Schindler et al., 1987). Indicative of the acceleration of erythropoiesis, there are parallel increases in the number of immature red blood cells, namely reticulocytes, in the blood and bone marrow (Japanese quail: Gildersleeve et al., 1985a,b; Schindler et al., 1987). In an analogous manner, erythropoiesis is depressed in polycythemic birds (Japanese quail: Rosse and Waldmann, 1966).

There are marked increases in the concentration of erythrocytes during embryonic development (chicken: Tazawa et al., 2011). These changes are illustrated in Figure 17.2. As might be expected, the concentration of erythrocytes is increased in response to high altitude

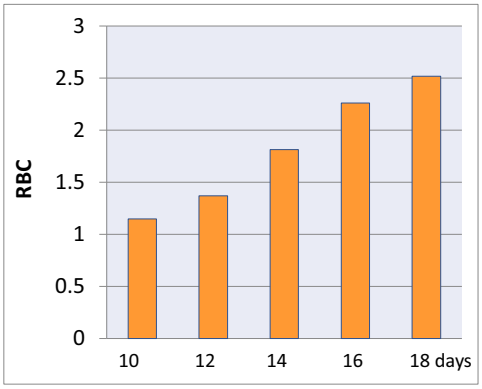

FIGURE 17.2 Changes in erythrocyte numbers (number × 10^6 per µl) during embryonic development of the chicken. *Data from Tazawa et al. (2011).*

(e.g., turkey embryos: Bagley et al., 1990). Similarly, and not unexpectedly, hematocrit is reduced with copper deficiency (chicken: Baumgartner et al., 1978). In chickens, there appears to be a sex difference in hematocrit and erythrocyte number between breeding males and females (Table 17.6), presumably due to the high concentrations of yolk precursors in the plasma.

There are also decreases in erythrocyte concentrations by some toxicants, e.g., following *in ovo* administration of 1-(2-chlorophenyl)-1-(4-chlorophenyl)-2,2,2-trichloroethane o,p'-DDT (Japanese quail: Bryan et al., 1989), chemicals such as acetophenylhydrazine and the organophosphorus pesticide, foschlor, reduce the circulating concentration of erythrocytes, inducing anemia in chickens (Coll and Ingram, 1978; Gromysz-Kałkowska et al., 1985). Moreover, petroleum oil decreases packed cell volume (mallard ducks: Lee et al., 2012). Some chemicals such as acetophenylhydrazine and foschlor reduce the circulating concentration of erythrocytes, inducing anemia in chickens (Coll and Ingram, 1978; Gromysz-Kałkowska et al., 1985). Similarly, hematocrit is depressed in seabirds from sites contaminated with petroleum oil (Fallon et al., 2018).

17.3.5 Production

Avian erythrocytes are produced in the bone marrow. In vitro, embryonic bone marrow cells have been demonstrated as capable of developing into erythrocytes (e.g., Japanese quail: Brandon et al., 2000).

The avian erythrocyte series can be summarized as follows:

- Erythroblasts (cell proliferation) →
- Polychromatic erythroblasts (reduce cell volume with hemoglobin synthesis initiated) → Reticulocytes (further reduce cell volume with hemoglobin synthesis) →
- Mature erythrocytes

(based on Williams, 1972).

17.3.6 Erythropoietin

Evidence for an avian erythropoietin (EPO) comes from the ability of chicken plasma to stimulate heme accumulation in chicken erythroid cells in vitro with plasma from anemic chickens being more effective (Coll and Ingram, 1978). Moreover, in vivo the rate of erythropoiesis changes in a manner consistent with control by EPO; being increased in anemia (chicken: Rosse and Waldmann, 1966) and depressed by polycythemia (Japanese quail: Rosse and Waldmann, 1966). During development of bone air sacs in the bones of posthatching pigeons, there are decreases in hemopoietic bone marrow as a percentage of body weight and increased distribution in ulna, radius, femur, tibiotarsus, scapula, furcula, and the caudal vertebrae (Schepelmann, 1990).

The structure of avian EPO has been deduced from cDNA [e.g., budgerigar (*Melopsittacus undulatus*)—XM_034073494.1; chicken (*Gallus gallus*)—KR063574.1; kakapo (*Strigops habroptila*)—XM_030474553.2; kiwi (*Apteryx rowi*)—XM_026063843.1; Swainson's thrush (*Catharus ustulatus*)—XM_033084268.1; Tibetan groundtit (*Pseudopodoces humilis*)—XM_014262263.1; wire-tailed manakin (*Pipra filicauda*)—Genbank XM_027712402; Zebra finch (*Taeniopygia guttata*)—XM_032745377].

EPO acts by binding to the EPO receptor (EpoR). The structures of the EpoR have been deduced (chicken: Hron et al., 2015). There is increased proliferation of avian erythroblasts with over-expression of EpoR (Mikulits et al., 2000). Moreover, iron repression of ferritin heavy chain expression is prevented by over-expression of both EpoR and c-Kit, another cytokine growth factor receptor (Mikulits et al., 2000).

TABLE 17.6 Comparison of erythrocyte concentrations and hematocrit in male and female chickens.

Gender of reproductively mature chickens	Erythrocyte concentration 10^6 µL^{-1} or 10^6 mm^{-3}	PCV/Hematocrit %
Male (rooster)	3.6	42.9
Females (laying hen)	2.8	29.8

17.3.7 Lifespan

Despite having a nucleus, avian erythrocytes do not divide failing to enter a new S phase (Williams, 1972). Bird erythrocytes have a very limited lifespan that is much less than in mammals (e.g., Brace and Atland, 1956; reviewed Beuchat and Chong, 1998) with all labeled cells disappearing in 42 days (ducks), 35 days (chickens—*Gallus gallus*) and 48 days (pigeons—*Columba livia*) (Rodman et al., 1957) and a mean survival time of 34 days in the (Japanese quail *Coturnix coturnix*: Nirmallan and Robinson, 1973).

The lifespan of avian erythrocytes is calculated as mean = 39.7 + (n = 4 species) S.E.M. 3.3 days. In contrast, the longevity of mammalian erythrocytes is longer at 85.6 + (n = 11 species) S.E.M. 10.5 days (Calculated from Röhme, 1981).

17.3.8 Hemoglobin

Hemoglobin binds to oxygen at the lungs and releases oxygen at the tissues. Avian hemoglobin has been purified (Chicken: Matsuda and Takae, 1963), crystallized, and characterized including X-ray analysis (e.g., bar-headed goose: greylag goose: Liang et al., 2001; ostrich: Sundaresan et al., 2009). As with mammals, hemoglobin is a tetrameric protein with four heme units. There are two α-globin and two β-globin together with four heme units, each containing ferrous iron ions in each hemoglobin molecule.

The molecular basis of the greater oxygen affinity and a lower Bohr effect of early embryonic hemoglobin has been established (Chapman et al., 1980). ATP and other nucleotides major determinants of oxygen saturation (chicken: Baumann et al., 2003).

There are multiple forms of avian hemoglobin with six forms in the chicken, four embryonic and two in the adult:

Embryo

Major forms

- Hb P with π α globin and ρ β
- Hb P′

Minor forms

- Hb M α^D globin
- Hb E α^A globin

Adult

Major form

- Hb A α^A globin

Minor form

- Hb D α^D globin

In the chicken, the relative contribution of two major embryonic hemoglobins peaks at four days of embryonic development and then decreases gradually. They are no longer detectable from 15 days. The two minor ones increase up to 6–7 days and then decrease but are still present in the blood at hatching (Cirotto et al., 1975). The shifts in composition of composition of α globin in chick embryo blood are summarized in Figure 17.3. During development, there are switches in which globin genes are expressed with for instance inactivation/silencing of the π gene for early embryonic hemoglobin in adult erythroblasts (chicken: Rincón-Arano et al., 2009; Ioudinkova et al., 2011) with methylation of the promoter region of the gene (chicken: Singal et al., 2002).

Inositol hexaphosphate and 2,3-BGP bind to a specific binding site in both oxygenated and deoxygenated avian

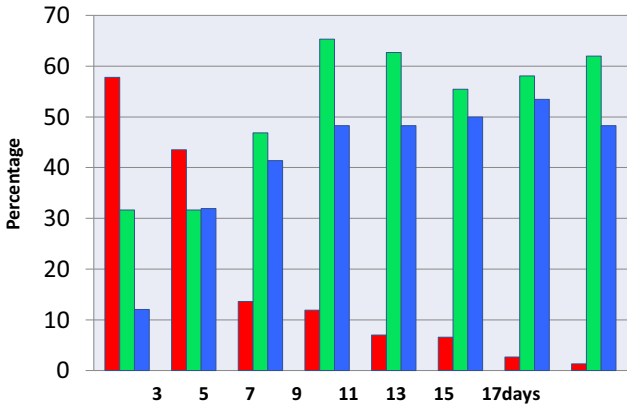

FIGURE 17.3 **Shifts in the proportion of α globins during embryonic development of the chicken (red π α globin, green α A globin, and blue α D globin).**

hemoglobin (chicken: Brygier et al., 1975). The binding of oxygen to hemoglobin is markedly affected by organic phosphates in the avian erythrocyte. In most birds, it is thought that the major regulator is inositol pentaphosphate, but in ostriches, there is evidence that inositol tetrakisphosphate (inositol-P_4) plays a critical role (Sundaresan et al., 2009). Inositol hexakisphosphate (inositol P_6) decreases the affinity of chicken or pigeon hemoglobin for oxygen (Vandecasserie et al., 1971). Similarly, inositol-P_5 lowers the oxygen affinity of hemoglobin (Isaacks et al., 1977).

Arteriovenous differences in the blood concentration of oxygen are constant in either resting or exercising birds being independent of body mass (Bishop and Butler, 1995).

17.3.8.1 Hemoglobin genes

In birds as in mammals, there are multiple hemoglobin genes: seven in the chicken (Reitman et al., 1993) and six in the zebra finch (Alev et al., 2009). These represent a small family of genes encoding α and β globins. The avian hemoglobin genes can be summarized as follows:

- Chicken π (Pi) α—homologous to duck π and orthologous to α1 in zebra finch
- Chicken α D—homologous to turkey, ostrich quail α D and orthologous to α2 in zebra finch
- Chicken α A—homologous to turkey, ostrich quail α A and orthologous to α3 in zebra finch
- Chicken ρ (Rho or P) β—possibly orthologous to β1 in zebra finch
- Chicken βH—possibly orthologous to β2 in zebra finch
- Chicken βA—homologous to turkey, duck, flamingo, condor, macaw, pigeon, and ostrich β major and orthologous to β3 in zebra finch
- Chicken β ε (Epsilon or E) with marked homologies to chicken ρ.

In adult zebra finches, hemoglobin consists of 74% α3 and 26% α2 and all β3 globin while in the embryo, hemoglobin consists of 28% α1, 55% α2, 16% α3, and 44% β1, 33% β2, and 24% β3 (Alev et al., 2009).

The α globin genes are located on chromosome 14 in the chicken. In embryonic erythrocytes, the region containing the α globin genes is located in a crown of DNA loops surrounding the nuclear matrix (Iarovaia et al., 2009).

17.3.8.2 Adaptations of hemoglobin to flight at high altitudes

The structures of hemoglobin in birds that fly at high altitudes have increased affinity for oxygen (see Figure 17.4). For instance, there are subtle changes to the protein structure (single substitutions in α globin) in both the bar-headed goose, a species that migrates across the Himalayas and the Andean goose (Jessen et al., 1991). Similarly, the oxygen affinity of hemoglobin in driving birds such as emperor penguins is increased (Meir and Ponganis, 2009). This can be readily seen from the left shift in the O_2—Hb dissociation curve for the bar-headed goose and the emperor penguin compared with the domestic duck (and most other birds) (see Figure 17.4).

17.3.8.3 Glycation of hemoglobin

Despite elevated circulating concentrations of glucose, the percentage of hemoglobin that is glycated is lower in most birds examined than in mammals, for example, <2% in rooks (*Corvus frugilegus*) and mute swans (*Cygnus olor*) (Miksik and Hodný, 1992; also reviewed: Beuchat and

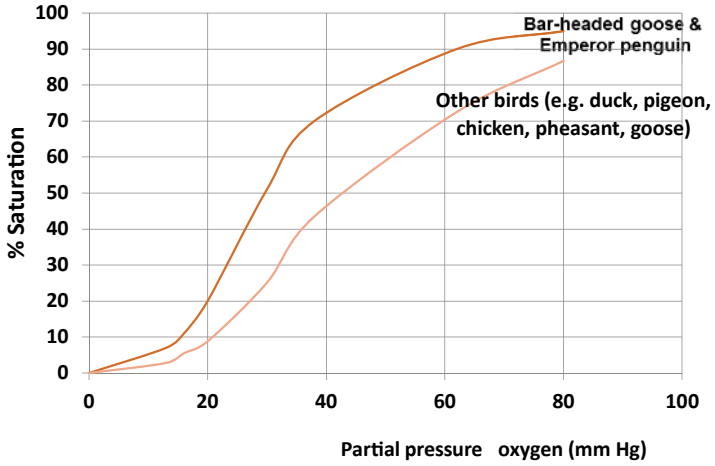

FIGURE 17.4 Oxygen dissociation curves for hemoglobin in avian erythrocytes. Data for calculated pigeon, domestic ducks and geese, Mucovy duck, chicken and red-necked pheasant from Christensen and Dill (1935) and for domestic goose, bar-headed geese and emperor penguins from Meir and Ponganis (2009).

Chong, 1998). Even in hummingbirds where plasma concentrations of glucose can be over 40 mmol/L, glycated hemoglobin is within the mammalian range (3.5–5.0) (Beuchat and Chong, 1998).

17.3.8.4 Hemoglobin and nutrition

In birds as might be expected, with low-iron availability, circulating concentrations of hemoglobin are reduced. Chickens together with the stable isotope ^{58}Fe have been proposed as a model for investigating iron availability (Tako et al., 2010).

17.3.9 Carbonic anhydrase

Carbonic anhydrase in erythrocytes catalyzes the reaction between carbon dioxide and water to yield carbonic acid. This in turn forms bicarbonate (HCO_3^-) and protons (H^+) reversibly.

$$CO_2 + H_2O \leftrightarrow H_2CO_3 \leftrightarrow HCO_3^- + H^+$$

Carbonic anhydrate (CA, EC 4.2.1.1) has been purified from avian erythrocytes (e.g., chicken: Bernstein and Schraer, 1972; ostrich: Ozensoy et al., 2005; pigeon: Ozensoy et al., 2011). Carbonic anhydrase activity is increased by β adrenergic agonists based on studies with Japanese quail erythrocytes (Igbo et al., 1994). Moreover, hypoxia increases carbonic anhydrase activity in avian erythrocytes (Glombitza et al., 1996).

There are increases in the amount of carbonic anhydrase II (CAII) and the isoenzyme CAIII relative to hemoglobin as female chickens commences egg production (Nishita et al., 2011a,b). Ferrous iron increases the activity of carbonic anhydrase from avian erythrocytes (Wu et al., 2007).

17.3.9.1 Intracellular pH

The intracellular pH in chicken erythrocytes is pH 7.219 (Kozma et al., 1995; Richardson and Swietach, 2016).

17.3.10 Transporters in erythrocyte plasma membrane

17.3.10.1 Anion transporter

The key anion transporter exchanges bicarbonate (HCO_3^-) for chloride (Cl^-) ions. The transcripts for the anion transporter have been characterized in the chicken with chicken erythroid cells having been demonstrated to express anion transport proteins (band 3) (Kim et al., 1988). The v-erbA oncogene suppresses expression of anion transport proteins (band 3) by chicken erythroid cells (Zenke et al., 1988). There are oxygen-sensitive membrane transporters in avian erythrocytes (Gibson et al., 2000). Another plasma membrane protein in the turkey erythrocyte is goblin, which is phosphorylated in the presence of β-adrenergic agonists (Alper et al., 1980).

17.3.10.2 Sodium and potassium transport

There is considerable movement of sodium (Na^+) and potassium (K^+) across the erythrocyte plasma membrane. The flux of sodium ions across the plasma membrane of erythrocytes from turkeys is two- to threefold that in humans (Palfrey and Greengard, 1981). The $Na^+/K^+/2Cl^-$ cotransporter in avian erythrocytes exhibits sensitivity to β-adrenergic agonists and to oxygen concentrations (reviewed in Gibson et al., 2000). Transport of potassium into chicken erythrocytes declines with age (Drew et al., 2002).

17.3.11 Glucose

Glucose entry into avian erythrocytes is low, being both nonsaturable and saturable carrier mediated; it can be inhibited by cytochalasin (Simons, 1983a,b). The 3-0-methylglucose uptake by pigeon erythrocytes that can be inhibited by cytochalasin B is low as there are only about 200 copies of the GLUT-1 protein per erythrocyte (compared to 300,000 in humans) (Diamond and Carruthers, 1993). Erythrocyte expression of GLUT-1 and GLUT-3 declines during differentiation of erythrocytes (Matthew et al., 1994).

17.3.11.1 Amino acids and urea

Amino acids are transported across the plasma membrane of the avian erythrocyte with uptake of glycine, leucine, and lysine being sodium dependent (Somes et al., 1981; Lerner et al., 1984). Lines of chickens have been selected with high and low amino acid transport phenotypes (Vargas and Devés, 2001; Angelo et al., 2005). Avian erythrocytes are reported to have little expression of urea-transporter-B (Liu et al., 2011).

17.3.12 Hormonal effect on erythrocytes

There are at least three β-adrenergic receptors in the cell membrane of the avian erythrocyte, namely βtrunc, β3C, and β4C-receptors (turkey: Chen et al., 1994; Baker, 2010). The turkey has been used as a model for β-adrenergic receptors. These are functional with β adrenergic receptor agonists increasing adenylate cyclase activity (Stadel et al., 1982; Peters et al., 1984). Avian β adrenergic receptors are desensitized by β adrenergic receptor agonists and sensitized by β adrenergic receptor antagonists due to structural changes (Stadel et al., 1982; Peters et al., 1984). The beta-adrenergic receptors on avian erythrocytes activate adenylate cyclase via G_s proteins (turkey: Ugur and Onaran, 1997).

Chick embryo erythrocytes have A2α adenosine receptors that also activate adenylate cyclase (Glombitza et al., 1996). There are progressive reductions in the erythrocyte responses to beta-adrenergic and A2 receptor agonists during embryonic development due to cGMP-inhibited phosphodiesterase 3 (Baumann et al., 1999).

At the beginning of second half of embryonic development, there is progressive hypoxia with release of norepinephrine. Carbonic anhydrase II activity and expression in embryonic avian erythrocytes is increased by norepinephrine, acting via β adrenergic receptors and cyclic adenosine monophosphate (cAMP) as the signal transducer (chicken: Dragon et al., 1996; Dragon and Baumann, 2001). In addition, cAMP increases 2,3-BPG (chicken: Dragon et al., 1996). Moreover, with hypoxia, erythrocyte ATP declines and oxygen affinity increases. There are similar effects of adenosine on avian erythrocytes acting via A_2 receptors and cAMP (white-tailed ptarmigan: Dragon et al., 1999; chicken: Glombitza et al., 1996; Dragon and Baumann, 2001). There is activation of Na^+-K^+-Cl^- co-transporters by cAMP leading to increases in avian erythrocyte volume (duck: Lytle, 1997).

There are multiple receptors to cytokines in the plasma membrane of avian erythrocyte. Receptors related to innate immunity are briefly covered in Section 17.3.11.

17.3.13 Effect of stressors of erythrocytes

There are, however, effects of stressors on the avian erythrocyte. For instance, exposure to crude oil is followed by degeneration of the erythrocyte mitochondria in herring gulls (*Larus argentatus*) and Atlantic puffins (*Fratercula arctica*) (Leighton, 1985). Avian erythrocytes exhibit marked increases in production of both hydrogen peroxide and super oxide in vitro in response to glucose or glucose 6-phosphate together with shifts in the oxygen dissociation curve for hemoglobin (Zhang et al., 2011). In contrast, the effects on either ROS or hemoglobin are not observed with mammalian red blood cells (Zhang et al., 2011). Similarly ROS are produced by mitochondria from avian erythrocyte for instance from quail or parrots (Montgomery et al., 2012). These effects may explain the shorter lifespan of avian erythrocytes (see above).

17.3.14 Avian erythrocytes and the innate immune system

Avian erythrocytes are part of the innate immune system. Chicken erythrocytes express transcripts including TLR 3, 9, and 21 and myxovirus resistance in a specific pathogen-associated molecular pattern (PAMP) manner as part of the innate immune response (Morera et al., 2011). In addition, not only do they express TLR and cytokines [IL-1γ, IL-2, IL-4, IL-6, IL-7, IL-8, IL-10, IL-12β, IFN-γ (Luan et al., 2016)] but also there is increased release of nitrite together with IL-8 after stimulation of TLR3 and of IFNs after stimulation of TLR21 (St. Paul et al., 2013). Chicken erythrocytes also express avian β-defensins (AvBDs) (AvBD1 to 7 together with AvBD9) and liver-expressed antimicrobial peptide-2 (Niu et al., 2018). Moreover, after activation by the opportunistic pathogenic yeast, *Candida albicans*, chicken erythrocytes release cytokines including IFN-gamma-like and migration inhibitory factor activities (Passantino et al., 2007). Another example of protective effects of avian erythrocytes is antifilm activity of histone from avian erythrocytes against *Staphylococcus aureus* (Rose-Martel et al., 2017).

17.4 Blood gases

Table 17.7 summarizes arterial and venous pO_2 in multiple species of resting birds. There is no change in arterial pO_2 during short-term (pigeon: Butler et al., 1977) or long-term flight (northern bald ibis: Bairlein et al., 2015). This is presumably due to the increased rate of respiration. Moreover, in chickens exercising on a treadmill, arterial pO_2 paradoxically increases (Gleeson and Blackenbury, 1984), again presumable due to increased respiration. In contrast, both arterial and venous pO_2 is decreased during a dive (Emperor penguin: Meir and Ponganis, 2009) and during the hypoxia resulting from high altitudes (Scott and Milsom, 2006). There are changes in pO_2 and pCO_2 during growth of chickens (Table 17.7). There is a decline in venous pO_2 during growth of meat-type (rapid growing) chickens, presumably reflecting the requirements of metabolism.

Arterial pCO_2 is influenced by respiration, particularly with panting. For instance, pCO_2 is reduced at elevated environmental temperatures (30°C) and exercise with the effect of exercise much greater at elevated temperatures (chickens running on a treadmill: Gleeson and Blackenbury, 1984). Moreover, pCO_2 is decreased in heat-stressed emus that are panting (Jones et al., 1983). However, venous pCO_2 is increased during the rapid growth phase (Table 17.8) and reduced during fasting in chickens (Christensen et al., 2012). It is reasonable to assume that these changes are due to shifts in metabolism.

17.5 Leukocytes

There are five types of leukocytes in birds:

- Heterophils (granulocyte or polymorphonuclear leukocytes)
- Lymphocytes
- Eosinophils (granulocyte or polymorphonuclear leukocytes)
- Monocytes
- Basophils (granulocyte or polymorphonuclear leukocytes).

Figure 17.6. shows the structure of avian leukocytes. Table 17.7 summarizes the concentrations of leukocytes and differential counts in both wild poultry and poultry. Klasing and colleagues estimated that chickens produce 0.76 g leukocytes per kilogram per day. Leukocytes are found in the "buffy" layer when the hematocrit of avian blood is being determined.

17.5.1 Number of leukocytes

There are physiological or pathological shifts in the circulating concentrations of leukocytes. For example, the blood concentration of leukocytes are almost half of adult levels in juvenile stork (white stork: Han et al., 2016). In addition, infecting chickens with *Plasmodium juxtanucleare* is followed by increase blood concentrations of leukocytes (Siveira et al., 2009). Similarly, there are increases in leukocyte concentrations with botulism (black-faced spoonbills: Chou et al., 2008) and following hypoxia (chickens: Maxwell et al., 1987). In contrast, leukocyte concentrations are depressed in captive compared to wild birds (Amazon parrots: Deem et al., 2005) and with mycotoxin ingestion (chickens: Andretta et al., 2012).

17.5.2 Heterophils

Heterophils are the functional equivalent of neutrophils in mammals (Harmon, 1998). There have been 78 proteins identified that are characteristic for heterophils (Sekelova et al., 2017). These include antibacterial proteins, calprotectin (MRP126), myeloid protein 1, Cathelicidin (CATHL)1, CATHL2, CATHL3, lysozyme G, lysozyme, and ribonuclease homolog (RSFR) (Sekelova et al., 2017).

17.5.2.1 Structure

Heterophils are polymorphonuclear leukocytes (Figure 17.6). They have a diameter of 10−15 μm (Sturkie, 1986). Avian heterophils are weakly basophilic and pseudoeosinophilic, staining brilliant red with Wright's stain (Sturkie, 1986). Based on electron microscopy studies, avian heterophils have the following structures:

- Nuclei with two or three lobes
- Sparse mitochondria
- Two types of granules
  - Dense oval or spherical granules with diameters between 0.4 and 1.8 μm
  - Less dense granules.

(ducks and geese: Maxwell, 1973).

Stressors such as corticosterone or LPS influence heterophil structure with reduced cross-sectional area and increased granule diameter (chickens: Shini et al., 2008).

17.5.2.2 Function

Heterophils play an important role in innate immunity with the following actions:

- Phagocytizing bacteria
- Attracting lymphocytes
- Releasing antimicrobial peptides
- Killing pathogens by oxidative bursts
- Exerting acute inflammatory responses

(reviewed Harmon, 1998).

17.5.2.2.1 Heterophils and phagocytosis

Heterophils are the major phagocytic leukocytes in birds (reviewed Harmon, 1998). Avian heterophils exhibit a superior ability to both phagocytize and kill bacteria than that of monocytes (Stabler et al., 1994). Moreover, phagocytosis is enhanced by opsonization of bacteria (Stabler et al., 1994). The phagocytic activity of heterophils is increased following priming with IFN γ (chicken: Kogut et al., 2005) or interleukin (IL)-2 (chicken: Kogut et al., 2002, 2003). The phagocytic activity of avian heterophils is influenced by both internal and external factors. For instance, avian heterophils show decreased phagocytic activity with age (ring dove: Terrón et al., 2004) and after feeding aflatoxin (chicken: Chang and Hamilton, 1979a).

Chicken heterophils that are infected with bacteria attract lymphocytes (Lam, 2002). Avian heterophils release superoxide (chicken and turkey: Stabler et al., 1994). Heterophils produce reactive oxygen following agonists

bind to Dectin-1; this latter being pattern recognition receptors for exogenous β-glucan (found on bacterial cell walls) (chicken: Nerren and Kogut, 2009). Activation of heterophils by ligand binding to TLR2 and TLR4 is followed by oxidative bursts (Guriec et al., 2018).

17.5.2.2.2 Heterophils and cytokines

Activation of heterophils include degranulation, and marked increased transcription of the proinflammatory cytokines, IL1β, IFNα, and IFNγ, together with some increase in IL8 and IL18 expression (Guriec et al., 2018). Binding of agonists to TLR2 (e.g., PAMPs) and TLR4 (LPS) activate heterophils while antagonists to TLR2 and TLR4 reduce heterophil activation (Guriec et al., 2018). Heterophils express activating triggering receptor expressed on myeloid cells (TREM) A (chicken: Viertlboeck et al., 2013).

17.5.2.2.3 Heterophils and antimicrobial peptides

Avian heterophils produce host antimicrobial peptides, specifically β-defensins, for instance, chicken heterophil peptide (CHP) 1 and CHP 2 (Sugiarto and Yu, 2004). Other antibacterial proteins produced by avian heterophils include calprotectin (MRP126), myeloid protein 1, cathelicidin (CATHL)1, CATHL2, CATHL3, lysozymeG, lysozyme, and RSFR (chicken: Sekelova et al., 2017). Both defensins and cathelicidins are highly cationic and antimicrobial.

There have been changes in the number of cathelicidins during avian evolution. The *CATHL1* gene has been duplicated in galliform birds. In contrast, the *CATHL2* gene is lost in birds of the orders *Sphenisciformes* and *Ciconiiformes*. In addition, the *CATHL1* gene is a pseudogene in falconiform birds and lost from birds in the orders *Passeriformes*, *Sphenisciformes*, and *Ciconiiformes* (Cheng et al., 2015).

17.5.2.2.4 Toll-like receptors and heterophils

Chicken heterophils express TLR1 type 1, TLR1 type 2, TLR1 type 3, TLR1 type 4, TLR2, TLR3, TLR4, TLR5, TLR7, TLR21, and TLR21 (Kogut et al., 2012). These can be activated by specific TLR agonists and bacteria (Farnell et al., 2003). Moreover, expression of TLR4 and TLR15 is up-regulated after *Eimeria tenella* challenge (Zhou et al., 2013).

17.5.2.2.5 Stressors and heterophil functioning

Stressors influence heterophil functioning. For instance, the magnitude of the oxidative bursts from heterophils is increased following stress (transportation in turkeys: Huff et al., 2010).

17.5.2.3 Number

Heterophils numbers in the blood are influenced by stressors with corticosterone increasing heterophil concentrations (chickens: Gross and Siegel, 1983) (Figure 17.7). Increases in the concentration of heterophils have been reported after the following stresses: hypoxia (exposure to low partial pressure of oxygen in chickens: Maxwell et al., 1987; removal of 30% blood in Japanese quail: Schindler et al., 1987), heat stress (chickens: Atlan et al., 2000), handling and transportation (Amazon parrots: McRee et al., 2018), and pesticide administration in Japanese quail (paraquat: Clark et al., 1988; chlorphenvinphos and foschlor: Gromysz-Kałkowski et al., 1985).

There is movement of heterophils out of the circulation into tissues. For instance, there are large increases in heterophils infiltrating the pulp of growing feathers injected with phytohemagglutinin-P (Sullivan and Erf, 2017). Heterophils accumulate in the peritoneal cavity in chickens that have been challenged i.p. with *Salmonella enteritis* (Kogut et al., 1995).

17.5.2.4 Production

Heterophils are produced in the bone marrow. In vitro embryonic bone marrow cells have been demonstrated to be capable of developing into heterophils (Japanese quail: Brandon et al., 2000).

17.5.3 Lymphocytes

Avian lymphocytes can be isolated using specific monoclonal antibodies. There are two types of B and T lymphocytes with B and T precursor cells developing, respectively, in the bursa Fabricius and thymus. The proportion of B and T lymphocytes in broiler chickens is the following:

- T type lymphocytes
  - $CD3^+$ 93.4%
  - $CD4^+$ $CD25^+$ 41.6%
  - $CD8^+$ $CD25^+$ 27.3%
- B type lymphocytes
  - $BU\text{-}1^+$ 19.3%
  - $BU\text{-}1^+$ MHC Class II^+ 2.7%

(broiler chicken: Jarosz et al., 2017). Chicken $CD4^+CD25^+$ cells are equivalent to regulatory T cells in mammals (formerly known as T suppressor cells) (Shanmugasundaram and Selvaraj, 2011). T and B lymphocytes express TREM A (chicken: Viertlboeck et al., 2013).

17.5.3.1 Structure

Avian lymphocytes are weakly basophilic. The structure of circulating avian lymphocytes was characterized by electron microscopy (ducks, geese, pigeons, turkeys, and Japanese quail: Maxwell, 1974) (see Figure 17.5). Avian lymphocytes have a nonlobed nucleus with a high nuclear: cytoplasmic ratio.

There are two structural types of lymphocytes in the circulation of birds, namely small and medium size

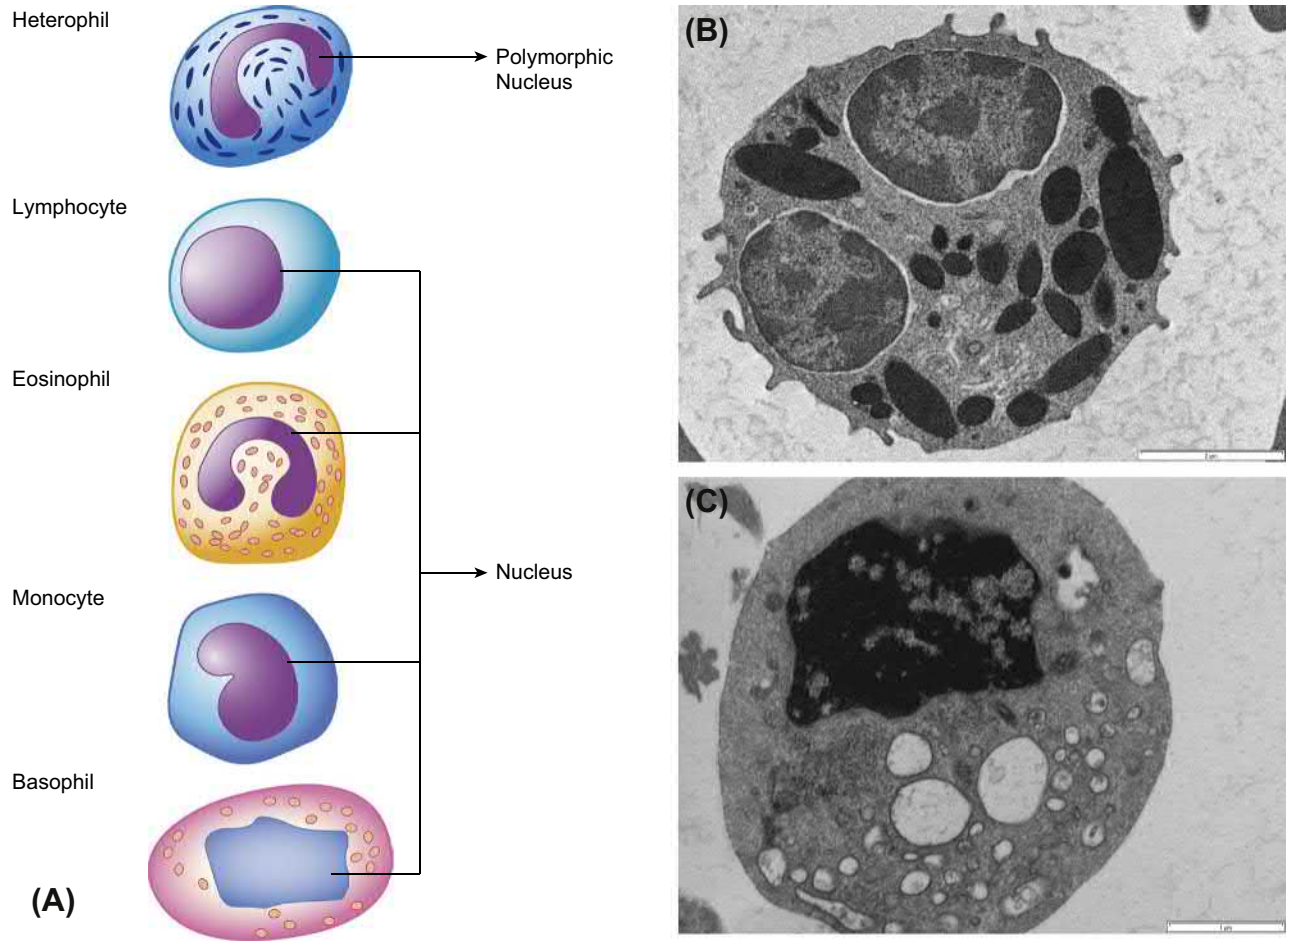

FIGURE 17.5 **Avian leukocytes.** (A) Schematic images of leukocytes. (B) Electron micrographs of heterophils from chicken peripheral blood. (C) Electron micrographs of agranular lymphocytes from chicken peripheral blood. *Reproduced from Shini et al. (2008).*

(Maxwell, 1974). In the small lymphocytes, the nucleus is pleomorphic in shape. The cytoplasm contains multiple mitochondria, Golgi apparatus, some endoplasmic reticulum, and a few granules. The small lymphocytes have extensive pseudopodia. The medium-sized lymphocytes are oval with a spherical nucleus. They have relatively few intracellular organelles (mitochondria, endoplasmic reticulum) and a few pseudopodia.

There are shifts in the structure of lymphocytes with physiology. Challenge with LPS is followed by reduced size (diameter and cross-sectional area) of circulating lymphocytes (chicken: Shini et al., 2008).

17.5.3.2 Function

Lymphocytes play important roles in both humoral and cell-mediated immunity. This is discussed in detail in Chapter 24.

Stressors influence lymphocyte functioning. For instance, lymphocyte expression of (heat shock protein) HSP 70 and HSP 90 is increased in chickens subjected to psychological stress for seven days (Pusch et al., 2018). Corticosterone suppresses proliferation of both T and B lymphocytes (Mehaisen et al., 2017).

17.5.3.3 Numbers

Circulating concentrations of lymphocytes are influenced by stresses. Administration of corticosterone is followed by decreases in blood concentrations of lymphocytes (chicken: Gross and Siegel) (Figure 17.7). In contrast, hypoxia increases lymphocytes numbers (Maxwell et al., 1987). Moreover, a transient increase in the blood concentration of lymphocytes occurs in turkeys after seven days after challenge with protozoan, *Eimeria adenoeides* (Gadde et al., 2009). There is movement of lymphocytes out of the circulation into tissues. There are large increases in lymphocytes (predominately $CD4^+$ T lymphocytes) infiltrating the pulp of growing feathers injected with phytohemagglutinin-P (Sullivan and Erf, 2017).

17.5.4 Eosinophils

17.5.4.1 Structure

Avian eosinophils are ovoid granulocytes with considerable cytoplasm (Figure 17.6). The round granules stain red after the uptake of the stain/dye eosin in histological slide preparation. The nucleus has two lobes (i.e., bilobed) (Sturkie, 1986). Electron microscopy revealed that avian eosinophils have multiple dense granules (0.1−1.6 μm diameter) with crystalline cores (Maxwell and Stiller, 1972).

17.5.4.2 Function

The functions of avian eosinophils are not well established (e.g., Campbell and Ellis, 2007). It is likely that avian eosinophils release specific cytokines in response to challenges.

17.5.4.3 Number

The numbers of eosinophils in the blood are elevated after some stresses. For instance, circulating concentrations of eosinophils were increased after handling and transportation (Amazon parrots: McRee et al., 2018) and in birds in captivity (rufous-collared sparrows: Ruiz et al., 2002). Similarly, infection with schistosomes, *Austrobilharzia variglandis*, is followed by consistent increases in the number of eosinophils per unit blood volume (chickens: Ferris and Bacha, 1986). In contrast, the concentrations of basophils are decreased after exposure to the pesticides, chlorphenvinphos, and foschlor (Japanese quail: Gromysz-Kałkowska et al., 1985). There were no effects of hypoxia on eosinophil numbers (chicken: Maxwell et al., 1987).

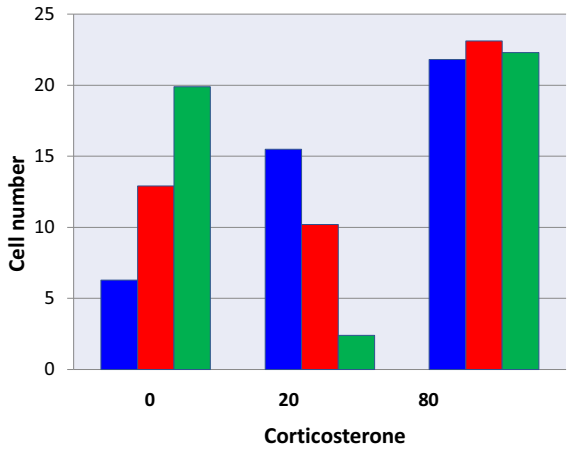

FIGURE 17.6 Effect of corticosterone (in diet in ppm) on heterophils (blue), lymphocytes (red), and total leukocytes (green) in young chickens. *Data from Gross and Siegel (1983).*

17.5.5 Monocytes

17.5.5.1 Structure

Avian monocytes are oval cells with considerable cytoplasm. Electron microscopy reveals that avian monocytes have multiple small granules (0.1−1.6 μm) with crystalline cores (Maxwell and Stiller, 1972). They have kidney-shaped nuclei and extensive cytoplasm containing a well-developed Golgi apparatus, rough endoplasmic reticulum, microtubules, vesicles, and mitochondria (ducks, geese, pigeons, turkeys, and Japanese quail: Maxwell, 1974).

17.5.5.2 Function

The functioning of avian monocytes is becoming understood. Monocytes are phagocytic, exert a chemotaxic effect on other leukocytes, release cytokines, produce nitric oxide (NO) and, in tissues, transform to macrophage (Grecchi et al., 1980). Opsonization of bacteria enhances their phagocytosis by avian monocytes (chicken: Stabler et al., 1994). Avian monocytes exert a chemitaxic on heterophils and lymphocytes due to their releasing macrophage inflammatory protein (MIP)-1β (Lam et al., 2002).

In response to LPS, monocytes release NO with increased expression of inducible NO synthase (chickens: Bowen et al., 2009). In turn, NO induces vasodilation. Moreover, in the presence of activators of TLR-2 and TLR-4, there is release of NO and increased expression of cytokines, IL-1β, IFNα, IFNγ, IL-8, and IL-13 together with the important receptors, TLR2 and TLR4 by monocytes (chicken: Guriec et al., 2018). Monocytes express TREM A (chicken: Viertlboeck et al., 2013).

Stressors influence monocyte functioning. Aflatoxins decrease the phagocytic activity of monocytes (chicken: Chang and Hamilton, 1979b).

17.5.5.3 Number

The blood concentration of monocytes is increased after vaccination against Newcastle disease virus (chicken: Taebipour et al., 2017). There are effects of some stressors on blood monocyte numbers. There are large increases (>threefold) in the blood concentrations of monocytes (monocytosis) in zinc deficient birds (chickens, turkeys, and quail—Wight et al., 1980). In addition, the percentage of monocytes is increased following stress (transportation in turkeys: Huff et al., 2010). Moreover, infection with schistosomes (*Austrobilharzia variglandis*) is followed by consistent increases in the number of monocytes per unit blood volume (chickens: Ferris and Bacha, 1986). Conversely, there were no effects of hypoxia on circulating monocyte numbers (chicken: Maxwell et al., 1987). There is movement of monocytes out of the circulation into tissues. For instance, there are increases in the number of

monocytes in intestinal villi of mallard ducks infected with the trematode intestinal fluke, *Sphaeridiotrema globulus* (Mucha and Huffman, 1991).

17.5.5.4 Production

Monocytes are produced in the bone marrow. In vitro, embryonic marrow cells have been reported as capable of developing into monocytes (e.g., Brandon et al., 2000).

17.5.6 Basophils

17.5.6.1 Structure

The nuclei and cytoplasmic granules take up basic stains, such as hematoxylin, giving a pale purple appearance (Sturkie, 1986). The ultrastructure of avian basophils has been reported (ducks and geese: Maxwell, 1973). Basophils are granulocytes. They contain cytoplasmic granules (see Figure 17.6). These vary in diameter from 0.1 to 0.8 µm diameter in ducks and geese and up to 1.0 µm diameter in turkeys (Maxwell, 1973). The nuclei of basophils are reported as polymorphic (Sturkie, 1986) or nonlobulated (ducks and geese) (Maxwell, 1973).

17.5.6.2 Function

Based on the situation in mammals (Voehringer, 2017), avian basophils are part of the innate immune system being proinflammatory cells associated with allergies and helminth infection. Like mast cells, basophils have receptors for IgE and release histamine.

17.5.6.3 Number

Basophil numbers in the blood are influenced by some stressors. Basophil cell number in the blood is increased with feed restriction (chickens: Maxwell et al., 1990, 1992a,b; ducks: Maxwell et al., 1992b). In addition, some other stresses influence the number of basophils in the blood of birds. The number of basophils in broiler chickens is increased by intermittent noise (Bedanova et al., 2010), by heat stress (Atlan et al., 2000) and after challenges with *P. juxtanucleare* (Siveira et al., 2009). In addition, the concentrations of basophils are increased after exposure to the insecticide chlorphenvinphos (Japanese quail: Gromysz-Kałkowska et al., 1985). In contrast, there were decreases in circulating basophil numbers in skylarks (*Alauda arvensis*) after LPS challenge (Hegemann et al., 2013). However, there was no effect of some stresses on the number of basophils per unit volume in the blood (handling and transportation in Amazon parrots: McRee et al., 2018; hypoxia in chickens: Maxwell et al., 1987). Basophils can move from the circulation to tissues. For instance, there are large increases in the number of basophils infiltrating the pulp of growing feathers injected with phytohemagglutinin-P (Sullivan and Erf, 2017).

17.5.7 Heterophil: lymphocyte ratios

The heterophil: lymphocyte (H:L) ratio as an indicator of stress in birds. The adrenal glucocorticoid, corticosterone, increases the H:L ratio (Gross and Siegel, 1983) (see Figure 17.7). As might be expected, H:L ratios are

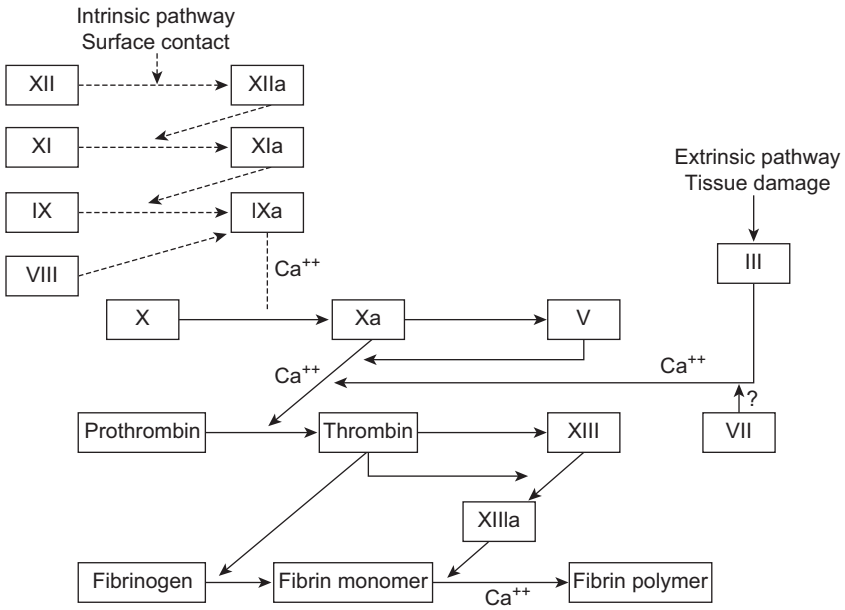

FIGURE 17.7 Cascade of coagulation of avian blood with a series of clotting factors.

increased by stress. The H:L ratio is increased with psychological stresses in multiple studies:

- Feeding at random times (chickens: Pusch et al., 2018).
- Social disruption (mixing two groups of birds) (chickens: Gross, 1990)
- Handling and transportation (Amazon parrots: McRee et al. (2018); chickens: Yalcin and Güler, 2012; turkeys (Huff et al., 2010).
- Intensive versus extensive systems in indigenous ducks (Kolluri et al., 2014).

The H:L ratio is also increased with physical stresses, albeit without complete consistency:

- Glucocorticoid administration (corticosterone: Gross and Siegel, 1983; Gross, 1990; Mehaisen et al., 2017; Weimer et al., 2018; dexamethasone: Huff et al., 2011).
- Ammonia (broiler chicks: McFarlane and Curtis)
- Disease (multiple passerine species: Wilcoxen et al., 2015)
- Electric shocking (chicken: McFarlane and Curtis, 1989)
- Fasting (Gross and Siegel, 1983; Gross, 1990) or feed restriction (chickens: Zulkifli et al., 2000; Azis, 2012)
- Heat stress (laying hens: Mashaly et al., 2004; broiler chicks: McFarlane and Curtis, 1989; in one line of broiler chicks but not another: Xu et al., 2018).
- Hypoxia (chickens: Maxwell et al. (1987).
- Injury (Adélie penguins: Vleck et al., 2000)
- Intermittent noise (broiler chickens: Bedanova et al., 2010).
- Killed *E. coli* (chickens: Gross and Siegel, 1983).
- LPS challenge on the H:L ratio (skylarks: Hegemann et al., 2013).
- Received feed contaminated with the mycotoxin, deoxynivalenol (chickens: Ghareeb et al., 2011, 2014).

In contrast, H:L ratios are depressed in the pesticide, malathion (chicken: Gross and Siegel, 1983).

17.6 Thrombocytes

In birds, thrombocytes are the functional equivalent of platelets in mammals. They, like leukocytes, are found in the "buffy" layer when the hematocrit of avian blood is being determined. Avian thrombocytes play important roles in both blood clotting and immune functioning. They should be considered as subtype of leukocytes (Seliger et al., 2012).

17.6.1 Structure

Avian thrombocytes have the following characteristics:

- Cell diameter 5.4 μm (Japanese quail: Belleville et al., 1982)—8.5 μm (Rhea: Gallo et al., 2015)
- Nuclear diameter 4.2 μm (Japanese quail: Belleville et al., 1982).

Avian thrombocytes can be confused with lymphocytes but are readily recognized using specific monoclonal antibodies (e.g., chicken: Horiuchi et al., 2004) or by expression of αVβ3 (Windau et al., 2013). The ultrastructure of the avian thrombocyte has been characterized (ducks, geese, pigeons, turkeys, and Japanese quail: Maxwell, 1974). Avian thrombocytes have an irregular shape with multiple pseudopodia. Similarly, the nucleus is irregular in shape. There is more cytoplasm than is seen in small lymphocytes. There are multiple small mitochondria, an endoplasmic reticulum, prominent microtubules, and a few dense granules.

17.6.2 Function

Like platelets in mammals, thrombocytes play an important role in hemostasis in birds. Avian thrombocytes have been demonstrated to form aggregates (chickens: Grant and Zucker, 1973; pigeon: O'Toole et al., 1994) with aggregation stimulated by serotonin (domestic ducks: Belamarich and Simoneit, 1973) and contact with collagen (duck: Stiller et al., 1975). Moreover, avian thrombocytes adhere to collagen with this stimulating degranulation and release of serotonin (chicken: Schmaier et al., 2011). Avian thrombocytes express α2bβ3 integrins, albeit at a lower level than in mammalian platelets (chicken: Schmaier et al., 2011). However, vaso-occlusion thrombosis is not observed in birds (Australian budgerigars: Schmaier et al., 2011).

Avian thrombocytes are part of the innate immune system. Evidence for this comes from the following. They are phagocytic (Carlson et al., 1968) with bacteria but probably not protozoa (chicken: Chang and Hamilton, 1979c; DaMatta et al., 1998). Chicken thrombocytes have been reported to exhibit increase phagocytosis in response to LPS (St Paul, 2012). Moreover, like leukocytes, produce TLR, inflammatory cytokines and other agents. There is marked expression of TLR2, TLR3, and TLR4 by chicken thrombocytes together with some expression of TLR5, TLR7, and TLR21 (St. Paul et al., 2012). In response to stimulation by LPS acting via TLR, there is increased expression of proinflammatory cytokines IL-1β, IL-6, and IL-8 together with the antiviral cytokines, IL12, and IFN-alpha by avian thrombocytes (chickens: Ferdous et al., 2008; St. Paul et al., 2012; Winkler et al., 2017). In addition, chicken thrombocytes release nitrite in response to LPS (St. Paul et al., 2012). Avian thrombocytes express both the activating TREM A (chicken: Viertlboeck et al., 2013) and the inhibitory TREM B (chicken: Turowski et al., 2016). Avian thrombocytes also have been reported to produce leukotriene B_4 (Jha et al., 2005) and prostaglandin E_2 (Scott and Owens, 2008). In addition, activating chicken Ig-like receptors are found in avian thrombocytes (Windau et al., 2013).

17.6.3 Number

Table 17.7. summarizes thrombocyte concentrations in wild birds and poultry. The number of thrombocytes in the

blood can be influenced by environmental factors. The number of thrombocytes per unit blood volume is also elevated by feed restriction (chickens: Maxwell et al., 1990). The circulating concentrations of thrombocytes is decreased (thrombocytopenia) with viral infections such as by bursal disease virus in chickens (Lima et al., 2005). Moreover, there are marked decreases in the concentration of thrombocytes in chickens with experimentally induced malaria following challenge with *P. juxtanucleare* (Siveira et al., 2009) or *P. gallinaceum* (de Macchi et al., 2013). Similarly, there are decreases in the number of thrombocytes following intravenous administration of cellulose microparticles (Wang et al., 2003). In contrast, thrombocyte numbers increase following challenge with LPS (chicken: Gehad et al., 2002). Pesticides can influence thrombocyte concentrations, being increased by foschor but decreased by chlorphenvinphos (Japanese quail: Gromysz-Kałkowska et al., 1985).

17.6.4 Production

Thrombocytes are produced from thromboblasts in the bone marrow. In vitro, embryonic marrow cells have been demonstrated to be capable of developing into thrombocytes (Japanese quail: Brandon et al., 2000). Thrombocyte production is stimulated by thrombopoietin (TPO) with avian TPO and its receptor c-Mpl proto-oncogene having been characterized (chickens: Bartunek et al., 2008). Expression of TPO is restricted to the liver and spleen while its receptor is expressed in bone marrow, lungs, and spleen (Bartunek et al., 2008).

17.6.5 Thrombopoietin

TPO stimulates production of thrombocytes. The structure of avian TPO has been deduced from cDNA [e.g., budgerigar (*Melopsittacus undulatus*)—Genbank XM_005146962.1; chicken: Bartunek et al., 2008]. It is expressed in the liver and spleen while its receptor is expressed in bone marrow together with lungs and spleen (chicken: Bartunek et al., 2008).

17.7 Other cells types in avian plasma

17.7.1 Reticulocytes

Reticulocytes are immature erythrocytes that can be found in the circulation of birds (e.g., red-tailed hawk: Johns et al., 2008; Japanese quail with 0.25×10^{-6} cells per mm^3: Gildersleeve et al.,1983b). These vary with physiological, toxicological, and pathological state. At the end of incubation, there is a marked increase in the reticulocyte (immature erythrocytes) index (zebra finches: Wagner et al., 2008). Low levels of reticulocytemia (maximum 4.5%) in chickens were induced by withdrawal of blood but higher concentrations of reticulocytes were induced by withdrawal of blood from birds infected with *Leucocytozoon caulleryi* (Ohnishi and Nishimura, 2001). There are marked increases in the number of reticulocytes in the circulation of American oystercatchers contaminated with oil (Fallon et al., 2018). Similarly, the number of reticulocytes are increased following intoxication with zinc (mallard ducks: Levengood et al., 2000) and fenitrothion (Szubartowska and Gromysz-Kałkowska, 1992).

17.7.2 Mott cells

Mott cells are detected in blood from laying hens (Cotter, 2015). These plasma cells contain both cytoplasmic and nuclear vacuoles and exhibit phagocytosis (Cotter, 2015).

17.7.3 Natural killer cells

Natural killer cells are also observed in avian blood (Cotter, 2015).

17.8 Parasites and blood cells

Parasites can infect blood cells in birds. *P. gallinaceum* organisms are found in erythrocytes, thrombocytes, and leukocytes in chickens infected with malaria (de Macchi et al., 2013; Granthon and Williams, 2017). Similarly, both avian erythrocytes and thrombocytes can be infected with *Toxoplasma gondii* organisms (Malkwitz et al., 2017). In contrast, *Leucocytozoon sabrazesi* infect thrombocytes but not other blood cells (chickens: Zhao et al., 2015).

Parasites also influence the numbers of leukocytes and thrombocytes. For instance, infection of pigeons with the erythrocyte parasite, *Haemoproteus columbae*, is accompanied by increases in leukocytes, decreases in lymphocytes, and increases in both basophils and eosinophils (Samani et al., 2016). Leukocyte numbers, specifically of heterophils, eosinophils, and monocytes, are increased in chickens infected with schistosome, *Austrobilharzia variglandis* (Ferris and Bacha, 1986).

17.9 Clotting

The overall scheme for clotting in birds is similar to that in mammals but clotting factors XI and XII appear to be missing in birds (reviewed Buzula et al., 2017). There are both extrinsic and intrinsic clotting systems (Doerr and Hamilton, 1981). Fibrinogen is cleaved by the protease, thrombin, to fibrin (Weissbach et al., 1991), which is then polymerizes. Prothrombin is activated to thrombin by a cascade of clotting factors.

The sequences of some of the avian clotting factors have been deduced from their genes or cDNA or following purification:

- Fibrinogen α chain [chicken: Gene ID: 396307]
- Fibrinogen β chain [chicken- Gene ID: 373926]
- F2 coagulation factor II/thrombin [chicken—Gene ID: 395306; ostrich: Frost et al., 2000].
- Thrombin [Japanese quail: Belleville et al., 1982]

The tertiary protein structure of the fibrinogen has been reported (chicken: Yang et al., 2000).

Clotting factors are produced by the liver (fibrinogen—chicken: Grieninger et al., 1989; prothrombin—ostrich: Frost et al., 2000). Plasma concentrations of fibrinogen have been reported as 1.8 g/L (Roy et al., 2014) and 3.1 g/L (chicken: Pliszczak-Krol et al., 2012). Fibrinogen concentrations are increased in laying hens infected with *Streptococcus equi* (Roy et al., 2014). Administration of turpentine evokes an acute phase response with increased plasma concentrations of fibrinogen (chicken: Grieninger et al., 1986). There are age-related shifts in circulating concentrations of clotting factors including plasminogen and fibrinogen but not tissue factor or tissue factor pathway inhibitor (Buzala et al., 2016).

Avian blood appears to clot more slowly than does mammalian blood (Japanese quail: Belleville et al., 1982). For instance, the whole blood clotting time is 38 min for Japanese quail compared to 8 min for human blood (Belleville et al., 1982). Avian blood does not clot in response to glass activation (Japanese quail: Belleville et al., 1982). Table 17.8 provides examples of clotting times in birds. Clotting times are increased in chickens receiving aflatoxin in their diet (Doerr et al., 1974).

Chapter 18

The cardiovascular system

Edward M. Dzialowski and Dane A. Crossley
Department of Biological Sciences, University of North Texas, Denton, TX, United States

18.1 Introduction

Birds have evolved a high-performance cardiovascular system to meet the rigorous demands of running, flying, swimming, or diving in a variety of environments, some of them very harsh. Sustained high levels of activity in these environments place severe demands on the transport capabilities of the cardiovascular system to provide adequate delivery of oxygen to working vascular beds and to provide efficient removal of metabolic products. Furthermore, birds are homeothermic organisms, and the cardiovascular system plays a major role in conserving or removing body heat. The descriptions of the component parts of the circulatory system in this chapter illustrate that these transport requirements are met in a variety of ways in birds inhabiting particular environmental niches. This chapter describes the morphology and functional aspects of the avian heart (Section 18.2), circulatory hemodynamics (Section 18.3), and the vascular tree (Section 18.4). A common thread running through this discussion is that the component parts of the circulation must cooperate in an integrated fashion in order to ensure tissue oxygen delivery matches tissue demands. This is done through the integrative control of the avian circulation by autoregulatory, humoral, and neural mechanisms (Section 18.5). Significant number of studies has examined the development of cardiovascular control in avian embryos (Section 18.5) which have expanded our understanding of this system throughout ontogeny. Finally, the cardiovascular system functions within a complex animal which interacts with the environment (Section 18.6).

Modern birds are derived from theropod dinosaurs (Padian and de Ricqles, 2009), while mammals have descended from a group of carnivorous reptiles, the cynodonts. These ancestral lines originated in the Triassic more than 200 million years ago, so in evolutionary terms, avian and mammalian stocks have been separated for a substantial period of time. As one might expect, significant differences in cardiovascular structure and function have arisen in the two groups since their separation, yet a number of similarities in their circulatory systems are also evident. Such similarities probably represent both the conservation of characteristics common to organisms ancestral to the two groups, a shared endothermic phenotype, and the results of convergent evolution once the stocks had divided. Unfortunately, our knowledge of cardiovascular structure and function remains far more limited in birds than in mammals. This review of the avian cardiovascular system encompasses the chapter from a previous edition of this volume (Whittow, 2000) that drew from a number of excellent previous reviews, including major works by Akester (1971), Jones and Johansen (1972), Bennett (1974), Baumel (1975), Akester (1979), Cabot and Cohen (1980), West et al. (1981), and Benzo (1986). We have updated and extended these works and summarize recent contributions in additional areas.

18.2 Heart

18.2.1 Gross structure and function

18.2.1.1 Functional anatomy

The avian heart, like that of the mammal, is a four-chambered, muscular fluid pump that intermittently pressurizes the central arteries, inducing blood flow to the capillary beds of both the systemic and pulmonary circulations. Functionally, these circuits lie in series with each other, and blood returns to the heart to be pressurized before entering either circuit. As in mammals, the right ventricle pressurizes the pulmonary circulation, and the left ventricle pressurizes the systemic circulation. In each case, the pressure differential between the central mean arterial pressure and the central venous pressure drives blood flow [the cardiac output (CO)] through the resistance to flow offered by the microvessels of the circulation. The left and right atria receive blood at central venous pressure before it enters the ventricles. In common with the atria of mammals, these chambers probably function more as blood reservoirs for their respective ventricles than as important "superchargers" for ventricular pressure. The resistance to blood flow, the peripheral resistance, is lower in the pulmonary

Sturkie's Avian Physiology. https://doi.org/10.1016/B978-0-12-819770-7.00042-6

than in the systemic circuit, so the right ventricle is required to generate less pressure than the left ventricle to produce the same volume flow rate. This difference in ventricular pressure is reflected in the gross anatomy of the ventricles, the myocardium of the right ventricle being thinner than that of the more powerful left ventricle.

In birds, the heart is located in the cranial part of the common thoracoabdominal cavity, with its long axis slightly to the right of the midline. It is partly enclosed dorsally and laterally by the lobes of the liver. A very thin but tough, fibrous pericardial sac encloses the heart.

This sac contains a small volume of serous fluid that provides lubrication for the rhythmic motion of the cardiac contraction cycle. The pericardium is loosely attached to the dorsal surface of the sternum and the surrounding air sacs and more firmly to the liver. It is also attached, via the peritoneum of the hepatic peritoneal cavities, to the vertebral column. These attachments secure the apex of the heart within the median incisura of the liver and in the caudoventral axis of the thoracoabdominal cavity. The outer fibrous layer of the pericardial sac is continuous with the outer adventitial layer of the large central blood vessels. The pericardial membrane is relatively noncompliant and therefore strongly resists large, rapid increases in cardiac size which might be caused by volume overload of a heart chamber. The noncompliant nature of the pericardial sac may result in some degree of mechanical coupling between the ventricles via the contained incompressible lubricating fluid. For example, an increase in diastolic pressure in one ventricle may be transmitted to the other, increasing pressure and decreasing compliance.

18.2.1.2 Heart size

In birds, heart mass scales in respect to body mass as $M_h = 0.014\ M_b^{0.91}$ (Bishop and Butler, 1995). In mammals, the relationship is $M_h = 0.0058 M_b^{0.98}$ (Prothero, 1979), where M_h is heart mass and M_b body mass. When compared with mammals, birds of a given body mass have a significantly heavier heart. This may be due to the high aerobic power output needed to sustain flapping flight. Furthermore, unlike mammals in which heart mass is almost directly proportional to body mass, in birds the exponent denoting proportionality is significantly less than one. This means that larger birds like swans, ducks, and geese tend to have proportionally smaller hearts in relation to their body mass than do smaller birds. Thus, heart mass represents about 1.1% of body mass for a bird like the racing pigeon (421 g), compared with 0.8% for the 2.95 kg Pekin duck (Grubb, 1983; Bishop and Butler, 1995). Heart size has also been shown to vary with flight capacity, with birds that continuously hover during flight having the largest hearts and poor fliers having the smallest hearts (Nespolo et al., 2018). For example, hummingbirds have proportionally larger hearts than all other birds (Bishop and Butler, 1995), reflecting the high aerobic demands of hovering flight. For 25 species of hummingbirds: $M_h = 0.025 M_b^{0.95}$ (Hartman, 1961). In contrast, the ornate tinamou (*Nothoprocta ornate*) and Chilean tinamou (*Nothoprocta perdicaria*) have heart masses that represent only 0.24 and 0.28% of body mass, respectively (Altimiras et al., 2017). In a number of migrating species, the heart hypertrophies before migration supporting morphological plasticity (see Section 18.6.1.2). Migrating birds have transcriptomic plasticity allowing changes in heart size, and therefore CO, that could be induced by seasonal humoral mechanisms.

Heart mass as a fraction of body mass is age dependent. Prior to hatching, the ventricles of pekin ducks (*Anas platyrhynchos domestica*) represents about 0.4% of body mass and increase significantly upon hatching to 0.75% of body mass (Sirsat et al., 2016). This increase in heart mass coincides with an increase in aerobic capacity of the hatchling. Similar increases have been observed in the chicken, Pekin duck, and emu after hatching (Price and Dzialowski, 2018). Of note species of the avian order Tinamiformes have lower heart to body mass ratio and heart growth is similar to American alligators (*Alligator mississippiensis*; Altimiras et al., 2017).

18.2.1.3 Cardiac chambers

The avian heart has two completely divided atria and ventricles. These chambers are functionally equivalent to those of the mammalian heart, serving to distribute CO to the systemic circulation and to the lungs. In life, the atria are rounded chambers, distended with blood during atrial diastole. In excised hearts they may collapse, causing auricles to appear. The right atrium tends to be much larger than the left. The wall of the avian atria and ventricles, as in mammals, consists of endocardial, myocardial, and epicardial layers. The atrial walls are generally thin, although atrial muscle is arranged in thick bundles forming muscular arches. The right and left transverse arches are arranged at right angles to the dorsal longitudinal arch and the interatrial septum. The transverse arches branch into smaller bundles which fuse with a circular muscle band (muscularis basianularis atrii) at the ventral limits of the atria. Contraction of atrial muscle nearly empties the atria. In many species, the atria lack functional inflow valves, so the importance of atrial contraction for ventricular filling may be slight.

The muscular architecture of the ventricles is more complex than that of the atria and includes a superficial layer, longitudinal muscle of the right ventricle, and sinuspiral and bulbospiral muscles. The left ventricle is cone-shaped and extends to the apex of the heart. Its right wall forms the interventricular septum. The free wall of the right ventricle is continuous with the outer portion of the wall of the left ventricle and wraps around the right side of the heart to enclose a crescent-shaped cavity which does not reach the apex of the heart. The muscular walls of the

two ventricles are differentially developed, the wall of the left ventricle being two to three times thicker than that of the right. In addition, the radius of curvature of the left venticle wall is smaller than that of the right (Figure 18.1). This implies both a greater mechanical advantage for pressure generation in the left than in the right ventricle and, according to LaPlace's law, a smaller wall tension for a given left ventricular pressure increment. Therefore, contraction of the myocardial layers of the thick, small radius wall of the left ventricle enables it to generate systolic pressures four–five times higher than those produced by the right ventricle, without rupturing. The larger radius of curvature and thinner free ventricular wall of the right ventricle reflects the lower systolic pressures generated by this chamber, made possible by the low-vascular resistance of the avian lungs. Another consequence of this geometry is that relatively large changes in stroke volume can be made by small changes in the degree of shortening of right ventricular muscle fibers.

18.2.1.4 Valves

Blood entering the left ventricle from the left atrium during atrial systole passes through an orifice guarded by a membranous atrioventricular (AV) valve, similar in general structure to a mammalian AV valve. The valve forms a continuous membrane around the aperture. The valve is tricuspid, not bicuspid as it is in mammals, but in the avian heart, the cusps of this valve are poorly defined. The anterior and posterior leaflets are small. The large aortic (medial) leaflet is connected to the bases of the left and noncoronary cusps of the adjacent aortic outflow valve by fibrous tissue. The free margin of the valve is well secured to the left ventricular endocardium by numerous inextensible chordae tendineae. This arrangement prevents valve eversion during ventricular systole.

Blood passing from the right atrium to the right ventricle enters through an orifice guarded by a muscular valve that is structurally unique to birds. In pronounced contrast to the fibrous structure characteristic of the mammalian tricuspid valve, in birds, the right AV valve consists of a single spiral flap of myocardium attached obliquely to the free wall of the right ventricle and the interventricular septum (Figure 18.2; Prosheva et al., 2015, 2016; Lu et al., 1993a). This spiral flap is apposed to a downward extension of the free wall of the right atrium. The atrial component of the valve extends toward the apex of the ventricle for a shorter distance than does the right ventricular flap. Most of the valve is made of ventricular myocardium and is bilaminar only in its upper portion. The mechanism of valve closure at the start of ventricular systole is unknown. It appears to close in part by active contraction of the muscular flap attached to the wall of the right ventricle (Prosheva et al., 2015). The muscular AV value is predicted to separate the two right atria and ventricle and contribute to right ventricular pressure generation (Prosheva et al., 2015).

The idea of valve closure depending at least partially on active muscular contraction is supported by evidence that at the cellular level both AV valves are closely approached by the electrical conducting system of the myocardium. A complete ring of Purkinje fibers encircles the right AV orifice and connects to the muscular AV valve (Lu et al., 1993a,b). An exception to this anatomical arrangement may be the penguin, in which Adams (1937) did not find a Purkinje ring. The majority of studies, summarized by Lu et al. (1993a,b), support the idea that both the atrial and ventricular muscular components of the right AV valve are excited to contract via the Purkinje system. However, Szabo et al. (1986) thought that there was an insulating layer of connective tissue between the Purkinje AV ring system and the left ventricular myocardium, suggesting that

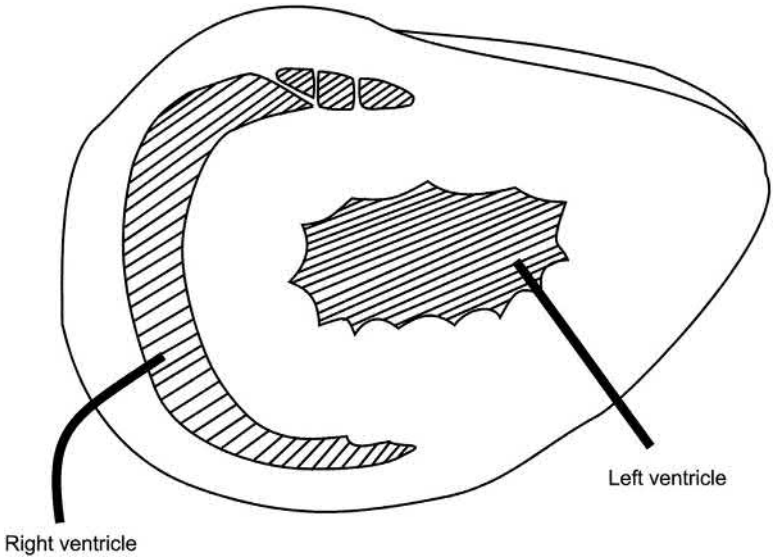

FIGURE 18.1 Transverse section through the ventricles of the avian heart. The lumen of each ventricle is shaded. *Reprinted from West et al. (1981).*

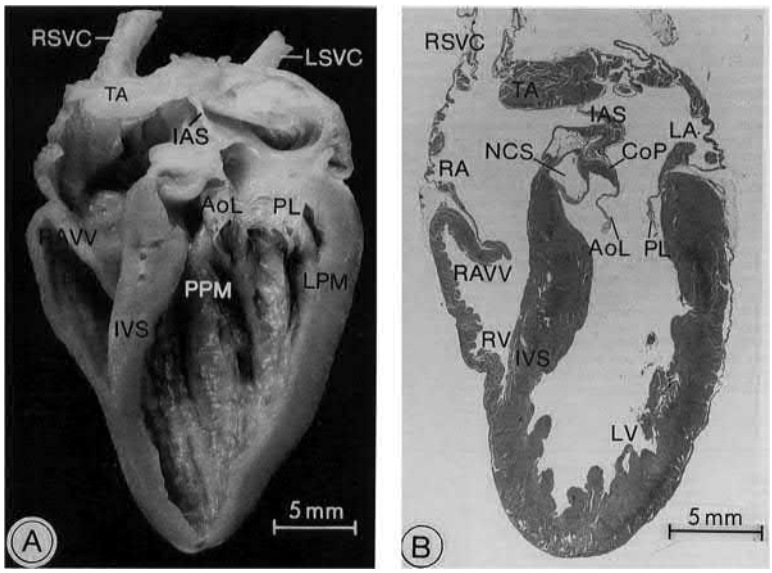

FIGURE 18.2 Anterior frontal views through the atria and ventricles of a chicken heart, showing both the right and left atrioventricular (AV) valves. (1993a).*

the muscle flap derived from the left ventricle may work passively. Definitive physiological experiments have not been performed to resolve this issue, but the balance of current evidence suggests that both portions of the valve are electrically activated before the ventricular myocardium to dynamically contract and close the AV orifice at the start of ventricular systole (Lu et al., 1993b). This is clearly very different from the closure mechanism in mammals, in which the leaflets of the tricuspid valve float up into the right AV orifice, moved by the AV pressure differential generated during ventricular systole itself.

The outflow valves from the right and left ventricles are, at first glance, more conventional (mammalian) in nature. The pulmonary outflow valve consists of three semilunar cusps. It prevents regurgitation from the pulmonary artery into the right ventricle, the valvules opening as pressure in the ventricle falls below that in the pulmonary trunk on ventricular diastole. There are also three semilunar cusps in the aortic outflow valve, but they are much more rigid than those of the pulmonary outflow valve and are firmly attached to underlying myocardium. The cusps are linked by a ring of fibrous tissue that lies within a complete ring of underlying, circumferentially arranged, myocardial cells. The ring is completed by an arch of cardiac muscle that lies between the left coronary cusp of the aortic outflow valve and the aortic leaflet of the left AV valve as shown in Figure 18.3 (Lu et al., 1993a). This anatomical arrangement contrasts with that in the mammalian heart, in which there is only connective tissue, not myocardium, between that

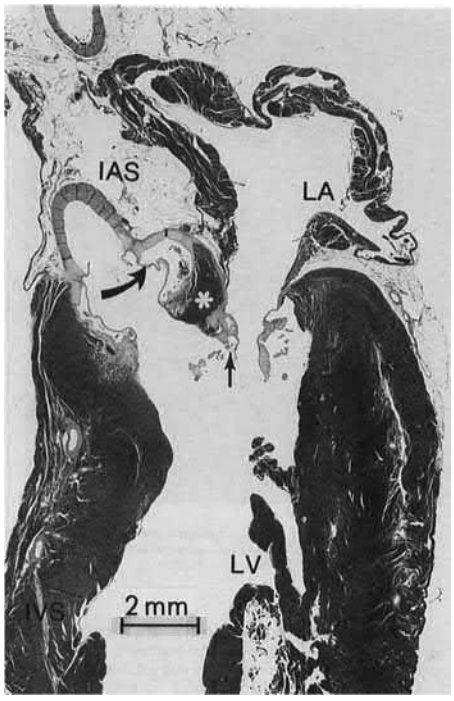

FIGURE 18.3 Photomicrograph of a histological section of the chicken heart, taken in a modified sagittal plane through the anterior column of the muscle arch, indicated by an asterisk. The muscle arch lies between the left coronary aortic valve cusp (*curved arrow*) and the aortic leaflet of the left AV valve (*straight arrow*). *IAS*, interatrial septum; *LA*, left atrium; *LV*, left ventricle. *From Lu et al. (1993a).*

part of the muscular ring lying between the aortic wall and the adjacent mitral valve; in mammals, the myocardial ring is incomplete. In the bird, however, this sphincter-like myocardial cylinder is potentially capable, on contraction, of constricting the left ventricular outflow tract. Lu et al. (1993a) propose that the muscular ring could act as a sphincter controlling the rate of left ventricular outflow by modulating outflow resistance. Another attractive possibility is that muscular contraction of the myocardial ring could close the relatively rigid cusps of the aortic outflow valve. The middle bundle branch of the Purkinje system is connected to the arch of muscle, so its contraction may start relatively early in the cardiac cycle. Obviously, physiological studies are needed to determine whether either of these intriguing mechanisms operates in the avian heart.

18.2.1.5 Coronary circulation

Oxygenated blood destined to supply the avian myocardium via the right and left coronary arteries enters the right ventral and left aortic sinuses, which lie immediately downstream from the cusps of the aortic outflow valve. Most birds have two entrances to the coronary circulation, although there is individual variation so that up to four openings have been observed. In chickens, the right ventral sinus leads into the right coronary artery, which then divides immediately into a superficial and a deep branch (Figure 18.4). The superficial branch follows the groove (coronary sulcus) between the right ventricle and atrium

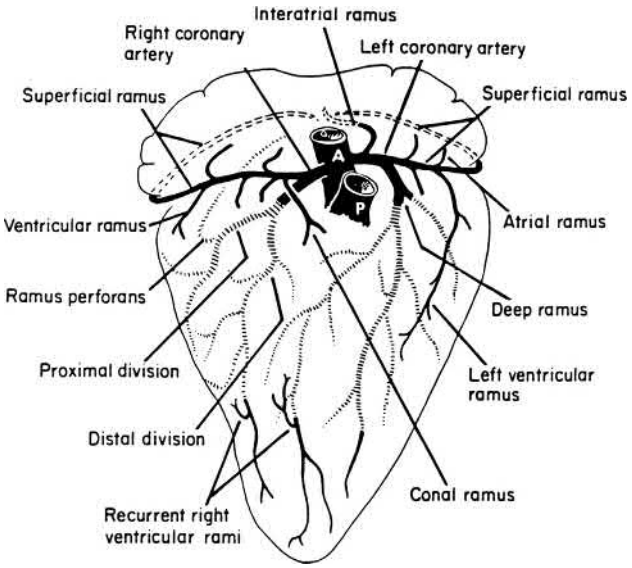

FIGURE 18.4 Arrangement of the coronary arteries of the chicken, *Gallus*, drawn from the cranioventral aspect. *Solid black and dashed lines* represent superficial portions of arteries. *Cross-hatched lines* represent deep arteries embedded in the myocardium of the ventral and right side of the interventricular septum. *A*, aorta; *P*, pulmonary trunk. *From West et al. (1981).*

and supplies the cardiac muscle of both chambers. The larger deep branch supplies the ventral wall of the right ventricle, the dorsal walls of both atria, and the muscular right AV valve. In most species, the right coronary artery is dominant and also supplies the ventricular septum, the heart apex, and much of the left ventricular myocardium. The left coronary artery arises from the left aortic sinus and also has a superficial branch which follows the left coronary sulcus. Another superficial branch gives off atrial and ventricular tributaries, and a deep branch supplies the ventral myocardium of the left ventricle. It is not uncommon in chickens for the left coronary artery to be dominant, in which case it supplies almost all of the left ventricular myocardium and the heart apex. There are frequent anastomoses between the branches of the coronary arteries, particularly near the coronary sulcus.

Five groups of cardiac veins, with frequently anastomosing small tributaries, return venous blood from the myocardium into the right atrium via a coronary sinus. Small cardiac veins open directly into the atria and the right ventricle. This basic anatomical pattern of coronary circulation is described in birds ranging from chicken, duck, and pigeon (West et al., 1981), quail (Kato et al., 2018), and ostrich (Bezuidenhout, 1984).

The rate of perfusion of avian myocardium is high compared with perfusion rates of most other avian tissues receiving around 8% of CO (see Section 18.4.2.3; Johansen, 1964; Jones et al., 1979; Ellerby et al., 2005). The constantly active cardiac muscle is perfused at a higher rate than resting skeletal muscle. During exercise in the guinea fowl, flow to the ventricles more than doubled (Ellerby et al., 2005). Presumably, as in mammals, the majority of avian coronary blood flow occurs in diastole, so we might expect coronary flow to increase if the diastolic interval is prolonged, provided arterial driving pressure does not fall.

18.2.2 Cardiac variables

The avian cardiovascular system is not merely a replica of the arrangement in mammals, despite similarities in performance between the two systems. Birds have larger hearts, bigger stroke volumes, lower heart rates, and higher CO than mammals of corresponding body mass (Grubb, 1983). In addition, in many avian species, mean arterial pressure is higher than that found in mammals of comparable body mass (see Smith, 1994). CO, the product of stroke volume and heart rate, is of particular interest because it is a major determinant of the rate of oxygen delivery to tissues.

In resting birds, left ventricular stroke volume (V_s) scales almost directly proportional with body mass (M_b) (Grubb, 1983; Seymour and Blaylock, 2000). For nine species of birds ranging in body mass from 0.035 kg (budgerigar) to 37.5 kg (emu), Grubb found that $V_s = 1.72M_b^{0.97}$, where

V_s is in milliliters and M_b is in kilograms. Seymour and Blaylock (2000) found a similar relationship in birds and $V_s = 0.99M_b^{1.03}$ in mammals. Heart rate (f_H, beats min^{-1}) at rest was found to be slower in larger birds: $f_H = 178.5M_b^{-0.282}$. CO (CO, mL kg^{-1} min^{-1}) at rest, the product of stroke volume and heart rate, therefore scaled with the mass of the bird as: $CO = 307.0M_b^{0.69}$. The corresponding relationship for mammalian CO is $CO = 166M_b^{0.79}$ (Holt et al., 1968). These results show that birds have a proportionally larger CO compared with a mammal of the same body mass. In larger birds, resting heart rate is slower than in smaller birds. Bishop and Butler (1995) found that for 49 species the allometric relationship for heart rate at rest was $f_H = 125M_b^{-0.37}$, while for birds in flight it was $f_H = 480M_b^{-0.19}$. It is interesting that the heart rate–body mass relationship during flight has a shallower slope than in resting animals, indicating larger species show a greater increase in heart rate in absolute terms in the transition from rest to flight. Bishop and Butler (1995) suggest that the body mass exponent of stroke volume in flight should be similar to that at rest ($M_b^{0.96}$), even though the absolute value of stroke volume may increase during flight. Therefore, in flight, it is predicted that CO will scale to body mass as the sum of the exponents for stroke volume and heart rate ($M_b^{0.77}$).

In flight, as at rest, larger species show lower coronary perfusion rates per mass of body tissue. It is likely that this reflects an optimization of the arterial oxygen supply at the tissue level, the body mass exponent for CO being very similar to the exponent for mass-specific oxygen consumption. Thus, natural selection probably acts on CO to maintain the arteriovenous O_2 difference at a similar level across different avian species. Stroke volume is constrained by cardiac geometry such that, on theoretical grounds, V_s should be closely proportional to M_h and M_b (Schmidt-Nielsen, 1984; Astrand and Rodahl, 1986). Therefore, the lower mass–specific CO of larger avian species, matching their lower mass–specific VO_2 levels, are reflected in their lower heart rates.

18.2.3 Fine structure and cardiac electrophysiology

18.2.3.1 Fine structure

Histologically the atria and ventricles are quite similar consisting of an external layer, the epicardium, which is separated from an inner endocardium by the mass of heart muscle, the myocardium. Ventricles are much thicker than the atria due to extensive proliferation of the myocardial layer. The epicardial and endocardial layers are morphologically similar, consisting of loose connective tissue and elastic fibers bordered by a single layer of squamous epithelial or endothelial cells, respectively. The atrial and ventricular septa have endocardial layers facing the lumens of their respective cavities with myocardial cells between them. In the sparrow and stork, the atrial septum is very thin and in some regions consists only of two apposed layers of endocardium.

The atrial and ventricular myocardia consist of striated muscle fibers, differing from those of mammals in three notable respects (Sommer and Johnson, 1969, 1970; Hirakow, 1970). (1) Striated muscle bands are prominent in mammalian cardiac muscle are also present in bird hearts, with the exception of the M-band. In mammalian cardiac muscle, the M-band is a line of protein molecules connecting adjacent myosin filaments. The significance of the lack of an M-band on the contractile properties of avian myocytes is unknown. (2) Avian cardiac muscle fibers are much smaller in diameter than mammalian fibers and hence there are many more of them in similarly sized hearts. Avian myocardial cells are typically 2–7 μm in diameter compared with the 10–15 μm diameter of mammalian cells. (3) Myocardial cells of all fish and reptiles (Shiels and Galli, 2014), including avian species lack transverse tubules (T-tubules) which are prominent in mammalian cardiac muscle. The membrane surrounding the muscle fibers (sarcolemma) consists of two parts, a cell membrane (plasmalemma) and an external layer interconnected with an interstitial network of collagenous fibers. In mammalian cardiac muscle, T-tubules form as invaginations of the plasmalemma, perpendicular to the long axis of the myofilaments. T-tubules lie next to, and form junctions with, sections of the sarcoplasmic reticulum (SR) (diads or triads). In mammals, the T-tubule system increases the surface area of the myocardial cells to the extent that the surface-to-volume ratio of a mouse cardiac cell (15 μm diameter) is the same as that of a finch (8 μm diameter). The finch and the mouse have similar cardiac frequencies (Bossen et al., 1978).

The connection between the SR and the sarcolemma occurs through "couplings" and in birds that lack a T-tubule system these couplings occur at the surface of the cell (Figure 18.5). Peripherial couplings are affected by junctional processes that extend from the cytoplasmic face of the SR (junctional sarcoplasmic reticulum, JSR) that are very closely opposed to the inner surface of the sarcolemma. Birds and the other reptiles possess an extended junctional sarcoplasmic reticulum or corbular JSR that is not associated with the sarcolemma (Perni et al., 2012; Shiels and Galli, 2014). Corbular JSR is much less developed in chicken than in passerine birds (Sommer et al., 1991). The volume of peripheral JSR in mouse hearts and the total volume of peripheral JSR (20%) and corbular JSR (80%) in the finch are virtually identical (Bossen et al., 1978).

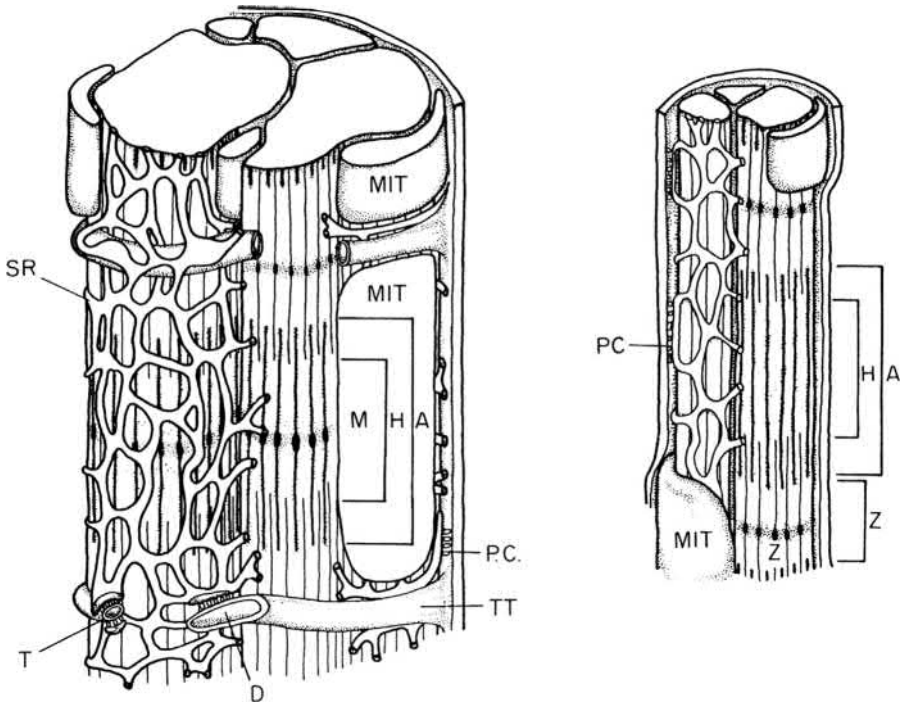

FIGURE 18.5 Comparison of mammalian (left) and avian (right) myocardial cells. The major distinguishing features of avian fibers are smaller cell diameters and absence of M bands and transverse (T)-tubules. *D*, diad junction; *M, H, A, I, Z*, bands of striated muscle; *MIT*, mitochondria; *PC*, peripheral coupling site; *SR*, sarcoplasmic reticulum; *T*, triad junction; *TT*, transverse tubule. *From Sommer and Johnson (1969).*

18.2.3.2 Excitation–contraction coupling

Excitation–contraction coupling describes how an electrical signal, the action potential (AP), traveling along the sarcolemma evokes calcium release from the SR in the region of the myofibrils, causing a change in actin–myosin interactions leading to muscle contraction. In cardiomyocytes, the transduction between the electrical signal and Ca^{2+} release from the JSR is affected by a transmitter which is, in fact, calcium itself. In the first step of this process, the AP causes voltage-gated L-type Ca^{2+} channels to open in the sarcolemmal membrane through a conformational change in the channels. Ca^{2+} enters the cell and diffuses to ryanodine receptor channels on the junctional processes where it acts as a ligand, opening Ca^{2+}-dependent Ca^{2+} channels which in turn release sequestered Ca^{2+} from the SR. The Ca^{2+}-dependent Ca^{2+} channels are Ryanodine receptor channels clustered in subcellular of Ca^{2+} release units (CRUs; Shiels and Galli, 2014). In the avian myocyte, CRUs are found either on the peripheral JSR near the L-type Ca^{2+} channels or at corbular JSR not associated with the sarcolemma. The release of Ca^{2+} from the corbular JSR CRUs is responsible for the rapid propagation of the Ca^{2+} signal to the center of the contracting myocyte (Sheard et al., 2019). This Ca^{2+}-induced Ca^{2+} release (CICR) is crucial for the physiological function of the bird heart in which the corbular JSR is the majority of the junctional SR. Furthermore, CICR allows exquisitely fine regulation of force generation in myocytes. Relaxation of the myocytes is due to the uptake of Ca^{2+} into the SR via sarco/endoplasmic reticulum Ca^{2+} ATPase (SERCA) and extrusion by Na^{+}/Ca^{2+} exchange. In cardiac muscle, contraction is "all or none," and force modulation must be done at the cellular level by regulating not only the amount of Ca^{2+} entering through the sarcolemma but also its effect on Ca^{2+} release from the SR.

18.2.3.3 Conduction system

The cardiac conduction system of the avian heart consists of the sinoatrial (SA) node, AV node, AV Purkinje ring, His bundle, and three bundle branches (Figure 18.6). Histologically, three types of cells are associated with the conducting system. (1) Pacemaker cells (P-cells) are small and spherical in shape and are found in both the SA and AV nodes. P-cells have the property of repetitive spontaneous depolarization. (2) Transitional cells (T-cells) are much smaller and have fewer microfibrils than cardiac muscle cells; their structure is intermediate between normal cardiac muscle cells and Purkinje fibers. (3) Purkinje fibers are large, elongated, brick-shaped cells containing few myofibrils. Many Purkinje cells, however, contain longitudinal fibers called intermediate filaments; these are part of the cytoskeleton, serving to maintain cell shape as the myocardium contracts. Purkinje cells may be up to five times the diameter of myocardial cells.

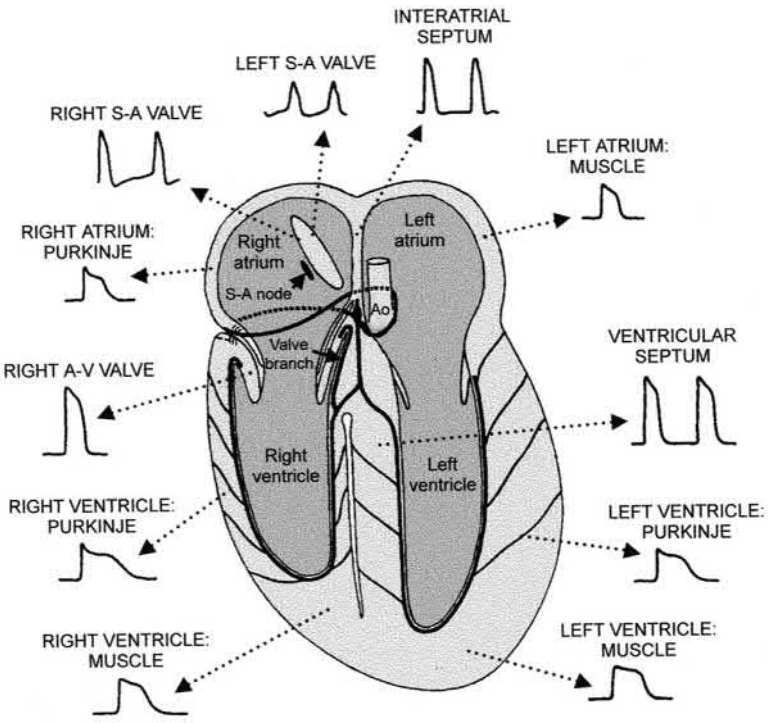

FIGURE 18.6 The Purkinje system of the bird heart and transmembrane action potentials recorded from cells at the indicated sites in chicken and turkey. *From Jones and Johansen (1972).*

The SA node is located close to the opening of the venae cavae into the right atrium although there is considerable species variation in birds. The SA node consists of P-cells and many T-cells enclosed in a loosely organized connective tissue sheath. The T-cells transmit impulses from the pacemaker to atrial muscle cells. The SA node morphologically, and perhaps physiologically, diffuses in birds, and the primary electrical pacemaker region appears to change position spontaneously within the node (Hill and Goldberg, 1980).

For normal cardiac function, all cardiac muscle fibers within a given cardiac chamber should contract more or less simultaneously, while it is essential that the atria contract before the ventricles. The wave of excitation initiated in the SA node is delayed at the AV node allowing the atria to empty before ventricular contraction begins. The electrical impulse which initiates contraction spreads through the atria and ventricles at rates in excess of 1 m s^{-1}, whereas conduction through the AV node is two to three orders of magnitude slower. Spread of excitation through myocardial muscle occurs from one muscle cell to the next as well as along specialized conducting pathways. Individual muscle cells are discrete entities, but they behave electrically as if they were all joined together to form a syncytium. This property results from low-electrical resistance in parts of the cell membrane where cell apposition is very close. Junctional complexes, the intercalated disks, commonly join myocytes end-to-end in avian myocardium, occurring at right angles to the long axis of the myofibrils. Intercalated disks consist of two components, desmosomes, which mechanically couple the cells together, and nexuses, which couple cells electrically. A nexus may be viewed as an array of unit electrical resistors with their number being inversely proportional to the electrical resistance between the cells (Sommer, 1983). Interestingly, there are few nexuses along the longitudinal axes of myocardial cells.

The speed at which the wave of electrical excitation propagates through the ventricles is enhanced by a specialized conducting system of Purkinje fibers but whether a specialized conducting system also exists in the atria of birds is controversial. In the atrium, waves of electrical and contractile activity proceed in the same direction, from the SA to AV nodes, which may mean that a specialized conducting system is unnecessary here. However, both atria contain Purkinje cells, and these have been described both morphologically and physiologically as being organized to preferentially direct the wave of activation toward the AV node (Davies, 1930; Hill and Goldberg, 1980). The contrarian view is that since the Purkinje cells in the atria are mixed diffusely among the normal myocardial cells then they may represent the remnants of an embryological anlage left over from the time when that anlage was building the ventricular conducting system (Sommer, 1983).

The atrial wave of excitation crosses to the ventricle through the AV node which, in birds, is a somewhat controversial structure because many morphological investigations have failed to locate it, although its presence

has been established in functional studies. In the chicken, the AV node is located in the right side of the base of the interatrial septum (Davies, 1930; Lu et al., 1993b; Ying et al., 1993) although in Indian fowl, *Pycnonotus cafer*, house sparrow, *Passer domesticus*, and in *Bubo bengalensis*, it is located in the left AV junction (Mathur, 1973). A right AV ring bundle with pacemaker properties is located in the right AV-junction associated with the AV node in the avian heart (Prosheva and Kaseva, 2016). The His bundle and its three bundle branches of Purkinje cells arise from the AV node. The right and left bundle branches emerge from the septum to form a network in the subendocardium of the right and left ventricles, respectively, penetrating the myocardium along the tracts of the coronary arteries (periarterial Purkinje fibers).

An indication of the theropod ancestry of birds can be inferred from the conducting system of the heart. Birds, unlike mammals, possess an AV ring of P-cells on the right side of the heart which runs up and around the right AV valve (Figure 18.7; Prosheva and Kaseva, 2016; and see Section 18.2.1.4). The middle bundle branch, after separating from the others, runs around the aorta and connects to the AV ring forming a figure eight (Lu et al., 1993b).

Purkinje cells conduct electrical impulses much faster than cardiac myocytes. In mammals, part of the reason for this high-conduction speed is that Purkinje cells lack a T-tubule system. T-tubules increase the surface area of the cell and therefore membrane capacitance (increasing the length of time a given amount of electrical charge will take to alter membrane potential); a high capacitance thus slows conduction velocity. However, in birds, there is no T-tubule system associated with either myocardial or Purkinje cells, yet the latter still conduct impulses at a faster rate. This is because conduction velocity varies directly with cell diameter, and avian Purkinje cells are much larger than myocardial cells. Furthermore, a higher conduction velocity may be fostered in Purkinje cells by intermediate filaments which serve to keep the cell round. Also, the electrical resistance between Purkinje cells is lower than that between myocardial cells because nexus size also increases with cell diameter, acting to further increase conduction velocity. Finally, in mammals with extremely large hearts (i.e., ungulates), the Purkinje cells within a bundle are tightly packed together and surrounded by an insulating membrane so that they behave electrically as a single fiber of a diameter equal to that of the whole bundle. Purkinje cells are likewise bundled in the avian heart but whether this enhances conduction velocity is uncertain because the bundles lack a connective tissue sheath and are therefore not insulated from surrounding tissues.

18.2.3.4 Electrophysiology

The Purkinje fibers follow the coronary arteries and therefore take a relatively short course through the thick left myocardium. This accounts for the rapidity of arrival of the wave of excitation at a given point on the surface of the left ventricular wall in the avian heart (Lewis, 1916). The sequence of depolarization is, according to Kisch (1951): right ventricle apex, right ventricle base, left ventricle base, and left ventricle apex. Moore (1965) mapped epicardial activation in the turkey and suggests that the apical third of the right ventricular epicardium is activated earliest, the upper basilar third is intermediate, and the pulmonary

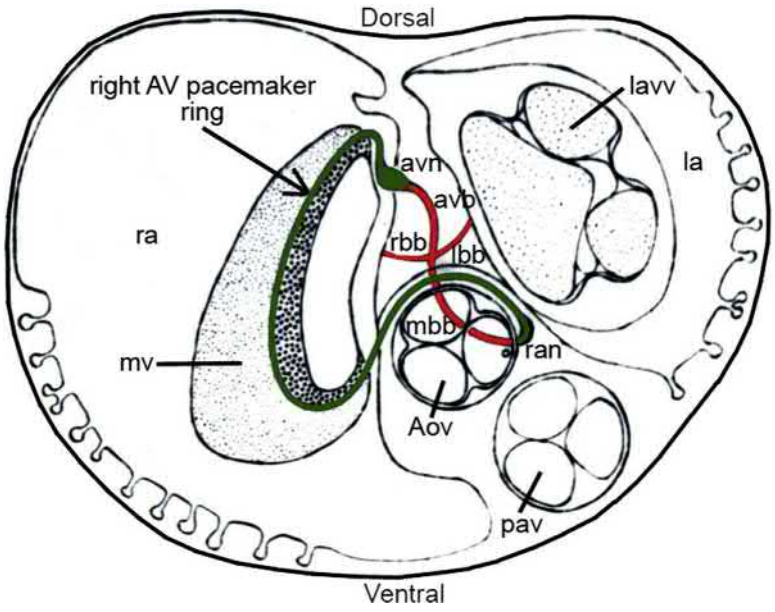

FIGURE 18.7 Diagram of the right atrioventricular pacemaker ring (green) and atrioventricular bundle (red) in the chicken heart. *Aov*, aortic valve; *avb*, atrioventricular bundle; *avn*, atrioventricular node; *la*, left atrium; *lavv*, left atrioventricular valve; *lbb*, left bundle branch; *mbb*, middle bundle branch; *mv*, muscular valve; *pav*, pulmonary artery valve; *ra*, right atrium; *ran*, retroaortic node; *rbb*, right bundle branch. *From Prosheva and Kaseva (2016).*

outflow tract is the last region activated in the whole heart. The anterior one-third of the septal region and the middle region of the left ventricle are activated before the basilar regions, the whole left ventricular epicardium being activated in 12.5 ms. Others have found somewhat different sequences of activation (Lewis, 1916; Mangold, 1919). Kisch suggests that the conducting system stimulates heart muscle only at places of direct contact between its terminal fibers and heart muscle and not along the entire course of the conducting system (Kisch, 1951) showing that subendocardial muscle is activated about 20 ms later than the earliest activated subepicardial muscle, which in turn suggests short cuts of the conductive system to subepicardial muscle. However, Davies (1930), Lu et al. (1993b), and Kharin (2004) suggest that since the bundle branches lack a fibrous sheath, there will be early and widespread propagation of the impulse in the septal region and thence along the bundle to all parts of the ventricles. Kharin (2004) mapping activation patterns with 64 electrodes in the chicken ventricle found earliest activation in both the right and left ventricle in a mosaic-like pattern. Repolarization of the ventricle follows a different pattern from that observed during depolarization (Kharin, 2004). Repolarization starts at the right ventricle apex and moves down to the left ventricle apex. This is then followed by repolarization of the left ventricle base and finally the right ventricle base.

The conducting system of the bird heart has been investigated by recording transmembrane potentials from cells in the heart of the chicken and turkey (Moore, 1965, 1967). The P-cells of the SA node, in the absence of any extrinsic influences, set the heart rate. Cells that function as pacemakers show a characteristic slow depolarization during diastole, the steepness of the depolarization being related to the degree of automaticity inherent in the cell (the fastest cells to depolarize drive the slower cells), whereas cells not spontaneously active show a steady membrane potential during diastole (Figure 18.6). APs recorded from the junction of the left SA valve with the sinus venosus show diastolic depolarization (prepotentials) with a slow transition to the ascending phase of the actual AP (Figure 18.6), in contrast to the relatively more rapid rise of the AP recorded in the right SA valve itself, indicating that cells in the right SA valve are triggered by the P-cells. The duration of APs recorded from ventricular muscle cells is longer than those recorded from atrial muscle cells (Figure 18.6). Purkinje fibers display a prominent sharp peak to their APs, which is followed by a distinct plateau, a feature not seen in APs from atrial or ventricular muscle cells. The duration of depolarization is also much longer in Purkinje fibers although diastolic depolarizations have not been recorded from avian Purkinje fibers. The longer duration of the Purkinje APs as compared with those of ventricular myocytes indicates a long refractory period which would tend to prevent extrasystole and possible fibrillation by assuring a concerted depolarization of the ventricular muscle (Moore, 1965). The myocytes of the right AV-valve also exhibit the characteristic depolarization of P-cells (Prosheva and Kaseva, 2015, 2016).

An electrocardiogram (ECG) shows the summed electrical activity of the heart (Figure 18.8). An ECG is recorded indirectly with electrodes placed on the body surface or just under the skin. (A direct ECG recording would be made by dividing the sternum and placing recording electrodes directly on the surface of the heart). In birds, as in mammals, three standard leads (I, II, and III) are used, following the model first conceived by Einthoven over 100 years ago. The body is a volume conductor of electricity, and the depolarization and repolarization waves that sweep across the heart can be reduced to a single electrical dipole. The dipole has magnitude (volts), direction, and sense (positive or negative), so it is a vector quantity. In Einthoven's concept, the cardiac vector is situated at the center of an equilateral triangle formed by the bipolar lead connections. Lead I connects across the thorax from the right (negative electrode) to the left (positive electrode) wing bases. Lead II is recorded between right wing base (negative electrode) and left thigh (positive electrode). Lead III is connected between the left wing base (negative electrode) and the left thigh (positive electrode). The arrangement of these leads is such that, in humans and many other mammals, the polarity of the recorded signals is positive. In contrast, in birds, the polarity of the major component of the ECG (ventricular contraction) is negative (Boukens et al., 2019, Figure 18.8).

There has been some controversy over what the typical avian ECG looks like (Figure 18.8). For instance, Kisch (1951) reported the presence of P, QRS, and T waves, whereas Mangold (1919) reported that the ECG of birds has no R component, but instead a deep S wave. Sturkie (1986) reported the presence of P, a dominant S, and T waves, a small R, but no Q wave. There is general agreement that it is absent in the chicken (Goldberg and Bolnick, 1980; Liu and Li, 2005), small in the turkey (McKenzie et al., 1971), and prominent in some duck ECGs (Cinar et al., 1996). Aside from being useful in monitoring heart rate, the ECG can also be used to access the timing of the various phases of the cardiac cycle, since components of the ECG can be identified with atrial (P wave) and ventricular (QRS or RS) depolarization as well as repolarization of the ventricles (T wave). The duration of the P wave is the period of atrial depolarization and repolarization while the P–R duration includes the conduction delay at the AV node. QRS or RS represents ventricular activation, and the T wave is the period in which the heart is completely depolarized. QT or RT duration represents the duration of a complete cycle of activation and relaxation of the ventricle. Most of these intervals are fixed, so it is primarily the period between the T and P waves (i.e., interbeat interval), which shortens and

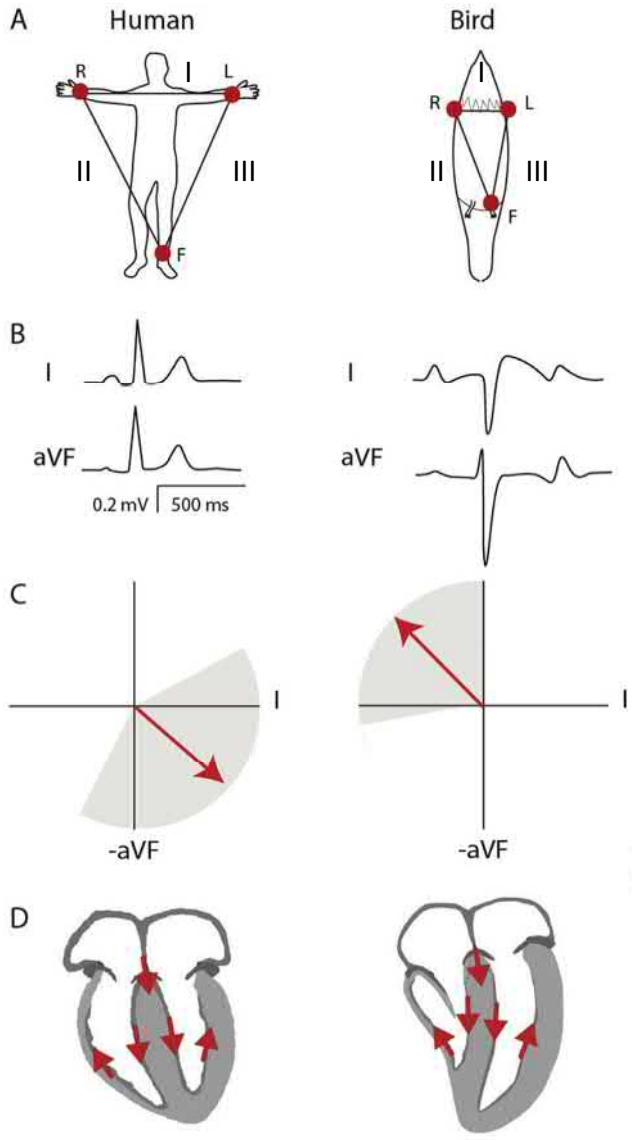

FIGURE 18.8 (A) Relationship of the three standard electrical leads (I, II, and III) as conceived by Einthoven in a human and a bird. (B) Electrocardiogram measured from Lead I and aVF of a human and a chicken (C). Vectorgrams based on Lead I and aVF for a human and a bird. (D). The pattern of ventricle electrical activation of the mammalian and avian ventricles. *From Boukens et al., 2019.*

lengthens with increases and decreases in heart rate, respectively. In fact, at very high-heart rates, the T wave of one beat may come to overlie the P wave of the next.

Bipolar recording of the standard limb leads means that the cardiac vector is projected along the line between the two electrodes (Figure 18.8). When all leads are used, then it is possible to reconstruct the orientation of the vectorcardiogram for any of the events of the cardiac cycle with respect to the plane of orientation of the leads. Standard leads lie in the frontal plane and, in mammals, the vectorcardiogram of the QRS is oriented downward (inferiorly) and to the left (Figure 18.8). In contrast, the vectorcardiogram of the QRS wave in the bird heart is close to −90 degrees, being oriented along the long axis of the body, and superior to the frontal plane. Hence, the QRS or RS wave is of negative polarity and barely represented in lead I with the highest voltages being recorded by leads II or III. The mean electrical axes of the P and T waves can be calculated in a similar fashion. By using other cardiac leads in addition to the standard limb lead I, Szabuniewicz and McCrady (1967) were able to determine the vectorcardiogram of the QRS or RS, P, and T waves of the heart in the chicken not only in the frontal plane (−77.1 degree) but also in the horizontal (+72.4 degrees) and sagittal (−55.4 degrees) planes.

As the mean electrical axis of the ventricular depolarization phase is negative while that for the repolarization phase is positive, then the QRS or RS component deflects downward or negatively while the T wave is upright or positive (Figure 18.8). Obviously, the heart does not markedly change its position in the chest with each beat. The waves deflect in opposite directions because depolarization causes the ventricular myocardium to become negative and repolarization drives the myocardium positive. Also, the time courses of these waves are different. Repolarization is slower than depolarization, so the T wave is more spread out than the QRS or RS wave. In this context, it should be noted that when the ECG is recorded just for purposes of monitoring heart rate, using a single pair of leads (usually II), the RS wave is often presented as deflecting positively. This is achieved by reversing the polarity of the lead II bipolar electrodes (inverting Einthoven's triangle, Figure 18.8) and is done for artistic reasons.

Further interpretation of the ECG of birds is complicated by variability in electrode recording sites, anatomical differences between species, and the absence of a large bank of data such as has been accumulated for humans and, to a lesser extent, other mammals. In fact, it seems most unlikely that rigorous, detailed investigation of the ECG of birds will ever be used for clinical diagnosis. Boulianne et al. (1992) suggest that only diseases that cause a shift in position of the heart in the torso, and therefore alter the MEA, can be successfully diagnosed by two-dimensional electrocardiography.

18.3 General circulatory hemodynamics

The three major constituents of the pulmonary and systemic circulations are (1) the arteries or distributing vessels, (2) the capillaries or exchange vessels, and (3) the veins which act as storage and return vessels. Arterioles and venules are muscular vessels located upstream and downstream of the capillary beds, respectively. They are regulatory vessels,

directly controlling blood flow distribution and indirectly controlling exchange of materials across capillary walls by adjustment of capillary pressure.

The major arteries bifurcate many times before the capillary beds and at each bifurcation vascular resistance increases (McDonald, 1974). Volume flow in the parent and daughter vessels remains the same in the steady state but flow velocity in the daughters falls to about 80% of that in the parent vessel. Therefore, the sum of the cross-sectional areas (πr^2, where r is internal radius) of both daughter vessels is greater than that of the parent vessel by about 25%. Hence as the vessels divide, flow velocity falls resulting in exceptionally low-capillary circulation flow velocity. This allows adequate time for exchange of blood gases, nutrients, and metabolites with the surrounding cells.

Pressure, generated by ventricle contraction, drives blood flow around the circulation. Poiseuille's law relates volume flow (Q) to the pressure drop ($P_1 - P_2$) along a tube of radius (r) and length (L) during steady flow, as follows:

$$\dot{Q} = (P_1 - P_2) \times \frac{\pi r^4}{8\,\mu L} \tag{18.1}$$

where μ is blood viscosity. Rearrangement of Eq. (18.1) provides a somewhat more familiar form,

$$\frac{\pi r^4}{8\,\mu L} = P_1 - P_2 \frac{}{\dot{Q}} \tag{18.2}$$

because the term on the left-hand side of Eq. (18.2) is vascular resistance (R). Consequently,

$$R = P_1 - P_2 \frac{}{\dot{Q}} \tag{18.3}$$

or, for the whole body, total peripheral resistance (TPR, kPa ml^{-1} min),

$$TRP = \frac{MAP - MVP}{CO} \tag{18.4}$$

where MAP is mean arterial pressure (kPa), MVP is mean venous pressure (kPa), and CO is CO (ml min^{-1}). In order to compare animals of different sizes, CO may be expressed on a unit weight basis (i.e., ml min^{-1} kg^{-1}).

Because the length (L) of any vascular channel is anatomically fixed and blood viscosity only varies by two to three times, the radius of the vessels dominate vascular resistance (Eq. 18.2). Consequently, with a given pressure drop, halving vessel radius will reduce flow to one 16th, as shown in Figure 18.9, for a change in vessel radius from, for instance, two units (center profile) to one (left profile). This has important implications for the control of blood flow distribution.

Poiseuille's Law (Eq. 18.1) applies to steady flow but in the major arteries flow is highly pulsatile. In pulsatile flow, due to the inertia of the blood and high heartbeat frequencies, flow amplitude may no longer vary linearly with the pressure gradient. Nevertheless, the extent of the deviation from Poiseuille's law can be assessed from a nondimensional constant α (Womersley, 1957)

$$\alpha = r\sqrt{\frac{2\pi f \rho}{\mu}} \tag{18.5}$$

where r is radius, f is heart rate, ρ is blood density, and μ is blood viscosity.

When $\alpha < 0.5$ for the fundamental frequency (i.e., heartbeat frequency), the phase lag is negligible and flow conforms approximately with that predicted by Poiseuille's equation. Calculations for the aorta of a duck give a value for α of 6.0–7.0 for the fundamental frequency (about 3 sec^{-1}) so that estimation of flow by the Poiseuille formula is not reliable. However, it is obvious that for any given heart frequency, the value of α is directly dependent on the size of the vessel. Hence, in the femoral artery, α is certainly below 1, and flow will vary approximately linearly with the pressure gradient in this vessel. The vessels of

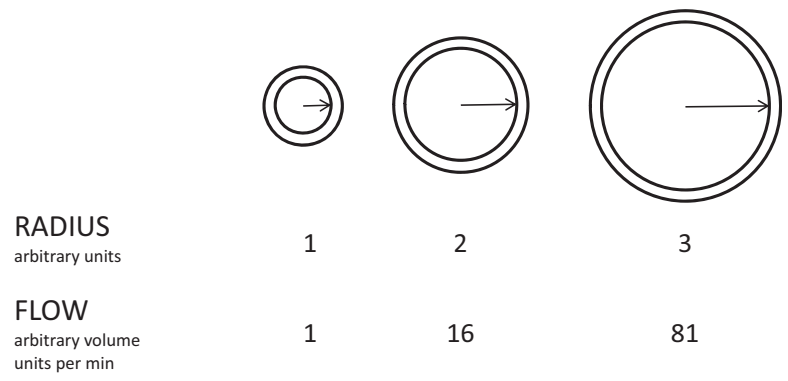

FIGURE 18.9 Effect of change in vessel radius as shown by the length of the *arrow*, on fluid flow with a constant driving pressure. Flow decreases in proportion to the fourth power of the decrease in radius. Radius dimensions and relative flow volumes are in arbitrary units.

the capillary circulation are small and α will be likewise, so application of Poiseuille's formula to this vascular bed would appear, superficially, to be most appropriate. Unfortunately, blood viscosity, which can be regarded as a constant in larger vessels, may vary unpredictably in vessels of capillary size (Section 18.4.2). Therefore, caution is the watchword when applying steady flow formulations to flow driven by an oscillating pump but, even so, pulsatile flow has a mean, steady flow component and Poiseuille's law can be applied to this component, as in calculations of total peripheral resistance (Eq. 18.4).

18.4 The vascular tree

18.4.1 Arterial system

18.4.1.1 Gross anatomy

At least six pairs of aortic arches appear in the embryos of all vertebrates, recapitulating their aquatic ancestry. In birds, not all arches are present at one time and some are extremely transitory, such as the fifth pair of aortic arches which make their appearance last. Only three arches persist in the adult, represented by the carotid artery (third arch), the aorta (fourth arch), and the pulmonary artery (sixth arch). In terrestrial vertebrates other than birds and mammals, both left and right branches of the fourth aortic arch are retained whereas only the right persists in birds and the left in mammals. In some avian species, a remnant of the left aortic arch may remain as a solid core of cells while in a few others, such as the belted kingfisher (*Ceryle alcyon*), the left arch remains patent and functional although it loses its connection with the root of the aorta (Glenny, 1940). In an interesting series of experiments, Stéphan (1949) demonstrated that ligation of the right aortic arch in the embryo causes the left to develop, as in mammals. Furthermore, wall shear stress differences in the embryonic right and left aortic arch leads to differential mechanosensitive gene expression in the two embryonic aortic arches (Karakaya et al., 2018). These findings suggest that the retention or disappearance of aortic arches is dependent upon hemodynamic conditions during development, and it may be that the persistence of the right arch simply results from the unique development of the ventricular outflow tract in birds.

The first major vascular bed supplied by the aorta is that of the heart. The coronary arteries, supplying the nutritional and respiratory circulation of heart muscle, arise from the ascending aorta close to the heart (Section 18.2.1.5). The ascending aorta then gives rise to two very large brachiocephalic trunks (Figure 18.10), supplying blood to the head, wings, and flight muscles. Each brachiocephalic vessel is usually larger in diameter than the

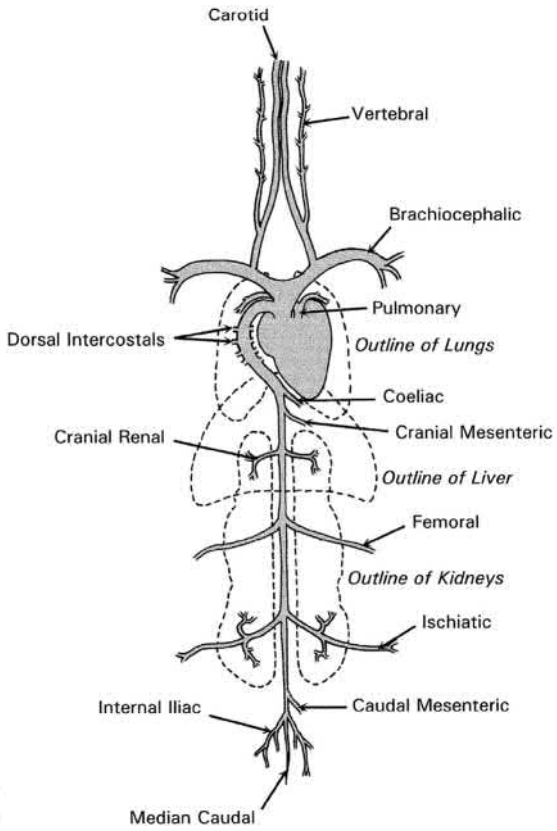

FIGURE 18.10 The major systemic arteries in the bird.

continuation of the aorta, reflecting the higher blood flow rates in the brachiocephalics.

All the arteries of the head and neck are branches of the carotid arteries. Surprising variation exists in the pattern of the carotid arteries close to the heart. The most common arrangement is two vessels of equal size running side by side (Figure 18.10). Other patterns are: (1) a single artery formed by fusion of both carotids (herons, bitterns, and kingfishers); (2) a single vessel due to loss of the right (passerines) or left (plovers) carotid; or (3) two arteries of unequal size (flamingos, sulfur-crested cockatoo).

Blood flow to the brain must not be interrupted or impairment of brain function rapidly ensues. The carotid arteries lie in a groove in the base of the neck vertebrae close to the axis of rotation and are therefore protected from possible obstruction due to compression from neck movements. Other safety measures are provided by anastomoses between the carotid and vertebral arteries and, at the base of the brain, by either an X-, I-, or H- shaped junction between the carotids. This intercarotid anastomosis has been found in all species of bird except those of the suborder Tyranni (Baumel and Gerchman, 1968). Birds do not possess a cerebral arterial circle of Willis comparable to that of

mammals but, since the intercarotid anastomosis is relatively large in many cases, it may represent a more effective collateral circulation than the mammalian arterial circle. Blood to the wings and flight muscles is supplied by the subclavian arteries. Each subclavian divides into two branches, the brachial (wing) and pectoral (flight muscles).

The descending aorta runs caudally, ventral to the vertebral column, giving off paired intercostal and lumbar arteries. Blood is supplied to organs within the abdomen and legs by the following vessels, originating from the descending aorta (see Figure 18.10):

Celiac artery	Liver, spleen, glandular stomach, gizzard, intestine, pancreas
Cranial mesenteric artery	Most of intestine, pancreas
Renal arteries	Kidneys (anterior portion), testes
Femoral arteries	Legs
Ischiatic arteries	Middle and posterior portions of kidney and legs; uterine region of oviduct
Caudal mesenteric artery	Rectum and cloaca
Internal iliac arteries	Walls of pelvis; oviduct
Caudal artery	Tail, terminal branch of aorta

There are in effect three pairs of renal arteries in birds, one pair arising from the aorta and two from the ischiatic arteries. However, in the gray heron (*Ardea cinerea)*, one pair of renal arteries arises from the femoral arteries instead of the ischiatics.

The ischiatic artery is the major vessel supplying the leg. At the level of the knee, it meets and joins the femoral artery to form the popliteal artery. This artery, passing into the lower leg, divides to form the anterior and posterior tibial arteries. In the tarsal region of the leg and in the axillary region of many birds, there are arteriovenous networks of vessels referred to as *rete mirabile*, particularly prominent in wading and aquatic birds (Midtgård, 1981). These structures serve as heat exchangers, since warm arterial blood is brought into close proximity to venous blood that has traversed the distal parts of the limbs and is therefore colder. The countercurrent arrangement of blood flow ensures that heat can be transferred from arterial to venous blood all along the length of the artery and vein apposed in the *rete*, thereby reducing heat loss to the environment by reducing the temperature of arterial blood flowing through peripheral thinner sections like the web of the foot or the wing.

18.4.1.2 Functional morphology of the arterial wall

The large arteries have two main functions. First, they serve as low-resistance conduits carrying blood to the arterioles for distribution to the peripheral vascular beds. Second, the whole arterial system serves as a pressure reservoir or *Windkessel*, accepting the volume of blood ejected by the heart and converting the highly pulsatile input into a steady flow of blood through the capillary beds. The *Windkessel* results from wall elasticity, particularly of those vessels closest to the heart.

The central arterial vessels are "elastic" while the more peripheral ones, certainly distal to the second order of branching, are "muscular." In elastic arteries, the vast majority of the wall is made up of layers of smooth muscle embedded in elastin fibers alternating with layers of collagen. One layer, composed of a combination of muscular, elastic, and collagen fibers, forms a single lamellar unit within the wall. Large numbers of concentric lamellar units make up the bulk of the wall of elastic arteries of pigeon, chicken, and the mute swan (*Cygnus olor*; Bussow, 1973). Interestingly, the lamellar units do not form complete cylinders around the vessel. This is particularly obvious in vessels very close to the heart where an individual lamella may extend around only one quarter, at most, of the vessel circumference.

Wall structure of the muscular arteries is very different. Muscular vessels consist largely of circumferentially arranged smooth muscle cells with elastic fibers distributed, either singly or in bundles, as a wide-meshed plexus between the muscle cells (Hodges, 1974). The collagenous components are transferred to the outer layer of the wall. An interesting embellishment of the normal structure of muscular arteries occurs in the cranial mesenteric artery of the chicken and turkey (Ball et al., 1963). This vessel is invested by longitudinally arranged smooth muscle fibers, the thickness of this layer being approximately the same as that of the circumferentially oriented smooth muscle within the wall proper. The functional significance of the external muscle layer is unclear, but it may serve to shorten the vessel to accommodate changes in its position brought about by gut movements.

The elastic arteries include the aortic arch and its major branches, the thoracic aorta up to about the level of the celiac artery, and the extrapulmonary portions of the pulmonary arteries, while all branches of the abdominal aorta as well as the caudal portion of the aorta itself are muscular. In most regions of the arterial tree, the change from an elastic to a muscular wall occurs rather abruptly, usually at a branch site. An exception to this is the aorta itself. In the aorta, the elastic and muscular portions are separated by a segment of the vessel extending from the celiac artery to the ischiatic arteries, whose wall structure fits neither description very well. Furthermore, in both the pigeon and turkey, the wall in this region is transversely asymmetric with a thick, muscular ventral wall, and a thin elastic dorsal wall.

The arteries *in vivo* expand and recoil with every heart beat although this behavior is seldom mimicked in *in vitro* experiments designed to study vessel mechanics. Instead,

the static rather than dynamic elastic behavior of the arterial wall is usually investigated. Essentially, a short length of excised blood vessel is inflated from a syringe and the pressure change induced by a given volume change is noted. These "pressure–volume loops" give an immediate and compelling view of how arterial elasticity changes with the degree of inflation.

Furthermore, by using blood vessels from different areas of the body, regional variations in elasticity are revealed. Pressure–volume loops are usually J-shaped, showing that the more a vessel is stretched the more resistant it becomes to further stretch (Speckmann and Ringer, 1966). The collagen fibers in the vessel wall inhibit expansion at high pressures, whereas the properties of elastin dominate at the lower pressure on the curve. It is the elastin compliance and the collagen stiffness working in concert that allows uniform and smooth expansion of the vessel wall over a range of distending pressures without formation of aneurysms. In contrast, a wall in which the properties of extension remain constant across the range of distending pressures would be prone to aneurysm formation. Rubber has a straight rather than J-shaped response to distension and aneurysms always occur in the wall of cylindrical balloons when they are inflated.

When a blood vessel is inflated, more pressure is required to expand it than is recovered during recoil of the elastic walls. The ratio between the energy recovered in deflation to that expended in inflation is a measure of the "resilience" of that vessel. Surprisingly, "resilience" is similar for both thoracic (elastic) and abdominal (muscular) aortae of the turkey. Over the range of arterial pressures encountered in turkeys, "resilience" lies between 85% and 87%, values well above those of most mammals and approaching those obtained for invertebrate blood vessels. In one sense, the higher the "resilience" the better because most of the energy cost of stretching elastic vessels with each cardiac ejection will be returned by elastic recoil on deflation. Unfortunately, if the "resilience" is too high, then the vessels may go into uncontrolled oscillations (resonance) particularly at the high repetition heart rates seen in many birds. Obviously, vascular engineering in birds is close to the edge.

Pressure–volume loops reveal characteristics specific to particular segments of whole vessels, whereas the properties of the materials making up a vessel wall are revealed by stress–strain curves (Figure 18.11A). Stress is the deforming force divided by the area of the vessel wall over which it is applied while strain is the ratio of the stretched radius to the unstretched radius of the vessel. Stress–strain curves for the ascending and descending aortae, the brachiocephalic arteries, and the thoracic aorta of the duck (*A. platyrhynchos*) are shown in Figure 18.11A. The stress–strain relationship for the abdominal aorta lies to the left of that for the other, more central, vessels indicating that, as in the turkey, the abdominal aorta is stiffer than the other vessels, a finding which would be expected given that the abdominal portions of the aortae of duck and turkey have more collagen than do more central segments of this vessel.

The slope of the line of a stress–strain curve is the elastic modulus of the material making up the blood vessel wall, but, since the slopes for blood vessels are nonlinear, the elastic modulus is continually changing. The incremental elastic modulus describes the elastic modulus for a small increment in strain (Bergel, 1961). Incremental elastic moduli for the duck aorta, which are similar to those for the turkey aorta (Speckman and Ringer, 1964), are shown in Figure 18.11B. The moduli for the abdominal aorta are well above that for the thoracic, confirming that the former is stiffer than the latter. Nevertheless, these moduli are one to two orders of magnitude below those obtained from arteries in corresponding parts of the mammalian vascular tree. In mammals, the lamellar units in the wall form complete cylinders so that those laminae containing primarily collagen must be stretched to the same extent as the more distensible muscular laminae. Consequently, such rigid laminae are more important in determining the degree of extension of the wall. However, in birds, arterial lamellar units do not form complete cylinders so there is some "series" coupling between the rigid and elastic components of the wall which allows more distensible laminae to be extended somewhat independently. Avian blood vessels have much thicker walls than mammalian vessels of the same diameter, thus compensating for their lower elastic modulus (Bussow, 1973).

18.4.1.3 Relationship between arterial pressure and flow

Each heartbeat sends a pulse through the arterial system which arrives later at sites more distal to the heart. The velocity at which the pulse wave travels is lowest in the most distensible vessels and increases in the stiffer peripheral vessels. In ducks, pulse wave velocity increases from 4.4 ± 0.8 m s^{-1} in the aortic arch to 11.7 ± 1.2 m s^{-1} in the abdominal aorta, with the major increase in velocity occurring in the thoracic aorta (Langille and Jones, 1975).

When the pulse transit time occupies a considerable proportion of each cardiac cycle, then significant phase changes occur between the pressure and flow pulses at different arterial sites. In ducks, the time taken for the pulse to travel from the heart to the distal end of the abdominal aorta is around 20 ms, which is about 5–10% of the cardiac cycle (Langille and Jones, 1975). Consequently, there are marked changes in the waveform of the systemic pressure pulse as it travels through the arterial system (Figure 18.12; Langille and Jones, 1975; Ruiz-Feria et al., 2004). Both pulse amplitude and the contour of the pulse waveform are altered, with pulse pressure increasing by about 25%. This

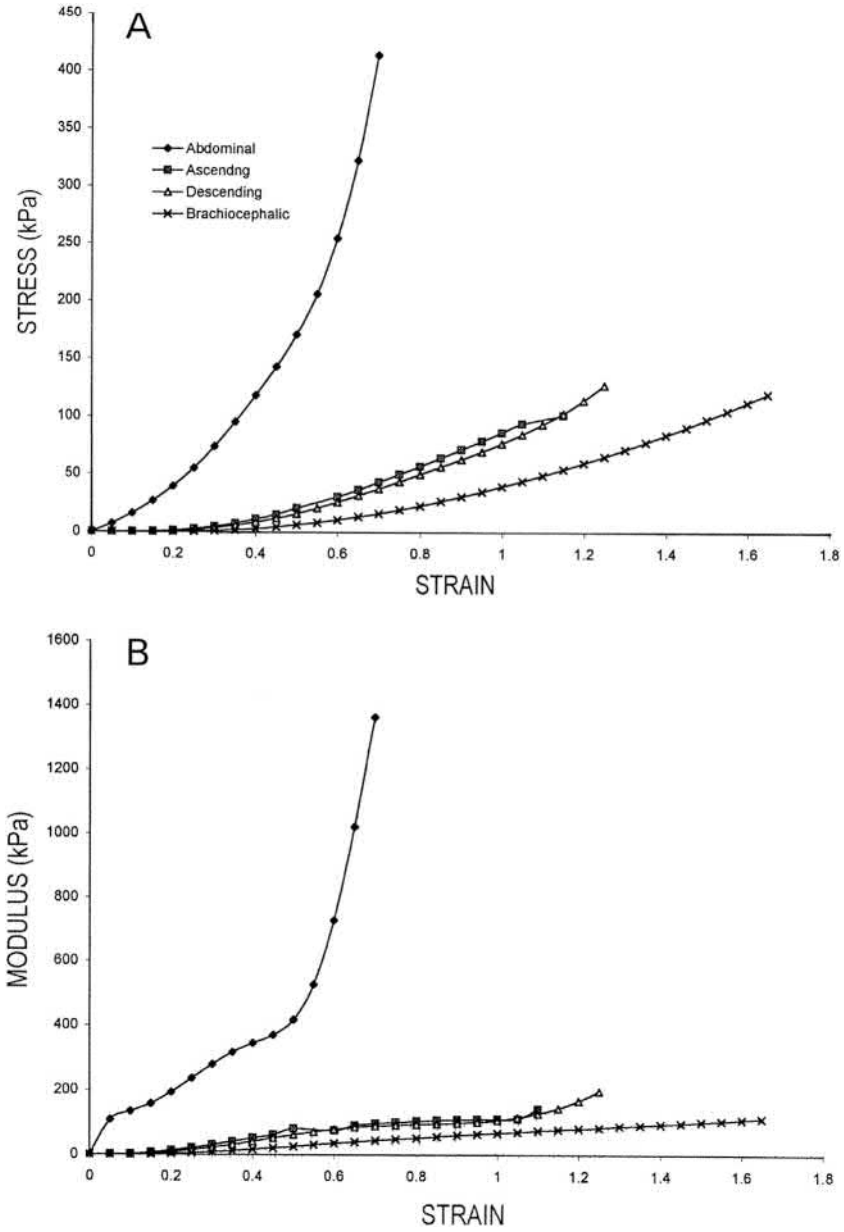

FIGURE 18.11 (A) Stress-strain curves for the blood vessel wall from four regions of the aorta in a duck (*Anas platyrhynchos*). (B) The static elastic modulus of these vessels derived from data in A. *From Braun and Jones (unpublished data).*

peaking of the pressure pulse results from a marked increase in the systolic portion with little change in the diastolic portion (Figure 18.12).

Peaking of the pressure pulse is due to wave transmission effects, primarily wave reflections. All forms of wave motion can be reflected by physical changes in the system they are traveling through. When such changes occur within the arterial system, incident pressure and flow waves will be reflected back toward the heart. These physical changes can be discrete discontinuities, such as those due to arterial branching (McDonald, 1974) or continuous variations in wall compliance due to an increase in arterial stiffening toward the periphery (Langille and Jones, 1975, 1976). However, the major reflecting site seems to be the terminal vascular bed. From this site, pressure and flow pulse waves are reflected back toward the heart to interfere, destructively or constructively, with the incident wave generated by cardiac contraction. This interference means that pressure and flow waves recorded simultaneously at any one site in the arterial system will be quite unlike those recorded at another. In a reflectionless system, pressure and flow pulses sampled at any given site should look similar to those recorded anywhere else in the system.

An essential question concerns the nature of the termination that the peripheral vascular beds present to outgoing

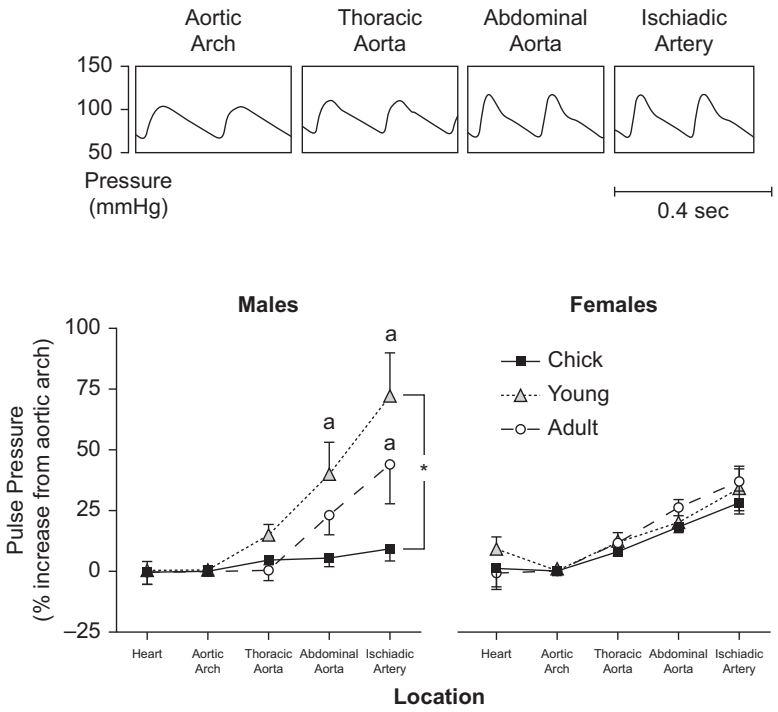

FIGURE 18.12 Pressure waves recorded simultaneous along the aortic arch, thoracic aorta, abdominal aorta, and the ischiadic artery. (A) Amplification and distortion of the pressure wave occurs during propagation along the aorta. (B) In all ages of chicken, pulse pressure increases with distance from the heart. *From Ruiz-Feria et al. (2004).*

pressure and flow waves. Peripheral beds are "closed" terminations if they present a relatively large impedance to pulsatile flow; they are "open" if they present a relatively low impedance. In higher vertebrates, reflections produce large oscillations in peripheral pressures that drive small oscillatory flows through the terminal vascular beds (Figure 18.12), indicating a high-terminal impedance; i.e., of the "closed" type. Hence, the pressure should be reflected at the closed end without a phase shift while, to satisfy the condition that high pressure oscillations are required to drive low-oscillatory flows through a high-terminal impedance, the reflected flow wave should be inverted. That is, the reflected wave should be 180 degrees out of phase with the incident wave. However, how much of the incident wave reaches the termination (because the incident pulse is attenuated, especially in the smaller vessels, as it propagates through the system) and how much of the reflected wave gets back to the heart (since its amplitude is also reduced by damping) is still a matter of speculation.

The reflection coefficient (that portion of the incident wave reflected by the terminal vascular beds) is extremely sensitive to the state of the peripheral vasculature. Under resting conditions, up to 80% of the incident wave may be reflected. Intense vasoconstriction occurring in ducks during forced diving or when voluntarily diving birds are trapped underwater and unable to surface causes 100% of the incident wave to be reflected. In contrast, vasodilatation of peripheral vascular beds, occurring during exercise or hemorrhage, may reduce the reflection coefficient to zero.

If the transit time of either pressure or flow waves through the arterial system becomes less than 5% of the cardiac cycle, then reflection effects on the shapes of these waves are not obvious. Nevertheless, reflections occur but they are diffuse, the pressure wave bouncing back and forth between the heart and periphery, until damped to extinction. In humans, atherosclerosis causes a loss of pressure pulse amplification as the pulse travels through the arterial system (O'Rourke et al., 1968); similar observations have been made in the turkey, *Meleagris* (Taylor, 1964), where atherosclerosis is very common (Ball et al., 1972; Manning and Middleton, 1972). Loss of pulse amplification in atherosclerosis results from a generalized stiffening of the major arteries, which acts to speed pulse wave propagation and thereby minimize wave transmission phenomena.

The hummingbird is among the smallest homeothermic vertebrates. Is it possible to predict the hemodynamics of the hummingbird from our knowledge of hemodynamics in the duck? Assuming pulse wave velocity is unaltered, then for similar conditions to hold in both hummingbird and duck, heart frequency rate (f_H) must increase in the same proportion as the linear dimension (L) of the animal decreases with reduction in body mass (M_b). For birds, the allometric equation relating f_H and M_b is $f_H = k_1 \bullet M_b^{-0.28}$ (Grubb, 1983; and see Section II,B), while $L = k_2 \bullet M_b^{-0.33}$ where k_1 and k_2 are constants.

According to this analysis, a hummingbird 400 times smaller than a duck will have a f_H 5.3 times higher but L will decrease nearly seven times. Even at the highest f_H

reported for the giant hummingbird (*Patagona gigas*) of 1020 beats min^{-1} (Lasiewski et al., 1967), pulse transit time as a proportion of the cardiac interval will be considerably less than that in the duck and reflection effects on pulse wave shapes will probably not be obvious (Jones, 1991).

18.4.2 Capillary beds

18.4.2.1 Gas exchange

Systemic capillaries form a vital functional interface between the blood and systemic tissues of birds. The diffusive pathway between erythrocytes in capillary blood and mitochondria in surrounding tissue represents the last in a series of resistances in the oxygen transport cascade from the lungs. Oxygen and carbon dioxide move between the systemic capillary blood and the surrounding tissue mitochondria by simple diffusion. Therefore, the diffusion distance from erythrocyte to mitochondrion and the partitioning of diffusion resistance along this route is of immense physiological interest. The concept of a capillary domain, a volume of tissue whose oxygen demands could potentially be satisfied by diffusion from one capillary, was first expounded by August Krogh in 1914 and remains a valuable concept in understanding gas exchange in muscle tissue (Krogh, 1919). A simple explanation of the factors important in capillary blood–tissue gas exchange, based on this model, is to be found in West (2008).

Studies on the systemic capillaries of birds, in particular those of flight muscle, have been dominated by two interesting themes: (1) the high workload of the avian pectoralis major muscle during flight, reflected in an increase in oxygen consumption of about five times that at rest (Butler et al., 1977), suggests that the functional anatomy of the pectoral muscle capillaries may reveal adaptations to both high tissue oxygen demand and mechanical tissue deformation during sarcomere shortening; and (2) some species fly at high altitudes (Hawkes et al., 2011; see Section 18.6). Therefore, there are specific adaptations in capillary density or geometric arrangement that facilitates the delivery of oxygen to the working pectoralis muscle in the face of a relatively low P_aO_2 (the pressure head for diffusion at the arterial end of systemic capillaries) caused by reduced atmospheric partial pressure of oxygen.

Three parameters may be considered in determining the capillarity of muscle. These are the number of capillaries per muscle fiber, the cross-sectional area of muscle fibers, and the geometrical arrangement of capillaries around each fiber (Snyder, 1990). Gray et al. (1983) found that sections of pure slow red muscle fibers from the anterior latissimus dorsi of chicken had 25% more capillaries per square millimeter than did sections of fast white fibers from the posterior part of this muscle. However, in six other species of birds ranging in mass from 11g to 6.2 kg, there was no significant correlation between fiber diameter and capillary number per fiber in slow red fibers and fast white fibers of the anterior and posterior latissimus dorsi respectively. Thus, tissue capillary density decreased in muscle with larger fibers. Snyder (1990) estimated the maximum diffusion distance from capillary to mitochondrion in slow red fibers and fast white fibers of the gastrocnemius muscle to be on average 18.4 and 36.5 μm, respectively. Torrella et al. (1999) found maximum diffusion distances ranging from 16.8 μm in the oxidative fibers of the mallard pectoralis to 34.4 μm in the glycolytic fibers of the mallard gastrocnemius. These are similar to the values obtained in mammals, suggesting that diffusion distance has been highly conserved in vertebrate evolution. Increasing the number of capillaries per fiber appears to produce diminishing returns such that beyond two capillaries per fiber there do not appear to be further measurable reductions in diffusion distance. In contrast to the situation in neonatal mammals, the capillary-to-fiber ratio in bird muscle appears to be fixed around hatching. Because the fibers hypertrophy during development, diffusion distances are shortest in newly hatched chicks—some 18 μm (Byers and Snyder, 1984).

The benefits conferred by reducing erythrocyte-to-mitochondrion diffusion distance depend on assumptions made about how the resistance to oxygen diffusion is distributed between source (blood) and sink (mitochondrion). It has been argued that the capillary-to-tissue interface represents the major resistance (Gayeski and Honig, 1986), in which case reducing the overall diffusion distance would be of limited effectiveness compared with increasing the area of this interface. However, compared with low-altitude birds, the mitochondria in flight muscle of the high-altitude flying bar-headed geese are found more toward the sarcolemma and capillaries (Scott et al., 2009).

Compared with the geometric arrangement in mammalian hindlimb muscle, there are a larger number of capillary branches running perpendicular to the long axis of muscle fibers in pigeon pectoralis muscle (Mathieu-Costello, 1991, Figure 18.13). These branch from capillaries running parallel to the long axes of the muscle fibers. The branch points move closer together as the pectoralis muscle shortens on the power stroke, but the perpendicular orientation of the branches to the long axis of the muscle fibers does not change appreciably during contraction. The short segments of capillary parallel to the muscle fiber between these branches bow as the muscle shortens, but do not become particularly tortuous. The branches perpendicular to the long axis of the muscle fibers run around the circumference of the fibers, and this arrangement together with their high density ensures that there is an effective envelope of capillary blood surrounding portions of the fibers. This results in very effective blood–tissue O_2

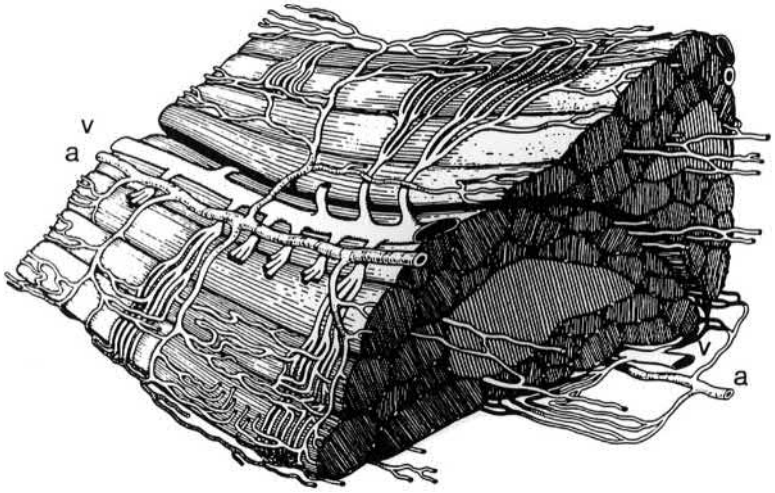

FIGURE 18.13 Schematic diagram illustrating the microvascular geometry in the pectoralis muscle of the pigeon. For clarity, the width and number of capillary branches running perpendicular to the long axis of the muscle fibers have been reduced. *a*, artery; *b*, vein. *From Mathieu-Costello et al. (1994).*

transfer (Ellis et al., 1983). Such an arrangement of capillary branches may compensate for the unfavorable rheological properties of avian blood compared with mammalian blood; these properties include relatively low-red cell deformability and a low-capillary hematocrit.

Flying hummingbirds have the highest mass-specific metabolic rate of any vertebrate, and hummingbird flight muscles have the highest oxygen demand of any vertebrate skeletal muscle. It would be expected, therefore, that the adaptations for effective gas exchange at the capillary level would be most obvious in these birds. These could include a reduced diffusion distance from the capillary to the mitochondria or possibly an increase in the capillary-to-fiber contact area. Increases in either of these factors would increase the flux of respiratory gases for a given drop in PO_2 across the capillary− mitochondrial diffusion distance. The ratio of capillary surface area to muscle fiber surface area is about twice as large in hummingbird flight muscle as in the rat soleus muscle, with similar mitochondrial density in the two muscles (Mathieu-Costello et al., 1992). Therefore, according to Fick's law, the rate of O_2 diffusion into the avian fiber would be about double that in the rat, all other factors being equal. This supports the idea that the large area of the capillary−muscle fiber interface in avian flight muscle plays an important role in enabling these muscles to maintain an extremely high-oxygen usage during flight. The respiration rates of muscle mitochondria in working hummingbird flight muscle are about double those in the locomotor muscles of mammals. Interestingly the size of this interface in the pectoralis muscle of the only actively flying mammal, the bat, is similar to that in hummingbird flight muscle.

The basic structure of the capillary network in the hummingbird is similar to that in pigeon flight muscle, although capillary density tends to be higher in the hummingbird. This results from the smaller cross-sectional area of the muscle fibers (one-half for aerobic and one 10th for glycolytic) rather than from a greater number of capillaries surrounding each fiber (Mathieu-Costello et al., 1992). The smaller cross-sectional area of fibers may be an adaptation to reduce the diffusion distance from capillary blood to the mitochondria. However, some experimental and theoretical evidence shows that the main drop in PO_2 occurs across the resistance offered by the capillary−fiber interface and PO_2 then declines more slowly, largely because of myoglobin facilitated diffusion (Honig et al., 1991). Thus, a large contact area between capillary and fiber is probably a more important factor in effective oxygen delivery than a short path between capillary and mitochondrion. This is particularly true for flight muscle in both birds and bats where fiber myoglobin content, and therefore the potential for facilitated diffusion, is high. Interestingly, a comparison of actively flying and sedentary pigeons showed little effect of flight conditioning on capillary−fiber relationships. Wild pigeons had a greater aerobic capacity than sedentary birds, achieved by a 30% greater cross-sectional area of aerobic fibers in the pectoralis together with a higher density of mitochondria. However, the capillary−fiber ratio was similar, as was capillary length−fiber volume at a given mitochondrial density (Mathieu-Costello et al., 1994). This finding is consistent with the results of Snyder and Coelho (1989), who caused hypertrophy of the right anterior latissimus dorsi of chickens by taping weights to the humerus. They found that the increased number of capillaries per fiber just matched fiber hypertrophy and concluded that muscle growth was the primary determinant of capillarity.

18.4.2.2 Microvascular fluid exchange

Capillary fluid balance is maintained by the dynamic interaction between hydrostatic and osmotic forces acting across the capillary wall, as first described by Starling over

100 years ago (Starling, 1896). Starling's original formulation has been modified and refined by Landis (1927) and Kedem and Katchalsky (1958), yielding the following equation to describe microvascular fluid exchange:

$$J_V = K_{FC}[(P_c - P_T) - \sigma_d(\pi_P - \pi_T)],$$

where J_V is net volume flow across the vascular wall, K_{FC} is capillary filtration coefficient, P_c and P_T are capillary and tissue fluid pressures, respectively, (π_P-π_T) is colloid osmotic pressure (COP) difference between plasma ($_P$) and tissue ($_T$), and σ_d is the osmotic reflection coefficient.

In the steady state, the capillary blood pressure opposes the blood COP to maintain tissue fluid balance. Blood pressure exceeds COP at the arteriolar end of the capillary and is usually below COP at the venous end. Fluids are secreted at the arteriolar and absorbed at the venous ends of the capillary. Hence, for adequate fluid exchange, COP pressure must offset capillary pressure, the latter reflecting arterial blood pressure (Landis and Pappenheimer, 1963). The value of COP is determined by the concentrations and species of blood proteins as well as by cations held in the plasma by the Donnan effect of the proteins (Guyton et al., 1975). However, it is now clear that microvascular fluid exchange is a dynamic process in which extravascular forces such as tissue fluid pressure, tissue COP, and the actual flow of lymph can influence transcapillary fluid movement (Taylor and Townsley, 1987). In addition to heterogeneity of Starling forces in different areas of the microvascular beds, there is also the possibility that heterogeneity of capillary membrane permeability will also contribute to differences between global and local values of the Starling pressures (Michel, 1997). In the light of recent knowledge, the simplistic steady state view of secretion at the arteriolar end of the capillary and absorption at the venous end of the capillary can only be regarded as a transient phenomenon at best.

Studies on avian species have contributed little to this discussion although microvascular fluid exchange in birds presents some unique and interesting features. For instance, in turkey and duck, the ratio of protein concentration in the interstitial fluid to that in the blood is much lower than the ratio in mammals (Hargens et al., 1974). Hargens et al. (1974) pointed out that the lower ratio in birds is correlated with a higher arterial blood pressure. Also, birds as a group seem to be highly resistant to hemorrhage, tolerating blood loss much better than mammals. Kovách and Balint (1969) have shown that increased hemorrhage tolerance becomes apparent only during prolonged bleeding because hemodilution continues in the pigeon through the period of blood loss, whereas in the rat no further hemodilution occurs after about 15−20 min of bleeding. Hemodilution is achieved by inflow of isotonic fluid with low-protein content.

The restoration of blood volume results from absorption of tissue fluid across the capillary walls due to reduced capillary pressure. This fall in capillary pressure could be brought about by an increase in the ratio between pre- and postcapillary resistances as well as by changes in arterial and venous pressures during hemorrhage. Resistance changes across the capillaries seem to be the most important factor in rapid restoration of blood volume in ducks. Blockade of α-adrenergic receptors eliminates vasoconstriction in the skeletal muscle, which forms the major reserve of tissue fluid and leads to a greatly retarded restoration of blood volume (Djojosugito et al., 1968). Djojosugito et al. (1968) attribute the difference in ability to restore blood volume after hemorrhage in ducks and cats to a very pronounced reflex vasoconstriction in duck skeletal musculature and to a capillary surface area in ducks three to five times that in the cat, a condition that increases the rate of absorption of fluid into the vascular system (Folkow et al., 1966).

Many birds, such as the emu and ostrich, have extremely long necks with the head being held a meter or more above the heart. Yet emu resting mean arterial blood pressure (Grubb et al., 1983) does not differ from that of a pigeon (Butler et al., 1977). An exceptionally high-blood pressure to overcome gravitational effects on circulation and to ensure flow to the head is not needed in these birds. In a fluid filled system, the gravitational pressure of blood in the veins will counterbalance the gravitational pressure in the arteries of the neck, much like the loop of a siphon. In other words, it is no more difficult for blood to flow uphill than downhill in a system of closed tubes like the circulation. Overall circulatory flow around the body occurs due to a pressure difference between the aorta and right atrium and it matters little what actual route the blood follows.

If pressure is measured in the cerebral circulation of a long-necked bird, this will be lower than that recorded in the aorta just outside the aortic valves by an amount sufficient to cause the required blood flow along the neck artery (a small difference) and by the gravitational effect due to the height the head is held above the heart. If the head is held one meter above the heart, pressure in the arteries of the head will be about 75 mmHg less than at the heart. Consequently, in the cranial capillary beds, it is now possible that the hydrostatic pressure will be lower than the COP of the blood, and fluid will be continuously removed from the interstitial spaces, with similar consequences as those following excessive alcohol consumption. As drunken ostriches are not a common sight, then countermeasures such as markedly increased arterial blood pressure, decreased arteriolar resistance, or reduced blood COP must be in effect. It is now possible to obtain a ready supply of long-necked ostriches and emus, and it is to be hoped that these countermeasures can be subjected to empirical investigation.

18.4.2.3 Distribution of blood flow at rest

The percentage of CO distributed at rest to different organs is closely related to their aerobic metabolic activity and their size. The distribution of CO is ultimately determined by the relative resistance of systemic vascular beds that are arranged in parallel throughout the body. Vascular resistance, in turn, is determined by a variety of hormonal, autoregulatory, and neural control mechanisms (see Section 18.5). Values obtained by different investigators for relative blood flow (% CO) to various organs differ widely, probably reflecting differences in experimental technique, species, and "resting" conditions. Nevertheless, it is apparent from the limited data available that the heart, liver, kidneys, and intestines receive relatively large percentages of the total CO (Figure 18.14). The avian brain appears to receive about 3% of CO, similar to the proportion of CO going to the brain in a small mammal like the rat at rest (Ollenberger and West, 1998).

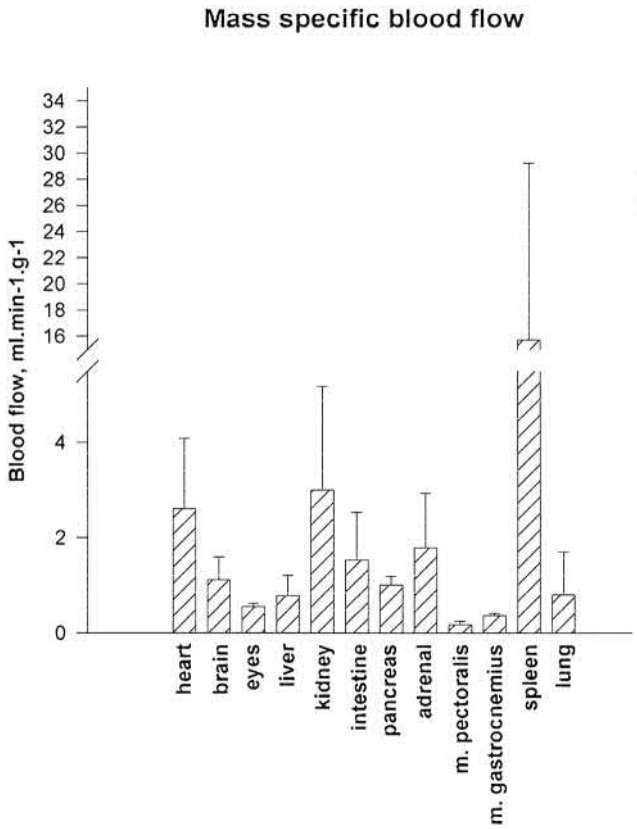

FIGURE 18.14 Mass-specific organ blood flow (mL $min^{-1}g^{-1}$) in birds at rest. Standard error bars are shown where appropriate. *Data are taken from Butler et al. (1988) (tufted duck), Duchamp and Barre (1993) (muscovy duckling), Faraci et al. (1985) (Pekin duck), Jones et al. (1979) (Pekin and mallard), Stephenson et al. (1994) (Pekin duck), and Wolfenson et al. (1978) (chicken).*

By far the highest resting blood flows thus far measured in any avian organ (about 16 mL $min^{-1}g^{-1}$ of wet tissue weight) are found in the spleen. This organ receives a disproportionately large percentage of total CO despite its small size. High-tissue flow rates also have been found in the mammalian spleen; a flow of some 12 mL $min^{-1}g^{-1}$ has been reported in conscious dogs (Grindlay et al., 1939). Such high rates are almost certainly related to the dual function of this organ: as a filter for aging erythrocytes, which are eliminated by the process of diapedesis; and as an organ of the reticuloendothelial system, in which the blood is cleaned by phagocytic reticuloendothelial cells as it passes through the splenic sinuses and pulp. Obviously, a high-flow rate is needed for this dual filtration role to be effective. In contrast to splenic blood flow, the rate of cerebral blood flow in birds is an order of magnitude less. Blood flow to the whole brain and to individual cerebral regions ranges from 0.43 to just over 2 mL min^{-1} g^{-1} under normoxic conditions, as shown in Figure 18.14 (Bickler and Julian 1992; Butler et al., 1988; Faraci and Fedde, 1986; Faraci et al., 1984; Grubb et al., 1977; Jones et al., 1979; Stephenson et al., 1994; Wolfenson et al., 1982a; Ellerby et al., 2005). Both the heart and kidneys have relatively high rates of mass-specific blood flow, reflecting the high oxygen demand of the contracting cardiac muscle and the activity of energy-dependent membrane pumps in renal tissue, respectively. Pectoral and gastrocnemius muscle, on the other hand, show relatively low-perfusion rates at rest (Figure 18.14).

18.4.3 Venous system

18.4.3.1 Functional development of venous system

The embryological development of the avian venous system follows a typical vertebrate pattern. At about the 15-somite stage of the avian embryo, paired cranial and caudal common cardinal veins develop from a vascular plexus in somatic mesoderm (Lillie, 1908; Sabin, 1917). The heart shifts caudally during embryonic development, and the cranial cardinal veins elongate to become the jugular veins. Subclavian veins, returning blood to the right side of the heart from the pectoral region and the wings, arise as tributaries of the caudal cardinal veins (Ede, 1964). The adult avian venous system cranial to the heart differs in detail from the mammalian pattern in that there are two cranial (superior) venae cavae. The right jugular vein is much larger in diameter than the left, and there is an anastomosis between the jugular veins at the base of the head, allowing some blood draining from the left side of the head and neck to return to the heart in the larger right jugular vein.

Development of the venous system caudal to the heart is primarily concerned with the formation of the physiologically important renal and hepatic portal venous circulations (see below). Subcardinal veins, which develop along with the embryonic kidney (mesonephros), initially provide renal drainage into the caudal cardinal veins. Eventually the anterior portions of the caudal cardinal veins disappear, and the subcardinals form a connection with the ductus venosus, this connection becoming the caudal vena cava. The liver develops around the ductus venosus, which subdivides into a capillary bed, forming the hepatic portal circulation. The cranial portion of the ductus venosus becomes the hepatic vein, and the caudal portion becomes the hepatic portal vein. Finally, the renal portal veins form a junction with the caudal vena cava via the common iliac veins, and the caudal subcardinal veins are replaced by the caudal renal veins.

18.4.3.2 Capacitance function

The walls of the veins in birds are, as in mammals, thinner than those of arteries so that venous distension depends on a positive transmural pressure gradient. The three basic components of blood vessel walls are present in veins: tunica intima, media, and externa. The tunica media is composed of circumferential smooth muscle fibers. In larger veins, elastic laminae appear in the tunica externa, which makes up most of the wall tissue. Veins near the heart are frequently invested with cardiac muscle fibers that are apparently functional. The caudal vena cava of the mallard can occasionally be seen to contract at the same frequency as the sinus venosus.

As in mammals, the avian venous system does not necessarily represent a passive conduit returning blood to the heart. The thin, distensible walls of veins mean that these vessels are relatively compliant compared with arteries. As applied to blood vessels, compliance is the ratio of the change in vessel volume (ΔV) resulting from a change in transmural distending pressure (ΔP):

$$\text{Compliance} = \Delta V/\Delta P.$$

In mammals, the entire vascular system has a compliance of about 3 mL blood (kg body mass mmHg)$^{-1}$. The compliance of the arterial vascular segment is only about 3% that of the venous segment (Rothe, 1983). Therefore, despite the smaller vascular pressures in the venous side of the circulation, at any one time about 60–80% of blood volume is contained in the veins. They are therefore referred to as capacitance vessels. The capacity of the venous circulation can change either passively by changes in transmural pressure or actively by changes in the contractile state of venous smooth muscle. A reduced transmural pressure and therefore a passive elastic recoil of compliant veins or a reduction in venous compliance by α-adrenergic mediated active contraction of smooth muscle in the venous walls (Section 18.5.2.4), would both serve to reduce venous capacitance. This transfers blood toward the heart. All other things being equal, this would increase atrial filling and therefore CO. The large veins of the domestic fowl are well innervated with adrenergic motor fibers (Bennett et al., 1974; Bennett and Malmfors, 1975b) and the density of this innervation suggests that there is active control of venous capacitance (Section 18.5.2.4). To date there are no physiological studies in birds analogous to those of adrenergic effects on venous capacitance function in mammals (Vanhoutte and Leusen, 1969).

18.4.3.3 Physiological role of veins in exercise and submersion

Venous pressure in pigeons flying in a low-speed wind tunnel increased to 2.5 mmHg from the resting value of 1.2 mmHg (Butler et al., 1977). CO increased 4.4 times during flight, mainly accomplished by an increase in heart rate at a constant stroke volume. In flight, the increased pressure gradient from the venous end of capillaries to the right ventricle increases venous return, right heart filling, and CO via the Frank–Starling relationship. Venous pressure is determined by the relationship between venous volume and compliance, which is reduced as venous smooth muscle contracts and the vein walls stiffen. In mammals, the venous beds of the liver, spleen, and skin act as blood reservoirs that can actively reduce capacitance during exercise, thereby increasing venous pressure and volume of venous return to the heart (Rothe, 1983). Whether these venous vascular beds also constrict during flight exercise in birds is currently unknown.

Active venoconstriction may also be important in the cardiovascular adjustments to diving in birds. Djojosugito et al. (1969) provided indirect evidence that venous pressure increased during diving in ducks and this was confirmed by Langille (1983), whose results suggested that this was due to active venoconstriction. In the latter study, cardiac stroke volume fell if central venous pressure was held constant during diving. This suggests that reduced ventricular contractility, caused by an increase in vagal motor nerve activity to the heart, is normally counteracted during diving by increased venoconstriction-induced filling via the Frank–Starling mechanism (see Section 18.5.3.2.3).

18.4.3.4 Renal portal system

In common with most other vertebrate groups, birds possess a renal portal circulation. Venous blood making its way back to the heart from the legs and the lower intestine of birds enters the kidneys through a renal portal system. Within the kidneys, this blood mixes with postglomerular

efferent arteriolar blood in peritubular sinuses that surround all nonmedullary nephron segments and eventually flows toward the renal veins. The physiological significance of the renal portal system is currently poorly understood. About 50−70% of total renal blood flow is contributed by the renal portal vein. However, this percentage is highly variable between animals and can change rapidly in the same individual for no apparent reason (Odlind, 1978). Part of the variability in flow can be attributed to the status of active, innervated renal portal valves within the iliac veins (Glahn et al., 1993). The valves receive dense reciprocal motor innervation from the parasympathetic and sympathetic divisions of the autonomic nervous system (see Section 18.5.2.3). Adrenergic stimulation produces relaxation of the smooth muscle of the valve, and cholinergic stimulation produces contraction. In contrast, smooth muscle of the renal portal vein itself shows a predominantly adrenergic contractile response typical of most vascular smooth muscle (Burrows et al., 1983). The distribution of vascular resistance within the portal system, governed by both the portal valve and the alternate, parallel venous pathways for blood returning to the heart determine the volume flow of renal portal blood.

There are several options for a "packet" of venous blood returning from the legs in the external iliac veins. (1) If the renal portal valve is open under the influence of sympathetic nervous system activation, blood can flow through the patent valve into the common iliac vein leading to the vena cava and directly back to the right side of the heart, bypassing the kidney. (2) If the valve is partially closed due to parasympathetic stimulation and resistance at the valve is high, blood can alternatively enter the renal portal system by flowing into the cranial and caudal portal veins. The portal veins are arranged functionally in parallel with the direct venous route provided by the common iliac vein and the vena cava. Blood entering the cranial and caudal portal systems eventually drains into the internal vertebral venous sinuses and caudal mesenteric veins, respectively, and makes its way back to the right side of the heart by this route. Anteriorly the caudal mesenteric vein connects with the portal system of the liver, providing another option for blood flow. The cranial and caudal portal veins are arranged in parallel with each other, and a "packet" of blood from the external iliac vein can enter one or the other, but not both. Therefore, variable fractions of venous blood derived from the legs, tail, and lower digestive tract can return directly to the right side of the heart (via the common iliac vein and vena cava) or enter the renal (cranial portal vein) or renal and hepatic portal systems (caudal portal vein). The overall pattern of venous flow will depend on the distribution of vascular resistance within the portal system.

Blood flowing from the renal glomeruli also enters the sinuses and contributes to pressure within them (Wideman et al., 1991), so any reduction in renal arterial pressure below the autoregulatory range should promote inflow to the sinuses from the portal veins. It is known that if the portal system is intact, birds can maintain total renal blood flow in the face of a fall in renal arterial pressure to 40−50 mmHg. Should arterial pressure fall, the glomerular vessels themselves can, by autoregulation, maintain glomerular filtration rate constant but only down to a minimum pressure of 70 mmHg (Wideman et al., 1992). The wider autoregulatory range for total renal blood flow may be due partially to an autoregulatory buffering effect by the portal system. Experimentally reducing portal blood flow leads to a narrowing of the range of arterial pressures over which total renal blood flow is maintained constant (Wideman et al., 1992). There are regional differences in renal blood flow, with the anterior part of the kidney apparently receiving a greater contribution from the portal veins. This suggests that renal arterial flow is normally lower in the anterior kidney.

The functional significance of the portal system in the environmental physiology of birds may be related to salt loading and dehydration. Dantzler (1989) has proposed that under these conditions, the adaptive response of the preglomerular arterial vessels of reptilian-type nephrons in the superficial renal cortex is to constrict, causing sustained cessation of filtration. Renal blood flow could be maintained under these conditions by a compensatory increase in portal flow, maintaining a nutritional blood supply to the cells of cortical nephrons (Wideman and Gregg, 1988).

18.4.4 Embryonic shunts

The circulatory system of the developing avian embryo has a number of vascular shunts found only during the embryonic stages (Dzialowski et al., 2011). These vascular shunts allow systemic venous return entering the right atria to bypass the nonventilated lungs, providing a right-to-left shunt. The first major embryonic shunt in embryonic birds is through a pair of ductus arteriosi (Dzialowski, 2018). In birds, these two embryonic vessels branch from the right and left pulmonary arteries and connect with the descending aorta (Figure 18.15). This arrangement is in contrast to the mammalian fetus that has a single ductus arteriosus connecting the pulmonary artery with the aorta in a position much closer to the heart and origin of these great vessels. During later stages of chicken embryonic development, White (1974) found that a large portion of venous return from the right anterior vena cava was shunted to the dorsal aorta through the paired ductus

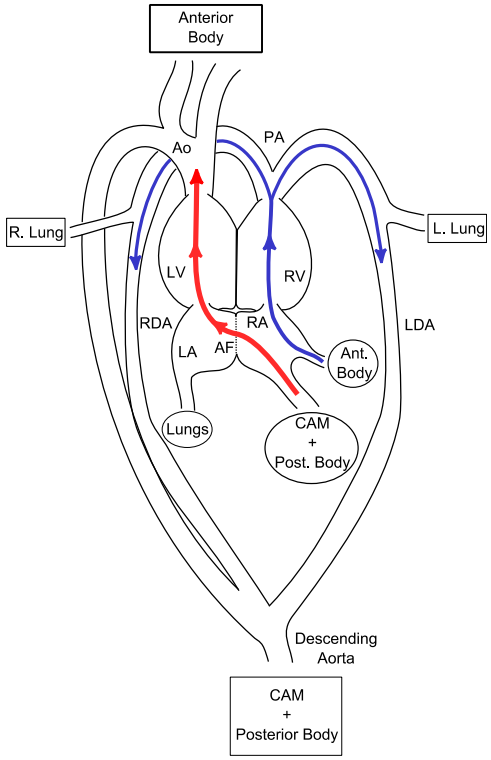

FIGURE 18.15 Embryonic circulation of a developing chicken embryo. The two right-to-left shunts are the left and right ductus arteriosi and the atrial foramina. *AF*, atrial foramina; Ao, aorta; *CAM*, chorioallantoic membrane; *LA*, left atrium; *LDA*, left ductus arteriosus; *LV*, left ventricle; *PA*, pulmonary artery; *RA*, right atrium; *RDA*, right ductus arteriosus; *RV*, right ventricle. *From Dzialowski et al. (2011).*

arteriosi. Tazawa and Takenka (1985) estimated that the ductus shunt 84% of right ventricular output to the dorsal aorta. A large fraction of dorsal aorta blood flow goes to the umbilical arteries and the embryonic gas exchanger, the chorioallantoic membrane (CAM). Patency of the mammalian ductus during the fetal stage is maintained in part by the relaxing influence of prostaglandins. Interestingly, there is no vasodilatory response to prostaglandins in the avian ductus (Dzialowski and Greyner, 2008; Greyner and Dzialowski, 2008). This difference could be due to the fact that the maternal placenta is the source of circulating prostaglandins in the mammalian fetus.

A second shunt exists between the two atria of the heart which functions like the mammalian fetal foramen ovale. The avian right and left atria are connected by perforations or foramina in the wall separating the atria. The right atrium receives posterior venous return, which includes oxygenated blood from the embryonic gas exchanger, the CAM (Figure 18.15; White, 1974). Tazawa and Takenka (1985) estimate that 60% of this posterior venous return flows through the atrial foramina resulting in a right-to-left shunt. This shunt ensures oxygenated blood flows to the anterior portion of the embryo through the carotid and subclavian arteries.

Both vascular shunts discussed above must close upon hatching to ensure adequate oxygenation of blood in the lungs. The ductus arteriosus is an oxygen sensitive blood vessel that constricts in response to increases in oxygen (Greyner and Dzialowski, 2008; Agren et al., 2007). In the embryonic chicken, the strength of oxygen-induced vasoconstriction increases during hatching. Using *in vitro* myography, the oxygen induced contractile strength of the ductus has been documented to triple between day 18 of incubation and external piping (Belanger et al., 2008). At the same time, arterial PO_2 in the hatching increases from around 30 −80 mmHg (Tazawa et al., 1983). By the time of hatching, the chicken ductus arteriosi are functionally closed (Belanger et al., 2008). Closure of the atrial foramina appears to be caused by pressure changes in the left atrium that occur with hatching (Jaffee, 1965). The perforations appear to behave in a valve-like manner, closing when the pressure in the left atrium becomes greater than the right atrium during hatching.

18.5 Control of the cardiovascular system

18.5.1 Control systems

Both the output of the heart and the resistance to blood flow in the vascular beds are subject to wide variations, depending on the activity type and intensity. CO varies in proportion to total body metabolic requirements while vascular resistance varies on a regional basis according to the blood flow requirements of different parts of the body. CO and resistance are both under the control of autoregulatory, humoral, hormonal, and neural influences. Arterial blood pressure is the product of CO and total peripheral resistance, and it is this pressure that produces the driving force to ensure adequate blood flow to the vascular beds. Blood pressure varies over a proportionally narrower range than either CO or peripheral resistance. Investigations of the regulation of cardiovascular function have been driven by the broad assumption that blood pressure is maintained within sensible limits to ensure adequate tissue perfusion in the face of the variations in CO and peripheral resistance imposed by changes in the external environment or in activity levels.

The cardiovascular system is controlled by several integrated mechanisms operating over time scales ranging from less than a second to months or longer. The most rapid adjustments in CO and peripheral resistance, which may occur within the span of a few heartbeats, are reflexogenic and primarily function to maintain short-term homeostasis and to affect rapid cardiovascular responses to changes in the internal or external environments. Autoregulatory mechanisms acting within vascular beds to modify blood flow as a result of local changes in metabolites or other

influences may operate on a time scale of seconds to minutes. Changes in humoral factors, such as levels of oxygen and carbon dioxide, pH, and metabolic products, can affect cardiovascular receptors or circulatory elements directly, producing changes in cardiac and vascular function directed toward correcting these disturbances on a time scale which may extend over long periods. An example of this is in birds undertaking extended migratory flights at high altitudes where inspired oxygen levels, and therefore blood oxygen levels, are much lower than at sea level. Circulating hormones can also affect both the peripheral circulation and the heart, and levels of many of these hormones in the blood may change depending on the activity state of the animal or on the time of year, as during molting or mating.

18.5.2 Control of peripheral blood flow

Contraction of smooth muscle in the walls of arteries provides the means for varying vessel caliber and the most effective location for altering blood flow by this means will be where the ratio of wall cross-sectional area to lumen area is maximal. The smallest arteries and arterioles possess the highest wall-to-lumen ratio, and it is here that the contraction of individual smooth muscle fibers, coordinated over the whole cross-section of the wall, will give the greatest change in resistance. The largest component of vascular resistance in the circulation is therefore set by the contractile tone of the smooth muscles in the walls of these vessels. Arterial smooth muscle tone is subject to modulation by several mechanisms: (1) intraluminal pressure changes, leading to mechanical autoregulation of blood flow; (2) humoral factors including oxygen tension, levels of local metabolites, extracellular ion concentrations, locally released vasoactive agents, and circulating hormones and vasoactive agents; as well as (3) transmitters released from autonomic nerve terminals.

Smooth muscle fibers in the walls of veins are also influenced by these factors, providing mechanisms for adjusting compliance of the venous walls and thus some control of the rate of blood return to the heart from the central venous pool. The influences of these regulatory factors on vascular function in birds are discussed in the following sections.

18.5.2.1 Mechanism of vascular reactivity

Regulation of smooth muscle contraction differs from skeletal muscle and involves activation of myosin light chain. Vascular smooth muscle contraction and relaxation are regulated by the phosphorylation and dephosphorylation state of the 20-kDa myosin light chain at Ser^{19} (MLC_{20}). In the phosphorylated state, smooth muscle contracts and produces vasoconstriction. Phosphorylation of MLC_{20} is mediated by Ca^{2+}-calmodulin-dependent MLC kinase (MLCK) that is activated by increased cytosolic Ca^{2+} due to Ca^{2+} release from sarcoplasmic reticulum stores and extracellular Ca^{2+} entry through membrane bound Ca^{2+} channels (Ganitkevich et al., 2002; Somlyo and Somlyo, 2003; Webb, 2003). Relaxation occurs when myosin light chain phosphatase (MLCP) dephosphorylates MLC_{20}. Several G-protein coupled receptor agonists inhibit MLCP leading to an increase in MLC phosphorylation and contraction without changes in cytoplasmic Ca^{2+} concentration. The result is an increase in Ca^{2+} sensitization (Ganitkevich et al., 2002; Somlyo and Somlyo, 2003; Webb, 2003).

Inhibition of MLCP involves a number of pathways in mammals. MLCP activity is inhibited by the RhoA/Rho-kinase pathway by phosphorylating the MLCP regulatory subunit, MYPT1. The second mechanism of MLCP inhibition in mammals is through phosphorylation of the smooth muscle-specific MLCP inhibitor protein CPI-17 (PKC potentiated inhibitor protein-17 kDa; Webb, 2003). Under physiological situations, Ca^{2+} release by the SR, Ca^{2+} influx, and Ca^{2+} sensitization act together to regulate vascular smooth muscle contraction. Their role in regulating avian smooth muscle contraction has only begun to be examined. The protein CPI-17 may not be involved in avian smooth muscle contraction as it was not detected in chicken smooth muscles from aorta, mesenteric artery, gizzard, or small intestine (Kitazawa et al., 2004). Additionally, there is contraction in response to PKC activation in adult chicken arteries (Kitazawa et al., 2004). In contrast, the Rho kinase inhibitors Y-27632 and hydroxyfasudil produced marked impairment of vessel contractions in femoral artery and ductus arteriosus of chicken embryos and emu (Zoer et al., 2010; Greyner and Dzialowski, 2008; Dzialowski and Greyner, 2008). The role of these pathways in avian vascular smooth muscle contraction needs further study.

18.5.2.2 Autoregulation

Vascular tone within a region of the circulation can be defined as the average level of contraction of smooth muscle fibers in the blood vessel walls within that region. At a steady intraluminal pressure and in the absence of extrinsic influences, spontaneous contractions of individual smooth muscles occur at an intrinsic rate. In resistance vessels, the smooth muscle cells are arranged at a right angle to, or on a shallow helix around, the axis of flow. The time-averaged tension generated by their contraction, in balance with the intraluminal pressure, will set vessel caliber and thus blood flow. An increase in arterial pressure will distend the vessel wall, increasing the caliber of the vessel and therefore reducing resistance to flow. As a result, blood flow through the vessel will increase. This wall distension also increases the frequency of contraction of the smooth muscles, and this increased vasomotion will

then act to reduce the caliber of the vessel, increasing its resistance and restoring blood flow toward its original level. Conversely, a reduction in pressure will reduce wall tension, resulting in a decrease in the rate of smooth muscle spontaneous activity. This leads to vasodilation and an increase in blood flow to offset the effects of reduced perfusion pressure. These myogenic changes in vascular caliber thus provide a mechanism to autoregulate blood flow around a preferred level in the face of variations in tissue perfusion pressure. In most vascular beds, autoregulatory mechanisms are probably limited to the modulation of local blood flow to ensure even blood distribution, as, for example, in the kidney where this mechanism is important in maintaining glomerular flow rate in the face of alterations in arterial blood pressure. Throughout the body local pressure-induced autoregulation will interact with locally released vasoactive agents and with neurogenically mediated vasomotion resulting from activation of autonomic reflexes to provide balanced adjustments in regional peripheral blood flow.

18.5.2.3 Humoral factors

Three broad classes of humoral factors affect blood flow in the peripheral vasculature. One class includes chemical factors such as PO_2, PCO_2, lactic acid and other metabolic byproducts, electrolyte concentrations, and pH that act directly on myocytes. The second class of factors consists of vasoactive agents typically released from local vascular endothelial cells. This group includes nitric oxide (NO), H_2S, prostaglandins, and endothelin (ET); these factors act on smooth muscle cells by receptor-mediated mechanisms. The third class includes circulating vasoactive agents, also acting via receptor-coupled mechanisms to modify smooth muscle contraction.

18.5.2.3.1 Chemical factors

If the metabolic rate of a tissue increases, for example, in skeletal muscle during exercise, regional blood flow will increase due partly to local vasodilation of resistance vessels and precapillary sphincters induced by an increase in the concentration of lactic acid and CO_2 and a fall in pH. Vasodilation under these circumstances is produced by alterations in Ca^{2+} flux and handling at the level of Ca^{2+} channels (Wray and Smith, 2004) and secondarily by direct chemical effects on the contractile apparatus of the vascular myocytes (Mellander and Johansson, 1968). Vasodilation may be further enhanced if local PO_2 falls or concentrations of extracellular ions such as K^+ increase. The resulting increase in blood flow is called functional hyperemia and serves to accelerate oxygen delivery to the muscle and to increase the clearance rate of tissue metabolites. During exercise, central arterial pressure may also rise (Butler, 1991; Saunders and Fedde, 1994) and local myogenic autoregulation would, as outlined in Section 18.5.2.2, attempt to limit the rise in blood flow; however in tissue operating at a high-metabolic rate, this mechanism is to a large extent overridden by local chemical vasodilatory influences. Vasodilation due to tissue hypoxia and buildup of metabolites also occurs during periods of ischemia, for example, when blood flow to a vascular bed is occluded as shown in Figure 18.16. Upon release of the occlusion, blood flow rises transiently to several times the preocclusion rate, with the increase in flow proportional to the duration of the occlusion. This reactive hyperemia acts to restore tissue oxygen levels and to remove metabolic products accumulating during the period of occlusion. Local hypoxia also reduces the vasoconstrictor effects of norepinephrine (NE) applied exogenously or released from sympathetic nerve terminals in avian arteries *in vitro*

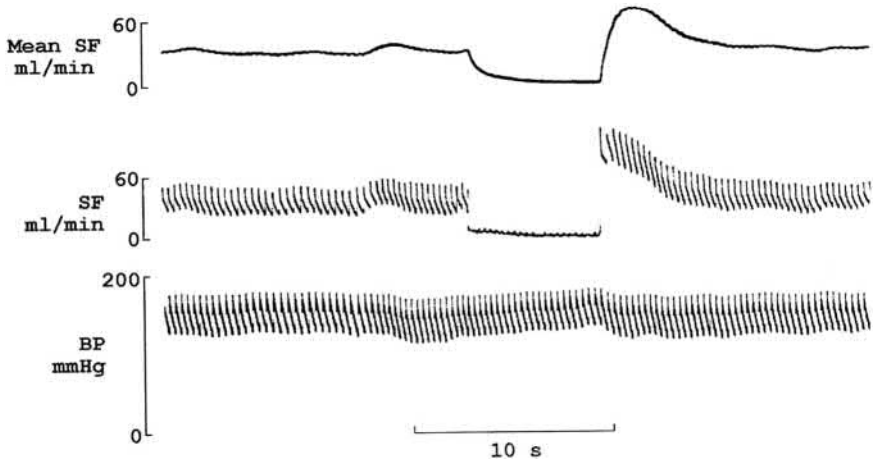

FIGURE 18.16 Change in pulsatile (SF) and mean (mean SF) blood flow in the sciatic artery of a duck in response to arterial occlusion. The period of occlusion is marked by zero flow. *BP*, arterial blood pressure. Note the hyperemia after the period of occlusion and the subsequent rapid return to the preocclusion flow rate with minimal change in pressure. *From Jones and Johansen (1972).*

(Gooden, 1980; and see Section 18.5.2.3.2), and might therefore be expected to reduce the *in vivo* effectiveness of vasoconstriction mediated neurogenically or by circulating catecholamines in support of the hyperemic response. Local hypercapnia also produces vasodilation, and in the hind limb vascular bed of the duck has an even stronger effect than hypoxia in inhibiting neurogenic or catecholamine induced vasoconstriction (Lacombe and Jones, 1990).

18.5.2.3.2 Locally released vasoactive agents

The endothelium-derived relaxing factor NO is a small, rapidly diffusible molecule released by enzymatic cleavage of L-arginine from vascular endothelial cells of vertebrates (see Donald et al., 2015 for review). In vertebrates, this molecule exerts a powerful vasodilatory effect by relaxing precontracted vascular smooth muscle. The release of NO as a result of acetylcholine (ACh) stimulation of endothelial cells provides part of the explanation for the vasodilatory effects of ACh in the circulation (Furchgott and Zawadzki, 1980). In the *in vitro* aorta and small resistance arteries, ACh acting at muscarinic receptors on endothelial cells provokes release of NO which produces local vasodilation (Hasegawa and Nishimura, 1991; Jarrett et al., 2013). NO can produce relaxation through activation of soluble guanylate cyclase which increases levels of cGMP. This activates a cGMP-dependent protein kinase that decreases intracellular Ca^{2+} levels leading to vasodilation.

Another factor provoking release of NO from avian vascular endothelial cells is angiotensin II (AII); the vasodilation produced by NO release has been proposed to cause the transient depressor effects on arterial blood pressure observed in some birds immediately after systemic injection of AII (Stallone et al., 1990; Hasegawa et al., 1993; Takei and Hasegawa, 1990). Mechanical stimuli such as flow-induced shear stress (see Section 18.5.2) can also elicit release of NO from endothelial cells in the vasculature of birds. This effect is well known in mammalian endothelial cells (Balligand et al., 2009) and, given that blood flow rates in birds are generally higher than those in mammals of comparable body size, such a mechanism could provide additional local adjustment of the degree of vasodilation within a vascular bed to match the immediate flow requirements of that bed.

Other locally released vasoactive agents, such as ET and H_2S, are important in adjusting regional blood flow in birds. ET is the most potent vasoconstrictor known in mammals (Inagami et al., 1995). In chickens, ET has been shown to produce contractions of femoral, mesenteric, and pulmonary arteries in the embryonic stages (Moonen and Villamor, 2011; Villamor et al., 2002) and pulmonary arteries from adults (Martinez-Lemus et al., 2003). In hatchling chickens, ET produced contraction at low doses and relaxation at higher doses (Moonen and Villamor, 2011). Moonen and Villamor (2011) suggest that contraction may be mediated by ET_A receptors and at higher doses ET_B receptors. Receptors for this peptide have been demonstrated on avian cardiac myocytes, and their activation causes an increase in contractile force (Kohmoto et al., 1993; Hassanpour et al., 2010). Recently, locally released H_2S has been found to be a potential important in regulating vessel tone. It has been found to produce both vasorelaxation and vasoconstriction in systemic vessels. Vasorelaxation by H_2S is proposed to act through K_{ATP} channels and cGMP levels in a fashion similar to NO (biological roles are reviewed in Kolluru et al., 2013). H_2S-mediated vasoconstriction in the mammalian aorta is mediated by downregulation of cAMP (Lim et al., 2008). In the one study looking at the pekin duck aorta, H_2S constricted the unstimulated aorta and produced a weak relaxation followed by constriction in the preconstricted vessel (Dombkowski et al., 2005). As with many of these pathways, further research is needed to determine the potential role of H_2S in regulating vessel tone in the avian system.

18.5.2.3.3 Circulating agents

Circulating catecholamines have powerful effects on all elements of the circulation in birds. The catecholamines epinephrine (EPI) and NE are released into the circulation from adrenal chromaffin cells and have direct effects on vascular smooth muscle. Significant amounts of NE are also released into the circulation by activation of the sympathetic nervous system (discussed in Section 18.5.2.4 below). A number of peptides which have vasoactive effects on mammalian vasculature are also present in avian plasma, but the specific actions of most of these peptides on the avian vasculature have not been investigated in detail. Of these peptides, the most extensively studied in birds with respect to vasomotion are AII and avian antidiuretic hormone (ADH).

Circulating NE levels in conscious ducks and fowl at rest are in the range of 3−5 nM (Lacombe and Jones, 1990; Kamimura et al., 1995), while the resting plasma level of EPI is about half the value for NE (Lacombe and Jones, 1990), as illustrated in Figure 18.17A. EPI appears to be released solely from the adrenal glands since removal of these glands eliminates EPI from the plasma (Lacombe and Jones, 1990). The loss of adrenal glands does not, however, markedly affect the resting level of circulating NE which must therefore be due to spill over into the plasma of NE released from sympathetic nerve terminals by autonomic efferent activity. Circulating levels of both EPI and NE vary under different physiological conditions. For example, plasma catecholamines can increase by factors ranging from 2 to greater than 1000 in ducks during involuntary submersion, with end dive levels being proportional to dive length as shown in Figure 18.17B (Huang et al., 1974; Hudson and Jones, 1982; Lacombe and Jones, 1990).

Both NE and EPI produce vasomotion in avian vascular smooth muscle, acting via α- and β-adrenergic receptors (Bolton and Bowman, 1969). NE, injected intravenously into conscious ducks, produces vasoconstriction throughout

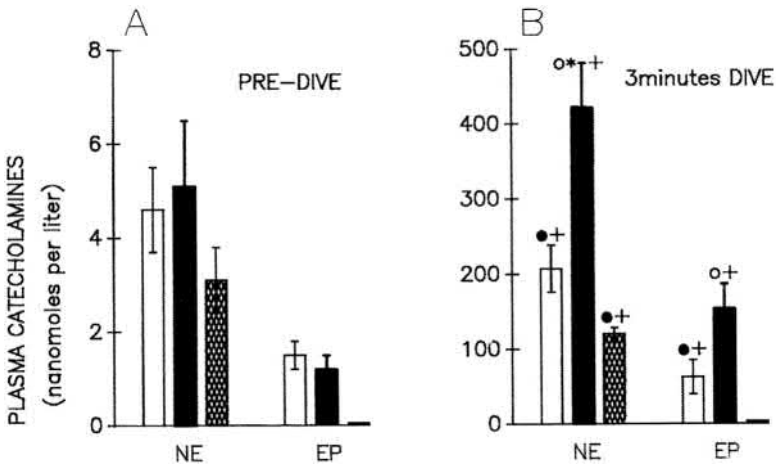

FIGURE 18.17 Plasma levels of norepinephrine (NE) and epinephrine (EPI) in intact (*open bars*), sham-operated (*filled bars*), and adrenalectomized (*cross-hatched bars*) ducks (A) before and (B) at the 3-min point during forced submergence. The *open circles* indicate significant differences from intact ducks; *closed circles*, differences from sham-operated animals; *asterisks*, differences from adrenalectomized animals; *plus signs*, differences from predive value. Adrenalectomy eliminated EPI but not NE from the plasma. Note ordinate scale change in (B). *From Lacombe and Jones (1990).*

the body. This vasoconstriction causes an increase in blood pressure produced by the collective effect of increases in resistance to flow in individual vascular beds in the body, illustrated in Figure 18.18, by increased resistance in the hind limb vascular bed. These vascular responses to NE are primarily mediated by α-adrenergic receptors (Butler et al., 1986; Wilson and West, 1986; Bolton and Bowman, 1969). Activation of α-adrenoceptors (ARs) on vascular smooth muscle acts through second-messenger systems to mobilize internal Ca^{2+}stores and to open membrane calcium channels, thus increasing intracellular Ca^{2+} concentration and activating the actin−myosin contractile apparatus (see Webb, 2003, Section 18.5.2.1). NE can also have a vasodilatory effect on the vasculature of birds, mediated through β-adrenergic receptors; however, this effect is only apparent systemically after pharmacological blockade of α-ARs (Butler et al., 1986). β-adrenergic vasodilation in the avian vasculature also works by activating intracellular second messengers, converting the actin−myosin complex to an inactive form to promote relaxation. Combined α- and β-adrenergic blockade appears to eliminate all direct effects of NE on bird vascular

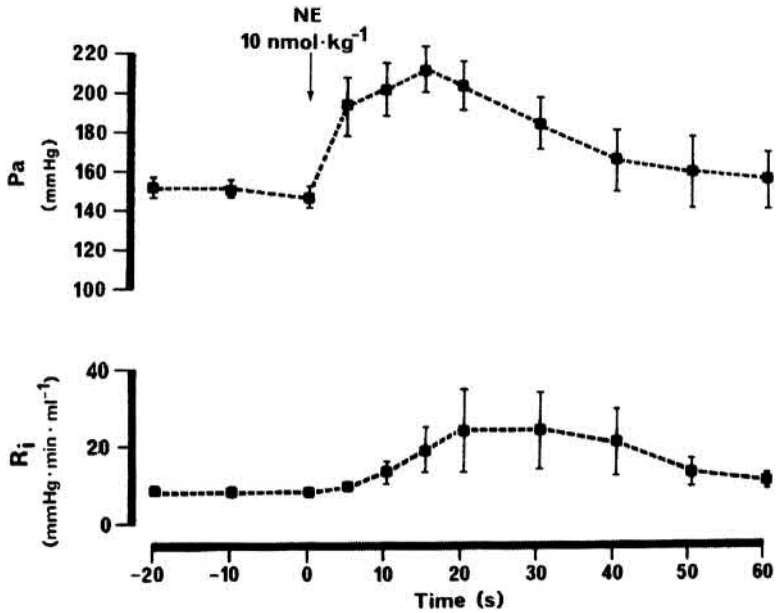

FIGURE 18.18 Responses of mean arterial blood pressure (P_a) and resistance to blood flow in the ischiatic artery (R_i) of an adult duck to a bolus intravenous injection of norepinephrine (NE, at *arrow*). The R_i values for each data point were calculated from the corresponding Pa and ischiatic blood flow values. *From Wilson and West (1986).*

smooth muscle. The overall effects of NE on peripheral resistance therefore depend on the relative abundance of α- and β-receptors in individual vascular beds. EPI also acts on ARs of vascular smooth muscle but binds to α-receptors with a higher affinity than to the β subtype, so exerts a stronger vasoconstrictive effect for the same receptor density than does NE.

Avian AII is similar to the corresponding mammalian peptide in its structure and in the biochemical pathway of its production (see reviews by Wilson, 1989; Henderson and Deacon, 1993). Renin, released from the juxtaglomerular cells lining glomerular afferent arterioles in the kidney, produces the peptide angiotensin I by hydrolysis of angiotensinogen, a plasma α-globulin. Angiotensin-converting enzyme, which has been identified in circulating plasma and fixed in the walls of blood vessels in birds (Henderson and Deacon, 1993), then cleaves angiotensin I to produce AII. A number of stimuli such as systemic hypotension, hypovolemia, decreased plasma or distal tubule ion concentrations (particularly Na^+), or the activation of juxtaglomerular β-receptors causes renin to be secreted into the plasma. This promotes an increase in circulating angiotensin I, making it available for conversion to AII. AII affects circulatory function at several levels, evoking responses in both the central nervous system and the peripheral vasculature. These responses are aimed at the conservation of water and electrolytes in order to counter the original rennin secreting stimulus.

Within the central nervous system, AII acts on receptors of some hypothalamic neurons to promote drinking behavior (Evered and Fitzsimmons, 1981). In the periphery exogenous or endogenous AII produces either an increase in systemic arterial blood pressure or a biphasic hypotensive−hypertensive response, depending on species. In ducks (Wilson and West, 1986; Butler et al., 1986) and pigeons (Evered and Fitzsimmons, 1981), systemic injections of AII produced dose-dependent increases in arterial blood pressure. Butler et al. (1986) and Wilson and West (1986) proposed that this response was due to vasoconstriction resulting from AII-mediated release of NE from sympathetic nerve terminals and enhanced EPI and NE release from the adrenal glands; in their experiments, α- and β-adrenergic blockade eliminated the pressor effects of AII injection. Indeed, Moore et al. (1981) maintained that AII has no direct vasoconstrictor effects on arterial smooth muscle in the fowl and Wilson (1989), in a review of the rennin−angiotensin system in birds, ascribes AII-induced vasoconstriction entirely to the effects of elevated catecholamine secretion.

In fowl and quail systemic circuits, AII injections produce a rapid, transient hypotension followed by a prolonged rise in arterial blood pressure (Nakamura et al., 1982; Takei and Hasegawa, 1990). The hypertensive phase of this response is mediated by adrenergic mechanisms, as in the duck and pigeon, but the transient hypotensive phase appears to be an indirect AII effect on vascular endothelial cells, working via the local release of NO from these cells as described in Section 18.5.2.3.2. *In vitro* isometric tension studies on the abdominal aorta of embryonic and adult chicken have shown AII induces a vasorelaxation that is inhibited by L-NAME and eliminated by removal of endothelium (Nishimura et al., 2003).

Arginine vasotocin (AVT), released from the posterior pituitary into the circulation under conditions of osmotic or hypovolemic challenge, is the avian homolog of the mammalian ADH arginine vasopressin. However, the effects on avian vasculature of increased endogenous AVT levels after salt loading or hemorrhage are not well understood, nor are the vasomotor effects of systemic AVT injections. In mammals, arginine vasopressin produces vasoconstriction in systemic arterioles and in glomerular afferent arterioles, both serving to facilitate antidiuresis. In birds, AVT also induces vasoconstriction of afferent glomerular arterioles (see Braun, 1982 for review), but its effects on the rest of the circulation are controversial. Several studies have reported no cardiovascular consequences of AVT injection, maintaining that the avian vasculature is not sensitive to this peptide even at doses many times greater than "physiological" levels (Simon-Oppermann et al., 1988; Robinzon et al., 1988). In contrast, Wilson and West (1986) in ducks and chickens and Brummermann and Simon (1990) in ducks found that systemic injections of AVT produced hypotension accompanied by tachycardia. The latter authors proposed that AVT directly relaxes vascular smooth muscle, producing a fall in arterial blood pressure which then evokes a baroreflex-mediated tachycardia. However, Robinzon et al. (1993) found in fowl that the direction of AVT-mediated vascular responses depended on the dose and method of application. Low doses given slowly by intravenous infusion produced hypertension similar to the mammalian response to arginine vasopressin, while bolus intravenous doses produced the hypotensive responses reported in other avian studies. Robinzon et al. (1993) therefore proposed that AVT acts primarily via modulation of vascular caliber but that the degree and direction of vasomotion was not uniform in beds throughout the body. While there appears to be consensus that AVT does have direct vascular effects in birds, the understanding of its specific actions must await further studies on isolated vascular beds *in situ* and on blood vessels *in vitro*.

18.5.2.4 Neural control

All parts of the systemic and pulmonary vascular trees, except capillary beds, are innervated by the autonomic nervous system. This innervation constitutes the final common pathway for rapid and flexible control by the

central nervous system of regional distribution of CO. Autonomic outflow to the vasculature is governed by a variety of reflexogenic inputs from visceral or somatic receptors relayed through brainstem and spinal cord pathways, and is also subject to influences originating at suprabulbar levels of the central nervous system. However, the degree of vasomotion produced in any region of the vasculature for a given intensity of autonomic drive will depend on the densities of effector terminals and postjunctional receptors in that region.

The location of autonomic terminals within the vascular wall is different in arteries and veins. Nerve fibers and terminals in the walls of arteries are, with some exceptions, limited to the tunica adventitia, extending as far as the outer elastic lamina marking the border between the adventitia and the tunica media (Bennett and Malmfors, 1970). In this respect, the innervation pattern of avian arteries is similar to that in mammals (see Hirst and Edwards, 1989 for a review of mammalian arterial innervation). In contrast to the arterial innervation pattern, nerve fibers and terminals in avian systemic veins are commonly opposed to smooth muscle in the tunica media, as well as being located in the adventitia (Bennet and Malmfors, 1970) and in this regard similar to mammals (see Shepherd and Vanhoutte, 1975 for a review of the innervation of mammalian veins).

In addition to intramural nerve fibers and terminals, large and small nerves course over the outer surfaces of both arteries and veins, and some vessels are completely surrounded by plexi of nerve fibers. Furthermore, throughout the body, nerves generally accompany blood vessels, running parallel with the vessels to form neurovascular bundles. These close associations between blood vessels and nerves have an important consequence for experimental investigations of neurogenic vasomotion. In assessing the effectiveness of neural control of vascular resistance in particular beds, electrical stimulation of autonomic nerves is commonly employed. However, some neural pathways to these beds may be interrupted if supply vessels to the beds are manipulated or sectioned (for example, to insert a blood flow probe) between the stimulus site and the expected site of vasomotion.

18.5.2.4.1 Systemic arterial innervation

The aorta from its origin to the junction with the celiac artery, the proximal brachiocephalic trunks, and the most proximal parts of the common carotid arteries are elastic vessels (see Section 18.4.1.2), having relatively little smooth muscle and thus a correspondingly sparse vasomotor innervation (Bennett and Malmfors, 1970; Bennett, 1971). The aorta, especially close to its root and adjacent to the root of the pulmonary trunk, has numerous small cells in the adventitia which contain catecholamines (Bennett, 1971). These cells occur singly or in clusters, appear to be similar to amine-containing cells of the carotid body, and are innervated by branches of the vagus nerve. While these cells may be a source of locally released catecholamines, it has also been suggested that these cells may constitute chemoreceptive "aortic bodies" (Bennett, 1971; Tcheng and Fu, 1962) similar to those found at the homologous site in mammals. In addition, the adventitia of the aortic arch is innervated by afferent vagal fibers with nerve terminals transducing wall stretch and thus signaling an index of central arterial blood pressure; these constitute the only systemic arterial baroreceptors in birds (Jones, 1973).

The transition from elastic to muscular wall structure occurs in the arterial tree distal to the branching points of major distribution arteries from the great vessels. This transition also marks an increase in the density of innervation of the arterial wall. In some arteries such as the ischiatic, varicose fibers can be seen in the media as well as at the medial−adventitial border (Bennett and Malmfors, 1970). Of the large muscular arteries, the common carotids appear to be the most heavily innervated (Bennett and Malmfors, 1970). Given that these arteries convey the majority of blood flow to the avian brain, this density of innervation possibly reflects a requirement for greater autonomic control of cephalic blood flow than in other beds. Vasomotor innervation of the smaller branches of arteries within individual vascular beds supplied by the large arteries has not been systematically described but in all beds muscular arterioles, which constitute the resistance vessels responsible for 70% to 80% of total peripheral resistance, are densely innervated (Folkow et al., 1966; Bennett and Malmfors, 1970).

The density of innervation of different regions of the arterial tree is variable among bird species, and this variation has important consequences for differences in regional neurogenic control of blood flow among species. Large arteries supplying hindlimb muscles in ducks, for instance, are more densely innervated than those in turkeys, and this difference is correlated functionally with an enhanced capability in the duck to generate and maintain neurogenically mediated intense peripheral vasoconstriction (Folkow et al., 1966). These authors proposed that this was a general physiological adaptation in diving birds, enabling the redistribution of blood flow away from those peripheral vascular beds able to withstand periods of ischemia and toward the central circulation, thus conserving blood oxygen for ischemia sensitive heart and brain tissue.

Electrical stimulation of the sympathetic innervation of a vascular bed evokes increases in vascular resistance in that bed, mimicking the effect of elevated vasoconstrictor outflow from the central nervous system. As illustrated in Figure 18.19, graded increases in stimulation frequency evoke proportionally larger increases in peripheral resistance in the hind limb vascular bed of the duck, producing a maximal increase of up to seven times the prestimulus

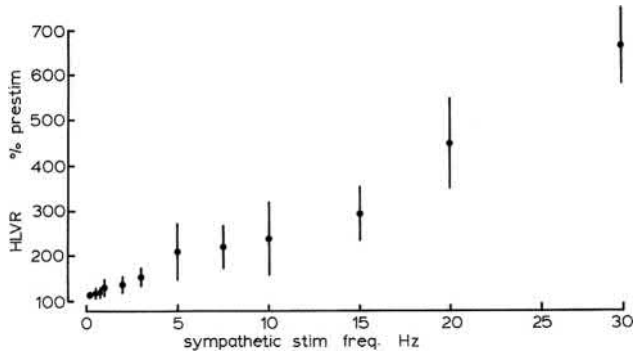

FIGURE 18.19 Relationship between frequency of electrical stimulation of the sympathetic innervation of the hind limb and vascular resistance of this bed (HLVR) in a duck. HLVR for each data point was calculated from the corresponding arterial pressure and ischiatic artery flow. Increases in HLVR are expressed in percentages relative to the prestimulus value. *From Smith (unpublished data).*

resistance value at a stimulation frequency of 30 Hz. In contrast, stimulus frequencies of less than 10 Hz are required to produce a maximal increase in resistance in the cat hind limb (Folkow, 1952). The hind limb vascular bed in the duck thus requires a greater degree of sympathetic drive than that of the cat to achieve the same order of increase in resistance to flow. This may reflect differences in the distribution of sympathetic terminals to the arteries in this bed in the two species. In support of this, Bennett and Malmfors (1970) noted that the pattern of adrenergic innervation of small intramuscular arteries in birds was not markedly different from that in mammals, but observed a higher terminal density in larger arteries of birds relative to mammals.

Some regions of the avian arterial vasculature have specialized wall structures and unusual innervation patterns, possibly reflecting enhanced capabilities for regional control of blood flow. The anterior mesenteric artery in several species of birds has, in addition to the normal circular smooth muscle in the media, an outer layer of longitudinal smooth muscle in the adventitia (Bolton, 1969; Bennett and Malmfors, 1970; Bell, 1969; Ball et al., 1963; see Section 18.4.1.2). Adrenergic fibers and varicose terminals are found at the adventitial−medial border in this as in other arteries, but these elements also extend into the longitudinal muscle itself, aligned in the direction of the muscle fibers. Longitudinal muscle of this vessel also receives cholinergic innervation (Bolton, 1967; Bell, 1969; Bennett and Malmfors, 1970), although this does not extend to the inner circular muscle (Bell, 1969). Adrenergic nerve stimulation produces contraction of the circular muscle which is mimicked and blocked by α-adrenergic agonists and antagonists, respectively (Bolton, 1969; Bell, 1969; Gooden, 1980). The longitudinal muscle is, however, relaxed by adrenergic nerve stimulation, acting through β-adrenergic receptors (Bolton, 1969; Bell, 1969). Stimulation of cholinergic nerve fibers in an *in vitro* preparation of a segment of the vessel caused the longitudinal muscle to contract, shortening the whole segment. This did not, however, markedly affect resistance to flow through the vessel but in the shortened state adrenergic vasoconstrictor responses of the circular muscle were found to be exaggerated (Bell, 1969). The cholinergic innervation of longitudinal muscle has thus been proposed to potentiate adrenergically mediated control of blood flow, possibly as an adaptation for rapid adjustment of intestinal blood flow during stress (Bell, 1969). The fact that increased sympathetic drive to this vessel has a relaxing effect on the longitudinal muscle as well as a constricting effect on the circular muscle would facilitate the effects of cholinergic input in shortening the vessel segment. Cholinergic input may also help adjust blood flow more precisely when the length of the anterior mesenteric artery changes during gross intestinal movements associated with digestion.

Coronary arteries also possess an outer coat of longitudinal muscle but adrenergic innervation of this muscle layer is very sparse. In these arteries, the majority of adrenergic nerve fibers and terminals are found at the adventitiomedial border, as in other arteries (Bennett and Malmfors, 1970). There are no reports of cholinergic innervation of the coronary arteries of birds. Cerebral arteries are, however, dually innervated by adrenergic and cholinergic fibers (Tagawa et al., 1979). Adrenergic varicosities are located in the adventitia near the border with the media throughout the cerebral circulation, in common with most other arteries of the body. Cholinergic fibers as well are located in the tunica adventitia but occur less frequently than adrenergic terminals (Tagawa et al., 1979). It is presumed that, since cerebral arteries have no smooth muscle in the adventitia, neurotransmitters released from both types of terminals diffuse into the media to act on muscle fibers there. Tagawa et al. (1979) also reported that, as in mammals, some of the cholinergic innervation of avian cerebral arteries appears to originate from central neurons, especially in the diencephalon, as well as from peripheral neurons. Studies in mammals have shown that the functional significance of reflexogenic vasomotion in overall control of cerebral blood flow is relatively minor compared with neurogenic control of blood flow in other vascular beds in the body; intracerebral blood distribution is influenced mainly by local and possibly circulating humoral factors (Kontos, 1981). This is likely to be true also in birds; Stephenson et al. (1994) estimated that neurogenic contributions to changes in cerebral blood flow in ducks during diving were minor.

18.5.2.4.2 Systemic venous innervation

Large veins in birds are more densely innervated than those in mammals. The density of noradrenergic innervation of the chicken caudal vena cava is graded, increasing in portions of the vessel more distal to the heart (Bennett, 1974; Bennett et al., 1974). The caudal vena cava has an outer coat of longitudinal muscle as well as an inner circular layer and both layers receive adrenergic innervation, with the orientation of the terminals and fibers following the direction of the muscle fibers in each layer (Bennett, 1974). There is also a sparse cholinergic innervation of this vessel. The superior venae cavae also have two muscle layers, with a similar adrenergic innervation pattern to the caudal vena cava (Bennett and Malmfors, 1970). The walls of the pectoral, subclavian, celiac, and jugular veins contain both circular and longitudinal smooth muscle. The innervation of these vessels is through a plexus of varicose fibers and terminals located primarily between the inner and outer muscle layers.

Functionally, adrenergic vasomotion appears to be preeminent in veins. Vasomotion of the caudal vena cava and other major veins is mediated primarily by α-adrenergic receptors producing vasoconstriction when activated; no functional β-adrenergic receptors are present (Bennett and Malmfors, 1974). Responses of venous smooth muscle to cholinergic nerve stimulation are weak and variable and probably do not contribute directly to neurogenic control of wall compliance; however, ACh released from cholinergic nerve terminals can modulate the release of NE from local adrenergic nerve terminals and thus may provide fine adjustments of adrenergically generated venomotor tone.

Sympathetically mediated contraction of smooth muscle in the major veins serves to decrease wall compliance and vessel diameter, thus providing a reflexogenic mechanism for reducing the volume of the central venous pool and increasing return of blood to the heart, as discussed in Section 18.4.3.2. Langille (1983) proposed that reflexogenic venoconstriction was responsible for the increased central venous pressure observed in ducks during involuntary submersion. This response may function to aid venous return to the heart to help maintain stroke volume in the face of a reduction in cardiac contractility which may develop during diving (Djojosugito et al., 1969; Langille, 1983).

The renal portal valves, located bilaterally where the external iliac veins join the junction of the caudal vena cava with the caudal renal veins, are unique to birds. These valves are in the form of sphincters of smooth muscle which can close off the direct route for blood flow from the external iliac veins to the caudal vena cava. Closure increases renal portal blood flow, venous blood from the external iliac vein being then partially redirected into the renal capillaries and thence to the caudal vena cava, as discussed in Section 18.4.3.4. The renal portal valve is heavily innervated by both adrenergic and cholinergic nerve fibers (Akester and Mann, 1969; Bennett and Malmfors, 1970) with reciprocal effects on the smooth muscle of the valve. Adrenergic nerve stimulation and sympathomimetic agents induce relaxation, mediated by β-adrenergic receptors, while cholinergic nerve stimulation and cholinomimetic agents produce contraction via muscarinic receptors (Bennett and Malmfors, 1975a; Sturkie et al., 1978). The importance of this valve in the control of venous blood distribution in the renal portal system has been the subject of some debate (Akester, 1967, Section 18.4.3.4). Functional studies of the avian kidney *in situ* by Glahn et al. (1993) have shown that the status of the renal portal valve affects total renal blood flow by altering the amount of flow in the renal portal system. In conditions of lowered arterial blood pressure in which renal arterial perfusion is below the range of autoregulation of glomerular blood flow, closure of the renal portal valve raises renal portal blood flow to compensate total renal blood flow (Glahn et al., 1993). Neural control of the renal portal valve may thus form a component of the suite of reflexogenic responses to hypotension or hypovolemia.

18.5.2.4.3 Pulmonary vessel innervation

Adrenergic innervation of the pulmonary artery in the fowl consists mostly of fibers with few varicose nerve terminals. Fibers and nerve terminals form a plexus at the adventitiomedial border of the artery, with some projections into the circular smooth muscle of the media. There is also smooth muscle oriented longitudinally in the adventitia, but innervation of this is very sparse (Bennett and Malmfors, 1970; Bennett, 1971). Some intrapulmonary arterial branches have dense adrenergic plexi occurring in short segments along their length (Bennett and Malmfors, 1970), which may help to redistribute blood flow to selected gas exchange areas within the lung to optimize local ventilation–perfusion ratios (Hebb, 1969).

The pulmonary veins proximal to the left atrium are very densely innervated with adrenergic nerve fibers and terminals, the density of this innervation being markedly greater than in the pulmonary arteries (Bennett, 1971). Abundant terminal varicosities and nerve fibers are located in a plexus at the adventitiomedial border, with some penetration into the media (Bennett, 1971; Bennett and Malmfors, 1970). There is also longitudinal smooth muscle present in the adventitia, with adrenergic terminals between the muscle fibers (Bennett, 1971; Bennett and Malmfors, 1970). The density of innervation of the longitudinal smooth muscle is reduced close to the left atrium, increasing distally along the vessel until the bifurcation to the lungs. At this junction, there is an abrupt decrease in density of innervation of the entire vessel wall, and within the lungs, the major

branches of the pulmonary veins are very sparsely innervated. Smaller branches of these vessels appear to have no innervation (Bennett, 1971).

18.5.2.4.4 Autonomic pathways

The cell bodies of adrenergic postganglionic vasoconstrictor neurons innervating the vasculature are located in paired paravertebral ganglion chains, in prevertebral ganglia and, in some cases, in small ganglia scattered throughout the viscera. Cells in the superior cervical ganglion (representing a fusion of the two most cranial cervical ganglia) innervate blood vessels of the head, including those of the salt and salivary glands, via cephalic extensions anastomosing with several cranial nerves (Bennett, 1974). In birds, pairs of sympathetic ganglia are associated with the cervical vertebrae, and cells in these ganglia innervate blood vessels of the neck. The presence of cervical paravertebral ganglia in birds constitutes a major difference in the organization of the sympathetic nervous system between this vertebrate group and mammals. In the caudal part of the neck, in the thorax, and in the wings of birds, the vasculature is innervated by neurons in the thoracic paravertebral ganglion chain. Sympathetic fibers reach wing vessels primarily through the brachial plexus. Some thoracic postganglionic neurons also contribute sympathetic fibers to the greater splanchnic nerves innervating anterior abdominal viscera via the celiac plexus (Bennet, 1971).

Vertebrae of the lumbar, sacral, and coccygeal spine are fused to form the synsacrum in birds. The paravertebral ganglion chains from each side in this region are fused in the midline at about the level of the sixth coccygeal segment in avian species so far examined, and this combined sympathetic trunk continues caudally to the pygostyle (Pick, 1970; Akester, 1979; Benzo, 1986). Axons from postganglionic neurons in this part of the sympathetic nervous system innervate abdominal and pelvic viscera via the lesser splanchnic nerves and aortic plexus, the hypogastric plexus, the pelvic plexus, and the cloacal plexus. Some sympathetic postganglionic somata are also located in prevertebral ganglia within these plexi. In addition, lumbosacral sympathetic neurons contribute vasoconstrictor axons to the hind limbs via the lumbosacral plexus (Benzo, 1986; Bennett, 1974).

Sympathetic preganglionic cell bodies that synapse on the postganglionic vasoconstrictor neurons are located in and near a bilateral column of neurons, the column of Terni, in the gray matter near the central canal of the spinal cord (see Section 18.5.3.2). All preganglionic axons innervating postganglionic neurons in the cervical sympathetic chain exit the spinal cord through ventral nerve roots of cranial thoracic segments; there are apparently no connections between the cervical spinal nerve roots and the sympathetic ganglia in the neck (Bennett, 1974; Akester, 1979; Pick, 1970). Although no detailed analysis has been done of the segmental locations of spinal preganglionic neurons projecting to postganglionic vasoconstrictor neurons innervating the thoracic, abdominal, pelvic, and limb regions, it is likely that the locations of these neurons follow the mammalian plan. That is, axons of preganglionic neurons in a particular spinal segment emerge from the cord in the ventral root of that segment to innervate postganglionic neurons in ganglia at that level or within one or two segments rostral or caudal to the exit site (see Gabella, 1976 for review).

Parasympathetic postganglionic neurons innervating the vascular smooth muscle of such organs as salt glands and salivary glands in the head of birds are located in autonomic ganglia near or embedded in the organs (Ash et al., 1969). Cell bodies of preganglionic neurons innervating parasympathetic postganglionic vasodilator neurons associated with structures in the head are located in the oculomotor, facial, glossopharyngeal, and vagal nuclei in the brainstem and course to peripheral ganglia via the respective cranial nerves associated with these nuclei (Akester, 1979). Postganglionic cholinergic nerve fibers innervating arteries and veins of the body originate from the somata of neurons located in plexuses associated with blood vessels themselves or, for vessels of the abdominal viscera, in prevertebral ganglia containing a mixture of adrenergic and cholinergic postganglionic neurons (Bennett and Malmfors, 1970; Bennett, 1974). The location of cells of origin of preganglionic axons innervating the postganglionic neurons producing vasodilation in the viscera and skeletal muscle has not been determined in detail. However, in birds, the parasympathetic outflow is organized in cranial and sacral tracts as it is in mammals. It would therefore be expected that preganglionic neuronal somata responsible for vasodilation in thoracic and anterior abdominal viscera and skeletal muscle in the upper part of the body are located in medullary vagal motor nuclei, with their axons running to postganglionic neurons via the vagus nerves. Similarly, vasodilation of posterior abdominal and pelvic viscera and skeletal muscle of the lower part of the body is likely to be mediated by preganglionic neurons with their somata located at sacral levels of the spinal cord and their axons innervating postganglionic neurons via the abdominal and pelvic autonomic nerves.

18.5.3 Control of the heart

18.5.3.1 Catecholamine effects on the heart

Both NE and EPI are present in circulating plasma of birds (see Section 18.5.2.3.3), and these amines have cardiac effects which include an increase in the rate of pacemaker depolarization (DeSantis et al., 1975; Bolton and Bowman, 1969) and augmented force of myocardial contraction (DeSantis et al., 1975; Bennett and Malmfors, 1974;

Bolton, 1967; Bolton and Bowman, 1969). In isolated heart preparations and in myocardial strips *in vitro*, NE has been found to be as effective as, or more potent than, equimolar EPI in producing inotropic and chronotropic augmentation. This is in marked contrast to the condition in the mammalian heart, in which EPI is the more potent stimulant (Gilman et al., 1990). In whole-animal experiments on birds, intravenously injected boluses of NE and EPI augment CO by transiently increasing both rate and force of contraction, contributing along with peripheral vasoconstriction to catecholamine-mediated hypertension (Wilson and Butler, 1983; Wilson and West, 1986; Bolton and Bowman, 1969; Butler et al., 1986). In the avian as in the mammalian heart, catecholamines appear to act primarily via β-adrenergic receptors on myocardial and P-cells (Bolton and Bowman, 1969; Butler et al., 1986; Bolton, 1967).

18.5.3.2 Neural control

18.5.3.2.1 Sympathetic innervation

18.5.3.2.1.1 Anatomy Postganglionic sympathetic nerve fibers arising from neuronal somata extrinsic to the heart form part of an intracardiac nerve plexus distributed throughout all four cardiac chambers. The adrenergic innervation of the proximal part of the venae cavae appears to be continuous with the intracardiac plexus associated with the right atrium (Bennett and Malmfors, 1970). Sympathetic nerve fibers form a network over the epicardial surface of the right atrium, with some fibers penetrating into the thin atrial wall to lie adjacent to bundles of myocardial cells and others passing through the wall to the subendocardium (Smith, 1971a). The overall appearance of the plexus is that of a three-dimensional latticework of fibers extending from the epicardium through the wall to the subendocardium, with varying concentrations of smooth nonvaricose and varicose nerve fibers and nerve endings in different regions of the atrial myocardium.

Bennett and Malmfors (1970) reported that the most densely innervated region of the heart was the external wall of the right atrium; furthermore, within this area the region adjacent to the confluence of the venae cavae with the wall contained the highest density of fibers and terminals. These authors referred to this area as the "sinuatrial node," presumably by analogy with the corresponding sharply defined SA node of the mammalian heart. There is, however, some evidence that the cells in the primary pacemaker site in the right atrium of the bird heart may have a functional organization different from that in the mammalian heart, in the area of the junction of the sinus venosus with the SA valves (Moore, 1965; and see Section 18.2.3.3). These valves are present in birds but are only represented by a vestigial flap in mammals. A large number of the nerve fibers in this area of the avian heart were varicose, running among the myocardial cells and aligned with the longitudinal axes of these cells. Another area with a high density of adrenergic terminals was in the right atrial wall near the AV border, an area corresponding to the AV node (Bennett and Malmfors, 1970, Section 18.2.3.3). Many nerve varicosities were also associated with blood vessels in the right atrial wall.

Bogusch (1974) reported in the fowl that the specialized cells of the pacemaker areas and conducting system in the right atrium are well innervated by nerve fibers with frequent varicosities and some bare nerve endings. In contrast, Yousuf (1965) found no investment of nerve fibers into the SA node region and few in the AV node in the sparrow heart. This disparity could be due to a species difference or to a relative lack of sensitivity of the silver stain; in any case, neither technique is neurotransmitter specific nor as sensitive as the amine fluorescence technique. Full details of the sympathetic innervation of the conducting tissues of the right atrium are still not clear.

The right AV valve has a central layer of connective tissue between two layers of cardiac muscle (Section 18.2.1.4), and nerve bundles have been observed in association with this connective tissue (Smith, 1971a). In this study, several general nerve stains as well as a cholinesterase-specific stain were used, but unfortunately no details are given regarding the specificity of staining of the valvular innervation. However, Bennett and Malmfors (1970) have shown that this valve is innervated by adrenergic nerve fibers with few terminals, arranged in a loose plexus in the leaves of the valve. These observations suggest the existence of some degree of neural control of this valve, possibly by both sympathetic and parasympathetic limbs of the autonomic nervous system.

Adrenergic innervation in the left atrium is less dense than in the right atrium, but denser than the ventricles. Adrenergic fibers and terminals of the left atrial cardiac plexus, while distributed in a three-dimensional pattern similar to that in the right atrium, appear to be more evenly spread throughout the left atrial wall with little variation in density. In addition, the interatrial septum also receives adrenergic innervation as an extension of the epicardial plexus (Akester, 1971; Akester et al., 1969). The distal portion of the left AV valve has a fibroelastic structure, while more proximally cardiac muscle is associated with the fibrous skeleton (Section 18.2.1.4). Smith (1971a) has described a fine network of nerve fibers, continuous with the left atrial subendocardial plexus, investing the fibroelastic portion of this valve; no mention of an innervation of the muscular portion of the valve was made in this study. The staining technique used was again not transmitter specific, so the left AV valve may be under sympathetic or parasympathetic influence, or both, or the

innervation observed may be afferent. However, regarding the latter possibility, Smith (1971a) states that no simple or specialized nerve endings typical of sensory receptors were observed in or near the left AV valve.

The avian ventricles are relatively sparsely innervated compared with the atria, but even so are more densely innervated than are the ventricles mammalian hearts (Smith, 1971b). Akester et al. (1969) and Akester (1971) reported adrenergic innervation of the interventricular septum, and Bennett and Malmfors (1970) observed that innervation of this region was denser than that in the rest of the ventricle walls. While these authors did not determine the intraseptal targets of innervation, it is possible that some of these axons may innervate intraseptal Purkinje cells since bare nerve endings have been observed close to these cells (Akester, 1971). Regarding the innervation of the pulmonary and aortic valves, Smith (1971a) reported that they were sparsely innervated in comparison with the left AV valve. Fibers in the pulmonary and aortic valves comprise a plexus arranged to form a widely spaced lattice in the basal parts of the valve leaflets.

In birds, the sympathetic cardiac nerves arise from the most rostral ganglia of the thorax and the most caudal cervical ganglia, but there is some variation in detail among different accounts (see Cabot and Cohen, 1980 for summary). Macdonald and Cohen (1970) and Cabot and Cohen (1980) describe the right sympathetic cardiac nerve in the pigeon as a single trunk formed by the anastomosis of postganglionic nerves arising from the three most caudal cervical ganglia. These ganglia are associated with spinal nerves contributing to the brachial plexus; the most caudal ganglion of this group is thus associated with the last spinal segment contributing to the brachial plexus. This description closely follows that of Malinovsky (1962) in the pigeon. In the chicken, however, the origin of the right cardiac sympathetic nerve is limited to the first thoracic paravertebral ganglion (as defined by its location caudal to the head of the first rib; Pick, 1970; Tummons and Sturkie, 1969).

There has been some controversy over the nomenclature of avian sympathetic ganglia. Birds have a sympathetic ganglion associated with each cervical spinal segment (Gabella, 1976; Pick, 1970) and this observation, as well as variations in opinion on numeration of the ribs in the bird, has made it difficult to be precise about the terminology for the most caudal ganglion contributing to the cardiac nerve. Malinovsky (1962) holds that this is the first thoracic ganglion, since it lies between the heads of the first and second ribs. However, Macdonald and Cohen (1970) have sided with earlier authors in noting that the first rib should not be considered to mark the first thoracic segment since this rib is reduced in size and does not form part of the ribcage proper. As Cabot and Cohen (1980) have pointed out, the issue of terminology is not critical when considering functional aspects of cardiac sympathetic outflow to the bird heart, but may become important when attempting to draw conclusions about the homology of this pathway with the sympathetic innervation of the mammalian heart. Mammals have no cervical paravertebral ganglion chain, and postganglionic neurons efferent to the heart in this vertebrate class are located in the middle cervical ganglion and the stellate ganglion, the latter being formed by the condensation of the caudal cervical and first thoracic ganglia. This arrangement has no parallel in birds.

Regardless of the number of ganglia contributing to the right cardiac sympathetic nerve, the course of this nerve to the heart appears to follow the same general pattern in all avian species so far examined. The nerve courses toward the heart in conjunction with a small vertebral vein arising from the lateral aspect of the vertebral column between the last cervical and first thoracic spinal segments. The vessel and nerve merge with the apical pleura of the lung and run together between the pleural fascia. At the ventral surface of the pleura close to the junction of the vertebral vein with the superior vena cava, the nerve turns caudally along the vena cava toward the heart, there forming two rami. The medial ramus divides further and its fascicles enter the cardiac plexus to distribute within the right atrial wall. The lateral ramus joins the right vagus nerve in the vicinity of the right pulmonary artery (Pick, 1970; Cabot and Cohen, 1977a, 1980; Tummons and Sturkie, 1969; Macdonald and Cohen, 1970; Malinovsky, 1962). The ganglionic origin of the left sympathetic cardiac nerve is similar to that of the right, arising in the chicken from paravertebral ganglion 14 (first thoracic) and in the pigeon by anastomosis of postganglionic branches from ganglia 12, 13, and 14 (Cabot and Cohen, 1980). In the pigeon, the largest branch contributing to the left sympathetic cardiac nerve arises from ganglion 14, as on the right side. In its path to the heart, the left cardiac nerve in the pigeon divides into two or more fascicles which run in parallel for a short distance then recombine before reaching the superior vena cava. This nerve ramifies again as it runs caudally along the vena cava toward the heart and the individual rami merge with the cardiac plexus of the left atrium.

The general locations of the cells of origin of the sympathetic postganglionic axons to the avian heart and the intraspinal locations of the cardiac sympathetic preganglionic neurons have been worked out in greatest detail in the pigeon by Cabot and Cohen and their coworkers. These workers used a combination of degeneration, neuroanatomical tracing, and electrophysiological stimulation and recording techniques. Macdonald and Cohen (1970) undertook a series of neuronal degeneration studies in order to determine the ganglionic distribution of the somata of postganglionic neurons supplying axons to the heart. After section of the right or left cardiac sympathetic nerve in the thorax, the greatest number of degenerating neurons was

found in ganglion 14, with lesser numbers in ganglia 12 and 13; no degenerating neurons were observed in ganglia rostral or caudal to this level. Postganglionic cells of origin of fibers in the cardiac sympathetic nerves were thus located bilaterally in the same sympathetic ganglia which give rise to the postganglionic nerves constituting the cardiac nerve. In experiments in which the ganglia themselves or the interganglionic sympathetic trunks were stimulated electrically, Macdonald and Cohen (1970) obtained positive cardiac chronotropic responses of short latency from ganglia 12 to 16, occasional longer-latency responses from ganglia 17 and 18, and none from ganglia caudal to 18. Experiments in which stimulation of ganglia was combined with sections of the sympathetic trunk above and below the stimulation site confirmed these results. These data were interpreted to mean that preganglionic axons originating in the spinal cord as caudally as the 16th segment converged on postganglionic cardiac neurons in ganglia 12 to 14. The longer latency cardiac responses to stimulation of ganglia 17 and 18 were attributed to sympathetic activation of the adrenal glands and consequent release of catecholamines into the bloodstream; nerves arising from ganglia 17 and 18 were observed to join the splanchnic nerves, branches of which innervate the adrenal medulla.

Avian sympathetic preganglionic neurons innervating the heart are located in the same area of the spinal gray matter as those innervating the blood vessels, near the midline dorsal and lateral to the central canal, and extending rostrocaudally throughout segments 14 to 21. Most of the preganglionic neurons are confined to a distinct cell column in the midline, the column of Terni, a nucleus peculiar to the avian spinal cord (Huber, 1936; Cabot and Cohen, 1980). This cell column is the probable homolog of the mammalian intermediolateral cell column. Leonard and Cohen (1975), in a study of the cytoarchitecture of the pigeon spinal gray, reported that the rostral and caudal extents of this nucleus were indistinct due to small clusters of cells which extended into the regions between segments 13 and 14 and caudal to segment 21. Neurotracer studies using retrograde transport of horseradish peroxidase have shown that spinal preganglionic neurons efferent to the postganglionic cells in ganglion 14 of the pigeon are present from the caudal portion of segment 14 to the rostral part of segment 17 (Cabot and Cohen, 1977a). This finding provides strong anatomical support for the earlier conclusion of Macdonald and Cohen (1970), reached on the basis of functional and degeneration studies, that spinal preganglionic inputs to cardiac postganglionic neurons originate from segments 14 to 16, with some inputs possibly coming from segment 17.

The protocol used by Cabot and Cohen (1977a) did not label cardiac preganglionic neurons specifically. The region of the spinal cord containing cardiac preganglionic motor neurons has been more precisely mapped by Cabot et al. (1991b). In this study, preganglionic neurons associated with ganglion 14 in the pigeon were labeled using fragment C of tetanus toxin (a nontoxic moiety which is retrogradely transported by axons), injected into sympathetic ganglion 14. These experiments confirmed the location of preganglionic neurons in the column of Terni and also demonstrated labeling of neurons lateral to this nucleus (Figure 18.20) in an area which, in the mammalian spinal cord, is occupied by sympathetic preganglionic neurons of the nucleus intercalatus spinalis (Petras and Cummings, 1972), a term that Cabot et al. (1991b) have applied to the corresponding area in the pigeon spinal cord. Their results show that cardiac neurons in the spinal cord are not confined to the column of Terni. Few studies have labeled cardiac postganglionic sympathetic neurons in the bird which innervate specific regions of the heart. This will be required to determine the intraspinal locations of groups of neurons controlling cardiac functions such as rate and contractility.

The descending projections from higher centers in the central nervous system to sympathetic preganglionic neurons controlling the heart have not in general been delineated in birds. However, Cabot et al. (1982), in a series of anatomical studies in the pigeon, determined that the overall pattern of projections to spinal preganglionic neurons is very similar to that found in mammals, and this anatomical data corroborate the results of earlier brain stimulation studies in the bird. In particular, Cabot et al. (1982) have shown anatomically that avian preganglionic

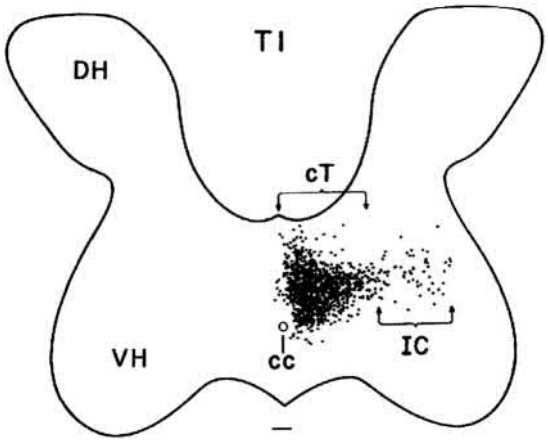

FIGURE 18.20 Mediolateral distribution of cell bodies of spinal preganglionic neurons labeled in the first thoracic segment (T1) of the spinal cord by an injection of a retrograde neurotracer (fragment C of tetanus toxin) into the right paravertebral ganglion 14 of the pigeon. The largest root of the cardiac sympathetic nerve in the pigeon arises from this ganglion. The diagram shows labeled neurons concentrated in the column of Terni [cT, large cluster of dots closest to the central canal (cc)], along with a lesser concentration of cells located more laterally in the nucleus intercalatus spinalis (IC). Although preganglionic neurons innervating the heart were not labeled specifically in this experiment, their cell bodies will be among the labeled population. *DH*, dorsal horn; *VH*, ventral horn. *Horizontal scale bar* represents 50 μm. *From Cabot et al. (1991a).*

neurons receive direct projections from diencephalic and medullary areas which, when electrically stimulated, provoke cardioaugmentation (Macdonald and Cohen, 1973; Folkow and Rubenstein, 1965; Kotilainen and Putkonen, 1974; Feigl and Folkow, 1963).

18.5.3.2.1.2 Sympathetic control Electrical activation of intramural adrenergic nerves in the avian heart produces augmented force of contraction and cardioacceleration. Bolton and Raper (1966) and Bolton (1967) first demonstrated sympathetically mediated augmentation of force of contraction of electrically paced strips of *in vitro* left ventricle from the fowl heart. In these studies, field stimulation excited both cholinergic and adrenergic nerves, and sympathetically mediated augmentatory effects were then pharmacologically isolated by the application of atropine to eliminate parasympathetic inhibitory effects. After muscarinic blockade, the increased contractile force produced by field stimulation was attributed to activation of adrenergic nerves since this effect could then be blocked by β-adrenergic antagonists. These data provided the first evidence in birds that the sympathetic nervous system can have a positive inotropic effect directly on ventricular myocardial cells.

Similar field stimulation experiments on left and right atria *in vitro* have shown that activation of intramural sympathetic nerves has powerful effects on these chambers. In the left atrium of the fowl heart, increased force of contraction of myocytes resulted from sympathetic nerve activation. These positive inotropic effects were blocked by β-adrenergic antagonists (Koch-Weser, 1971; Bennett and Malmfors, 1974, 1975b). The right atrium *in vitro* responds to field stimulation of intramural sympathetic nerves with an increase in force of contraction and rate of pacemaker discharge, with both effects mediated by β-adrenergic receptors (Pappano and Loffelholz, 1974).

In the isolated chicken heart perfused *in vitro* by Langendorff's method, stimulation of the attached right cardiac sympathetic nerve produces positive chronotropic effects (heart rate increased from 186 to 292 beats min^{-1}; Sturkie and Poorvin, 1973). The basal heart rate of this isolated preparation, supplied with adequate oxygen in the perfusate at 40°C, might be expected to be similar to that of the *in situ* chicken heart after bilateral section of the vagus and cardiac sympathetic nerves ("decentralized" state), but this was not the case. The mean rate of *in situ* decentralized hearts was in the range of 235−285 beats per min (Tummons and Sturkie, 1968, 1969). Under these conditions, stimulation of the peripheral stump of the right cardiac sympathetic nerve increased heart rate to 345 beats per min, an increase of 48%. By comparison, stimulation of the right cardiac nerve stump attached to isolated hearts *in vitro* produced a mean heart rate of 292 beats per min. That is, maximal sympathetic stimulation in this preparation could only raise heart rate to a level equivalent to the basal rate of the decentralized heart *in situ.* However, even though basal heart rate was different in these preparations, the proportional increase in rate during sympathetic stimulation was the same in both cases. Thus sympathetically mediated chronotropic effects in the isolated heart may, in relative terms, reflect the capabilities of this control system in the *in vivo* heart.

In a beating heart *in vivo*, stimulation of the cardiac sympathetic nerves produces cardioacceleration. Tummons and Sturkie (1968), in the unanesthetized chicken, showed that either cardiac sympathetic nerve could produce this effect when stimulated: activation of the right nerve increased heart rate by 48% above the prestimulation value, while activation of the nerve on the left side increased heart rate by 32%. In the pigeon, however, Macdonald and Cohen (1970) found that only the right cardiac nerve mediated cardioacceleration when stimulated (Figure 18.21, top panel) while stimulation of the left cardiac nerve altered the appearance of the T wave of the ECG without a chronotropic effect (bottom panel, Figure 18.21). Such functional asymmetry in cardiac control has also been reported for the mammalian heart (Randall, 1994).

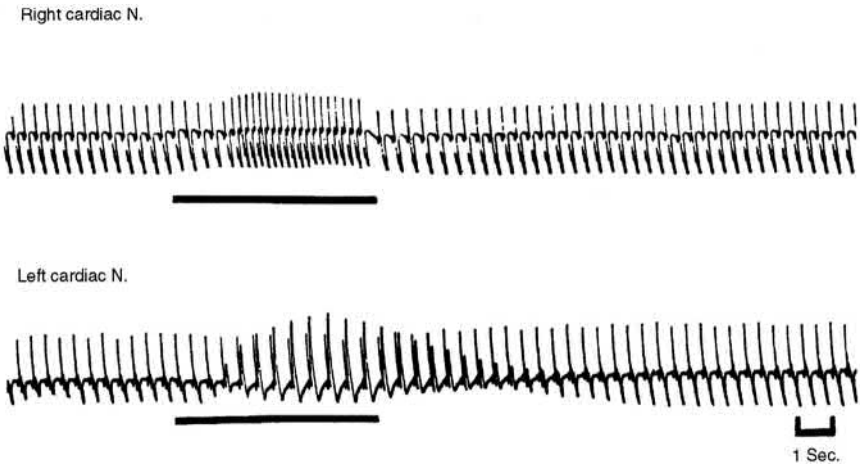

FIGURE 18.21 Electrocardiograms showing heart rate responses in the pigeon to electrical stimulation of the right (top) and left (bottom) cardiac sympathetic nerves. The duration of the stimulus train delivered to each nerve is indicated by the length of the solid bars under the traces. *From Macdonald and Cohen (1970).*

In the right atrium, the role of the dense adrenergic innervation of the SA area (see Section 18.5.3.2.1) in controlling heart rate is obvious, and a number of studies have shown that adjustments of heart rate *in vivo* are made by the sympathetic nervous system under a variety of physiological conditions. Furthermore, the anatomical evidence for widespread cardiac innervation and the data cited above for sympathetic influences on myocardial contractility in the atria and ventricles implies that the sympathetic nervous system can also produce both global and regional enhancement of contractility. Two important functional consequences of this arrangement are that (1) different patterns of sympathetic outflow from the central nervous system to individual chambers of the heart provide the means for augmenting regional contractility differentially to match the chambers' pumping actions to the hydraulic impedances into which they are working and (2) the output of each chamber can be controlled independently of pumping rate. However, to understand the function of this control system more thoroughly, it is necessary to establish whether different populations of pre- and postganglionic sympathetic neurons do in fact innervate different cardiac regions and whether such subpopulations may be differentially activated through reflexes driven by receptors in specific cardiac or vascular reflexogenic zones. Such an analysis is complicated by the location, remote from the heart, of cells of origin of the postganglionic sympathetic axons innervating the cardiac chambers, in contrast to the intracardiac locations of the postganglionic parasympathetic neurons.

Most studies of sympathetic control of cardiac function have affirmed the role of NE as the transmitter released by avian postganglionic terminals on the myocardium. However, the bird heart contains EPI as well as NE (Sturkie and Poorvin, 1973; De Santis et al., 1975; and data summarized in Holzbauer and Sharman, 1972). It has been suggested that, in other organs such as the rectum of the fowl, adrenergic terminals may release EPI (Komori et al., 1979). In the isolated chicken heart, De Santis et al. (1975) proposed that both EPI and NE may act as sympathetic neurotransmitters, on the basis of two main lines of evidence. First, sympathetic nerve stimulation, infusion of tyramine (a compound provoking the release of endogenous amines from sympathetic nerve terminals) or depolarization of intracardiac nerve terminals with a potassium-enriched perfusate all produced elevated NE and EPI efflux from the heart. Second, exogenously applied NE and EPI were equipotent in augmenting cardiac rate and strength of contraction. These authors also treated hearts with 6-hydroxydopamine to destroy sympathetic nerve endings and found that this reduced the intracardiac concentrations of both EPI and NE to very low levels. But De Santis et al. (1975) did not perform the critical experiment of determining the effect of chemical sympathectomy on release of catecholamines during cardiac nerve stimulation. Sturkie and Poorvin (1973), on the other hand, concluded that even though they and other workers had identified stores of both EPI and NE in the heart, only NE appeared to be released during sympathetic nerve stimulation. These authors concluded that EPI was sequestered in nonneuronal stores and would not, therefore, be involved in neurogenic control of the myocardium. Currently the most widely accepted view is that NE is the primary sympathetic neurotransmitter in the avian heart, as in the mammalian heart.

Autonomic tone is usually taken to mean the level of spontaneous and ongoing activity in autonomic nerves to the heart under "basal" or "resting" conditions (that is, when the animal is not actively moving or engaged in major physiological responses to its environment). Since monitoring spontaneous nerve activity is technically difficult in any preparation other than the acutely anesthetized animal instrumented for nerve recording, the level of basal heart rate is usually taken as the major indicator of cardiac autonomic tone as rate is easily measured under a variety of conditions in the whole animal. An added complication in analyzing tonic autonomic drive to the heart is that both autonomic limbs can strongly affect rate. Since rate is driven in opposite directions by parasympathetic and sympathetic inputs, the chronotropic effects of tonic activity in one limb can only be accurately assessed in the absence of influences from the other limb. Autonomic inputs to the heart can be selectively ablated by a variety of means including surgical section of the vagus or cardiac sympathetic nerves, chemical sympathectomy (by pretreatment with agents which destroy adrenergic nerve terminals or by adrenergic blockade), blockade of cardiac vagal effects with atropine, or a combination of these methods.

The level of sympathetic tone to the heart can be quantified by determining the change from basal heart rate produced by any of the above methods for functional sympathectomy after vagal influences on the heart are removed. Widely varying levels of sympathetic tone have been reported among bird species and even among different studies of the same species. A portion of this variability is likely due to the use of anesthetics. Baseline heart rate itself will change as a consequence of general anesthesia, and anesthetics will also have a blunting effect on autonomic control of the heart (Vatner and Braunwald, 1975; Brill and Jones, 1981; Lumb and Jones, 1984). Therefore the most accurate assessment of cardiac sympathetic tone would be made in awake, spontaneously breathing animals in a quiescent state after vagal influences on the heart have been eliminated.

Johansen and Reite (1964) investigated the level of autonomic tone to the heart in both awake ducks and those under general anesthesia; the authors did not differentiate between these states in reporting their data, claiming that

this made no difference to the outcome of the experiments. In vagotomized ducks in this study, β-adrenergic blockade produced a large fall in heart rate, implying the existence of strong resting sympathetic tone. Tummons and Sturkie (1969) reported that, in awake chickens at six days after recovery from surgical division of the cardiac sympathetic nerves, heart rate was about 16% less than that in intact animals. In anesthetized ducks, Kobinger and Oda (1969), using pharmacological agents to inhibit sympathetic function at central and peripheral levels of the nervous system, also found evidence for significant sympathetic tone to the heart. On the central side, they showed that clonidine mediated depression of vasopressor areas in the medulla, including the sympathetic cardiomotor area, led to a reduction in heart rate. On the peripheral side, depletion of NE from peripheral sympathetic terminals with reserpine, or prevention of NE release from these terminals, also significantly reduced cardiac rate. None of these experiments was done with accompanying vagal blockade. In contrast to the results of Kobinger and Oda (1969), Folkow et al. (1967) found no significant change in heart rate after β-adrenergic blockade in the same species. However, a complicating factor in the latter study was that the agent used (an experimental β-blocker then under development) was acknowledged by the authors to have a partial β-agonist effect which may have offset any effects of β-blockade on basal heart rate. Butler and Jones (1968; 1971) reported no significant change in heart rate in unanesthetized ducks after β-blockade with propranolol, an agent free of intrinsic β-agonist effects. In awake chickens, Butler (1967) found that β-blockade with the vagi intact produced a significant fall in heart rate to 75% of the control rate. β-blockade after vagotomy produced less of an effect, reducing heart rate to 82% of the level in animals with intact vagi. These results show that significant sympathetic tone is present in the chicken, reinforcing the contention that the level of this tone can only be accurately assessed in the absence of parasympathetic input to the heart. However, the results of Butler (1967) contrast with those of Tummons and Sturkie (1970), who found that sectioning the sympathetic nerve produced a fall of about 16% in heart rate from the level before nerve section, while vagotomy produced a rise of about the same proportion. Combined vagotomy and sympathetic nerve section resulted in a heart rate not significantly different from that in intact animals. The authors therefore concluded that, in resting intact animals, the balance between tonic sympathetic and parasympathetic inputs to the heart maintained rate at the same level as the intrinsic rate in animals after cardiac decentralization. It is clear from the foregoing discussion that further studies of tonic sympathetic drive to the heart must be rigorous in taking both the state of anesthesia and the level of concomitant parasympathetic drive into account.

An electrophysiological analysis of the compound AP of the right cardiac nerve in the pigeon has shown that axons in this nerve can be categorized into two groups separable by conduction velocity, as shown in Figure 18.22 (Cabot and Cohen, 1977a). Fibers of the more slowly conducting group (range 0.4–2 m s^{-1}) were shown to mediate sympathetic cardioacceleration. The range of conduction velocities of these axons lies within that of unmyelinated sympathetic postganglionic fibers known to innervate the viscera (Gabella, 1976), and morphological analysis of the pigeon

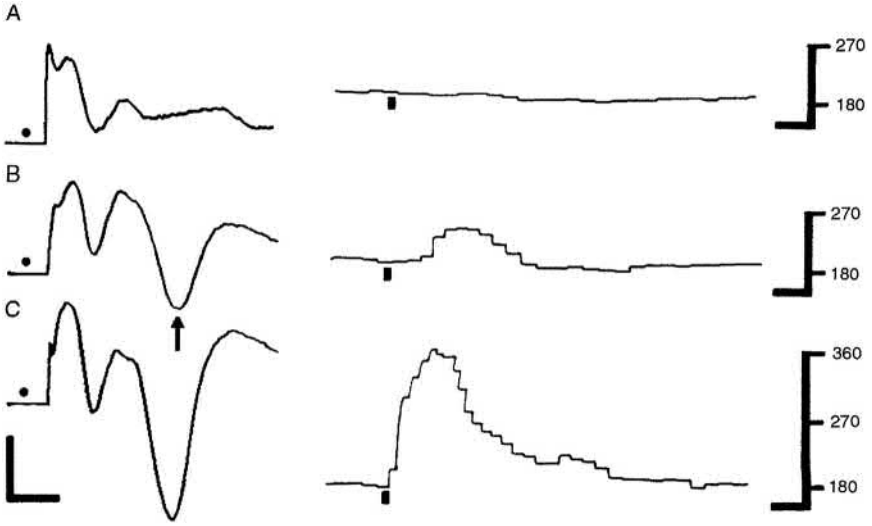

FIGURE 18.22 Correlation between components of the compound action potentials evoked by graded electrical stimulation of the right cardiac sympathetic nerve and chronotropic responses of the heart in the pigeon. The traces on the left represent the compound action potential at three intensities of stimulation increasing from A to C (*round dots* associated with each trace indicate the start of the stimulation, which consisted of a 200-ms train of 50 Hz pulses). For these traces, the vertical calibration bar represents 100 μV and the horizontal bar represents 5 ms. The traces on the right represent beat-by-beat ratemeter recordings showing heart rate responses produced by the same stimuli (*filled squares* under each trace) which evoke the nerve responses on the left. The calibration bars to the right of each trace indicate heart rate in beats min^{-1}. For these traces, the horizontal bar represents 1 s. The onset of the component of the compound action potential indicating conduction of cardioaccelerator fibers is indicated by the *arrow* in trace B; this component strengthens with increased stimulus intensity in trace C, as does the degree of cardioacceleration. *From Cabot and Cohen (1977a).*

right cardiac nerve confirms that 67% of axons in this nerve are unmyelinated (Macdonald and Cohen, 1970). The faster-conducting group of fibers in this nerve (range 2–5.6 m s^{-1}) are likely to be myelinated axons. These make up the remaining 33% of the total number of axons and probably represent so-called "sympathetic afferent" fibers (Malliani et al., 1979) with receptor endings in the heart, great vessels, or lungs. Afferent fibers in cardiac nerves have been shown to participate in cardiopressor reflexes in the pigeon (Cabot and Cohen, 1977b).

18.5.3.2.2 Parasympathetic innervation

18.5.3.2.2.1 Anatomy Efferent neurons with their cell bodies in the heart form the final common pathway for parasympathetic control of cardiac function. These postganglionic neurons receive synaptic inputs from terminals of preganglionic neurons with their somata in the brainstem and their axons coursing to the heart in the vagus nerves. It is generally accepted that parasympathetic efferent neurons in the heart are cholinergic, releasing ACh at their myocardial terminals; this neurotransmitter acts to modify myocardial function through postjunctional muscarinic receptors. Indeed, most of the anatomical studies of parasympathetic innervation of the heart have used a histochemical reaction indicating the presence of AChE as a marker to determine the distribution of cholinergic fibers and terminals of the cardiac plexus, as well as the locations of intracardiac neurons. Cabot and Cohen (1980) have extensively reviewed the cholinergic innervation of the heart, so a brief synopsis of that review and the contributions of later workers are combined below.

In all avian species so far examined, all four cardiac chambers receive AChE-positive innervation (Hirsch, 1963; Yousuf, 1965; Smith, 1971a,b; Akester and Akester, 1971; Mathur and Mathur, 1974; Rickenbacher and Müller, 1979; Kirby et al., 1987). Smith (1971a,b), in studies of the innervation pattern in the chicken heart, determined that cholinergic nerves, nerve fibers, and terminals formed a subepicardial ground plexus throughout the atria and ventricles, penetrating into the myocardium. Some fibers were observed to run all the way to the endocardial region where they contributed to a subendocardial plexus which was also distributed throughout the atria and ventricles. In many avian species, the overall intracardiac distribution of cholinergic innervation parallels the distribution of adrenergic fibers and terminals (Bennett and Malmfors, 1970). The right atrium has been a particular focus for anatomical studies of cholinergic innervation in view of the location of the primary pacemaker in this chamber and the vagally mediated inhibition of pacemaker node discharge rate. Yousuf (1965) noted in the sparrow heart that the region around the SA node was the first part of the heart to receive extrinsic cholinergic innervation during embryological development and observed that in later developmental stages this area and the right atrial wall near the AV node were heavily innervated. However, no nerve fibers were observed to enter the SA node area proper, and only a few fibers were present among the AV nodal cells. This pattern has also been observed in the pigeon heart (Mathur and Mather, 1974). However, Gossrau (as summarized in Akester, 1971) reported that in pigeon, chaffinch, and canary hearts the pacemaker region had a dense AChE-positive innervation, while in duck and chicken, this area was sparsely innervated. Differences among these studies may be partly species dependent, although the contrasting results of Mathur and Mathur (1974) and Gossrau in the pigeon heart may be due to differences in the techniques used. Bogusch (1974) observed a dense cholinergic innervation pattern around subepicardial Purkinje fibers of the fowl right atrium but noted that the density of this innervation decreased as the conducting fibers approached the AV border. In this study, multiple nerve terminals were only loosely associated with Purkinje fibers, leaving some doubt as to the nature of the neuroeffector–tissue relationship in cholinergic control of conduction in the atrium. SA valve remnants have also been reported to be the targets of cholinergic innervation in the bird heart (Akester, 1971; Mathur and Mathur, 1974).

Cholinergic innervation of the left atrium and the ventricles has been less extensively studied than that of the right atrium, but the general pattern of subepicardial and subendocardial plexi with individual nerve fibers and terminals extending into the myocardium, as described by Smith (1971b), appears to hold. Extensive cholinergic innervation has been described in the interatrial and interventricular septa (Akester, 1971), the right AV valve leaflets (Akester, 1971; Mathur and Mathur, 1974), and the left AV valve. Here the AChE-positive nerve fibers enter the basal half of the valve from the subendocardial plexus (Smith, 1971a). The cholinergic innervation of the avian chordate tendineae is controversial: Smith (1971b) reported no nerve fibers present in chordae tendineae of the chicken heart, while Mathur and Mathur (1974) found in the pigeon heart that these structures were innervated. The function of such innervation is obscure since the chordae tendineae contain no actively contracting tissue, serving only to anchor the papillary muscles to the aortic valve leaflets. It is most likely that the nerve fibers observed in these structures are efferents *en route* to either the valves or the papillary muscle, but some fibers may subserve an afferent function.

The adventitia of coronary arteries associated with all chambers of the bird heart is innervated by cholinergic nerve fibers (Hirsch, 1963; Akester, 1971; Smith, 1971a) but the origin of this innervation is not known. Cholinergic fibers innervating coronary arteries may originate from postganglionic parasympathetic neurons within the heart or

may possibly be extrinsic "sympathetic cholinergic" fibers; in either case, this innervation probably functions to increase coronary blood flow by promoting vasodilation.

In development of the chick heart, Rickenbacher and Müller (1979) determined that cell bodies of intracardiac neurons, clustered into ganglia, first developed in the left ventricle, then a large group of ganglia became evident around the coronary sulcus and the ventral surface of the ventricles and, lastly, ganglia developed in association with the dorsal atrial walls.

In the adult avian heart, ganglia are located primarily in the subepicardial plexus, usually in association with plexus nerves and frequently near the branch points of these nerves. The somata of intracardiac neurons have been characterized as multipolar (possessing more than two processes; Smith, 1971b; Yousuf, 1965), but these observations are limited to the hearts of only two species (chicken and sparrow, respectively). No morphological data exist on the variation of somatic dimensions or on the length or specific projection targets of the processes of intracardiac neurons in any avian species.

Histochemical reactions for AChE have been the primary tool used in analyzing the distribution of intracardiac neurons in the bird heart, and there seems little doubt that these techniques allow visualization of most if not all of these neurons. Such anatomical data, along with evidence from the functional studies cited below, supports the contention that the phenotype of avian intracardiac neurons is cholinergic. However, AChE has been detected in some nonneuronal elements associated with the nervous system (see review by Fibiger, 1982) and demonstration of the presence of this enzyme in neuronal somata in the heart, although necessary, may not be a sufficient criterion for designating these cells cholinergic. In the central nervous system, the most widely accepted indicator of cholinergic function is the presence of choline acetyltransferase (ChAT), an enzyme in the pathway for ACh synthesis (Fibiger, 1982). Reliable antibodies directed against ChAT are now commercially available and have begun to be applied to the mammalian peripheral autonomic nervous system. A similar application of ChAT immunohistochemical techniques to the avian heart would help verify the assumption that intracardiac neurons in this vertebrate group are in fact of cholinergic phenotype.

In their analysis of the distribution of the intracardiac ganglia during development, Rickenbacher and Müller (1979) found that the right ventricle wall contained about half of the total number of ganglia, the right atrium about one-fifth, the left ventricle about one-sixth, and the left atrium possessed the fewest ganglia. In the adult bird heart, no quantitative studies of regional neuron distribution have been done to date, so the absolute number of neurons associated with each chamber is not known. However the general pattern of distribution of intracardiac neurons in the adult heart has been established (see Cabot and Cohen, 1980 for review). Ganglia containing variable numbers of neurons are present on both dorsal and ventral aspects of the left and right atria and ventricles (Yousuf, 1965; Smith, 1971a,b; Rickenbacher and Müller, 1979; Kirby et al., 1987; reviewed by Cabot and Cohen, 1980). Smith (1971b) has reported that a larger proportion of the total number of intracardiac ganglia is found in the ventricles of bird hearts than is the case in mammalian ventricles. Ganglia have been observed near but not within the SA node region (Yousuf, 1965; Smith, 1971b). Yousuf (1965) reported that some neurons in the sulcus terminalis appeared to send projections in the direction of the nodal tissue. The AV nodal region was also reported to be devoid of ganglia (Yousuf, 1965; Smith, 1971b; Mathur and Mathur, 1974), but this region and the AV bundle appeared to be innervated by axons from ganglion neurons in the nearby AV sulcus (Yousuf, 1965). Smith (1971b) described high concentrations of ganglia within the dorsal right atrial wall near the ostia of the superior and inferior venae cavae, near the roots of the pulmonary veins on the dorsal aspect of the left atrium, within the dorsal portion of the AV groove, and clustered around the roots of the pulmonary artery and aorta. In the ventricles, neurons are located in a scattered pattern reaching from the AV groove to the apex on the ventral surface (Smith, 1971b; Rickenbacher and Müller, 1979). There are also numerous ganglia associated with nerves accompanying atrial and ventricular coronary arteries (Mathur and Mathur, 1974; Smith, 1971b).

Studies in the mammalian heart have shown that a number of neuropeptides are colocalized in axons, terminals, and somata of cholinergic intracardiac neurons, as well as in preganglionic terminals contacting these neurons (Steele et al., 1994, 1996). Peptides constitute an important class of neuromodulators in the peripheral autonomic nervous system, and their presence in specific combinations in some peripheral neurons has been proposed to chemically code subpopulations of these neurons for specific functions such as vasomotion or control of muscle cell contractility. In the bird heart, substance P and vasoactive intestinal peptide have been found in intracardiac neurons and their terminals, while somatostatin is present in intracardiac terminals but not in cell bodies (Corvetti et al., 1988). These neuropeptides have been shown to exert powerful modulatory effects on mammalian intracardiac neuronal activity and cardiodynamics (Armour et al., 1993), and their presence in the bird heart indicates that they may play a prominent role in modulation of ganglionic and neuroeffector transmission in this vertebrate group. This constitutes a promising but as yet unexplored area for the comparative study of mechanisms of neural control of the heart.

The course of the avian vagus nerve and its cardiac branches has been described for a number of species (see Pick, 1970; Jones and Johansen, 1972; Cabot and Cohen, 1980).

Cabot and Cohen (1980) points out that descriptions of the course and major branches of this nerve are consistent among species, so a general summary of the avian vagal cardiac innervation will be given here, based on the comprehensive reports of Malinovsky (1962) and Cohen et al. (1970) in the pigeon and the reviews cited above. Inside the cranium, the peripheral trunks of the vagus and glossopharyngeal nerves originate bilaterally from large ganglia composed of a fusion of the proximal ganglion of the glossopharyngeal nerve and the jugular ganglion of the vagus nerve. The trunks of these nerves emerge together from the skull through the jugular foramen, and immediately outside the foramen an anastomosis (of Staderini) connects the vagal trunk to the petrosal ganglion of the glossopharyngeal nerve. The vagal trunk continues caudad in the neck along the dorsomedial aspect of the internal jugular vein, passing over the cervical spinal nerves on their ventral sides. No major vagal branches arise from the trunk along its cervical portion, although Malinovsky (1962) described occasional small anastomoses with the nearby cervical sympathetic trunk. At the level of the thoracic inlet, the nodose (alternatively termed distal vagal) ganglia are present as spindle-shaped enlargements of the vagal trunks, as shown in Figure 18.23. Several afferent nerves carrying the axons of receptors important in the control of cardiovascular and respiratory functions arise

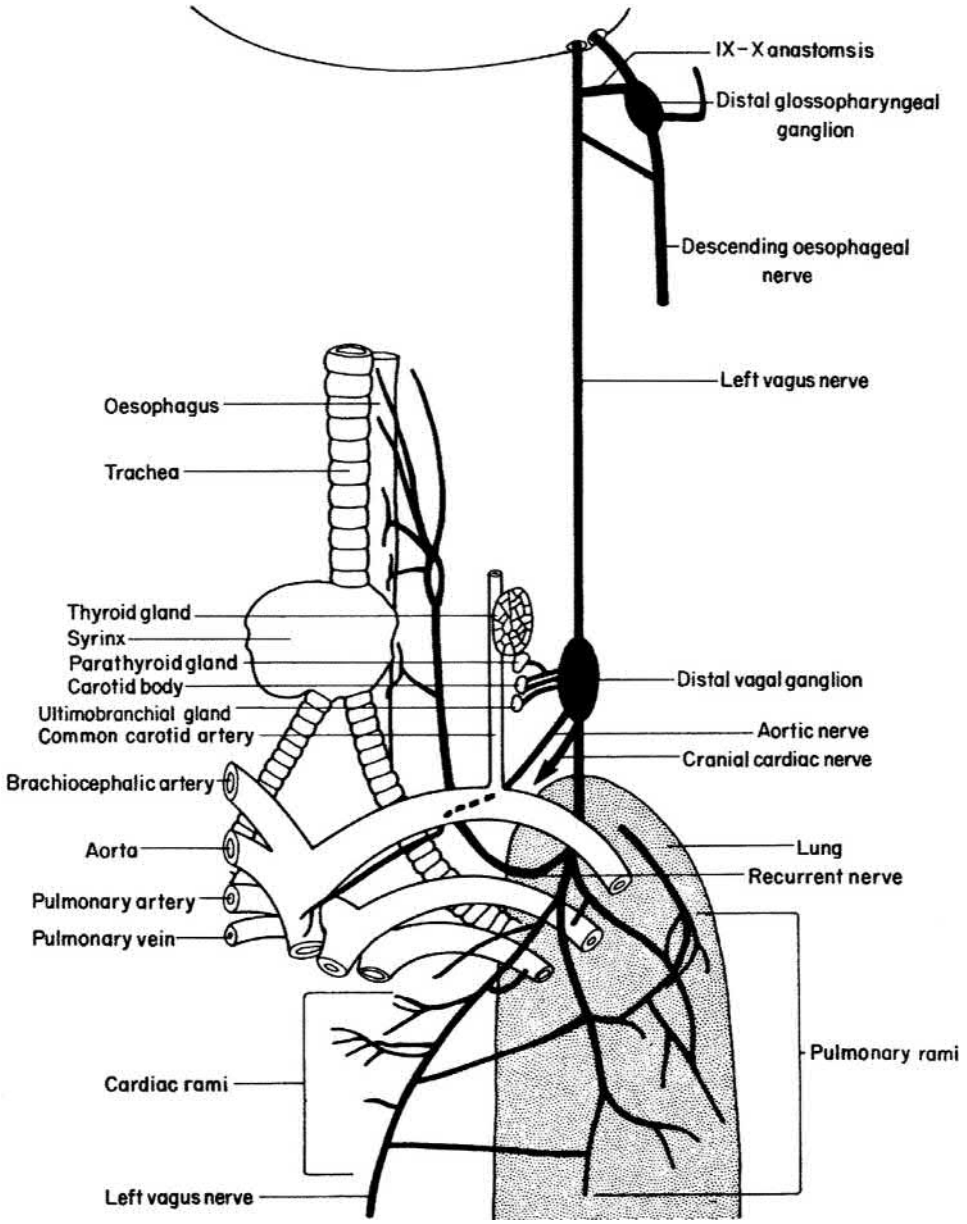

FIGURE 18.23 Schematic diagram depicting a ventral view of the pathway of the left vagus nerve in the area of the upper thorax of the duck. Details of the vagal innervation of the carotid body, ultimobranchial, thyroid, and parathyroid glands, and the aorta are illustrated. *From Jones and Johansen (1972).*

from each nodose ganglion. Along the length of this ganglion, branches arise which extend medially to innervate the thyroid, parathyroid, and ultimobranchial glands, and the carotid body (Figure 18.23).

The latter structure constitutes the primary locus for peripheral chemoreceptors sensing arterial oxygen and carbon dioxide tensions and pH in the bird (Jones and Purves, 1970; see Section 18.5.4.1). Branches exiting from the caudal portion of the nodose ganglion course to the root of the aorta. On the right side, Nonidez (1935) reported two such branches in the chick, which he designated "depressor" and "accessory depressor" nerves by analogy with the mammalian condition. Nonidez (1935) reported no equivalent nerve on the left side, but in other species, nerves from the nodose ganglion coursing to the aortic root (designated aortic nerves) have been reported to be present bilaterally (Jones and Purves, 1970; Jones, 1973; Cohen et al., 1970; Jones et al., 1983; Smith and Jones, 1990; 1992; summarized by Smith, 1994; see Figure 18.23). These nerves ramify into a plexus in the aortic wall. Jones (1973) first demonstrated that the aortic nerves carried arterial blood pressure information centripetally and that aortic baroreceptors were involved in regulating and maintaining arterial blood pressure in the duck.

A few millimeters caudal to the nodose ganglion the vagal trunk splits, as shown in Figure 18.24, to form several major divisions as it approaches the pulmonary artery. Two of these circumscribe the pulmonary artery, rejoin, and continue as the main vagal trunk *en route* to the abdominal cavity while a third forms the recurrent laryngeal nerve, coursing craniad along the trachea; no cardiac vagal branches arise from this nerve. Another major vagal branch courses to the heart to enter the dorsal cardiac plexus (Jones and Johansen, 1972; shown in Figure 18.23). The remaining vagal branches form part of the pulmonary innervation, running to the lungs along the pulmonary arteries. The main vagal trunk, after reforming caudal to the pulmonary artery, passes ventral to the ipsilateral bronchus and over the dorsal surface of the heart. From this portion of the trunk, a variable number of smaller branches arise and enter the cardiac plexus. On the right side, these branches enter the heart near the SA and AV nodes and at the caval ostia; on both the left and right sides of the heart, vagal branches also enter the cardiac plexus in the vicinity of the AV groove. That the cardiac nerves described here constitute

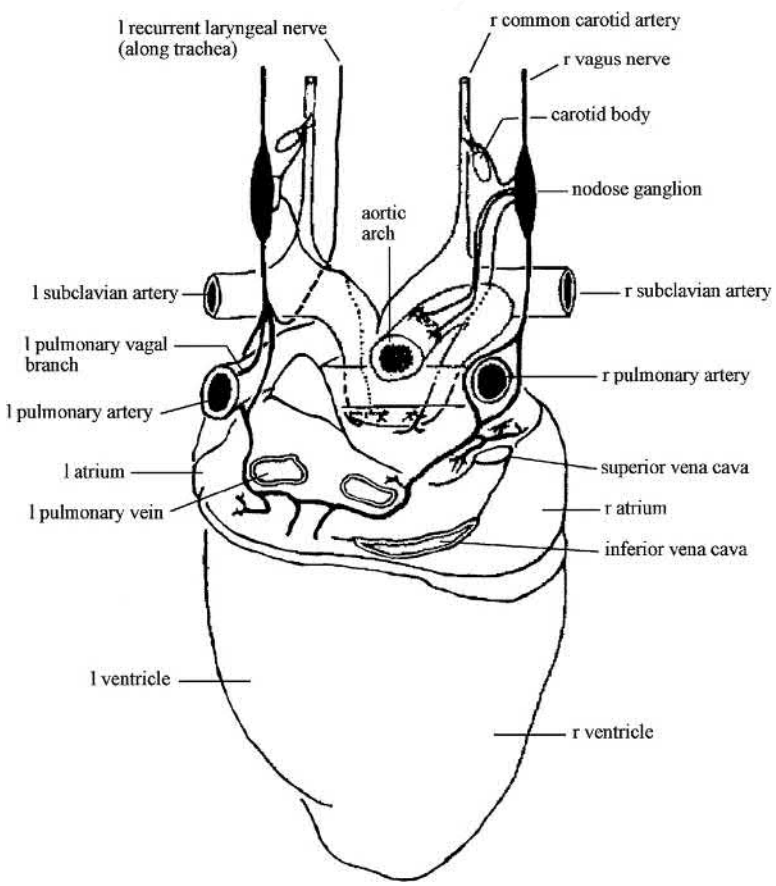

FIGURE 18.24 Schematic diagram to illustrate a dorsal view of the generalized vagal innervation of the avian heart. Note the pathways of the vagal branches as these nerves split close to the pulmonary arteries. For clarity, the right pulmonary and right recurrent laryngeal branches are not shown, and the right pulmonary vein, depicted next to the left, is not labeled (r, right; l, left). *From Cabot and Cohen (1980).*

the major efferent vagal innervation of the heart has been confirmed by functional studies in which electrical stimulation of the vagal trunk was combined with surgical section of the trunk and the various cardiac branches (Cohen et al., 1970). Caudal to the origin of the most inferior cardiac branches, the left and right vagal trunks pass ventral to the pulmonary veins where both turn medially, coming to lie in close approximation as they course to the abdominal viscera (Figure 18.24).

The location in the central nervous system of cells of origin of vagal cardioinhibitory fibers in birds has been investigated by a variety of anatomical and physiological techniques. The extent of the medullary regions containing vagal preganglionic motor neurons innervating pharyngeal structures and thoracic and abdominal viscera was originally defined anatomically by determining the extent of retrograde degeneration of neuronal somata after section of the cervical vagus nerve (Cohen et al., 1970) and by retrograde labeling of vagal neurons with neurotracers applied to the peripheral vagus nerve (Katz and Karten, 1979; 1983a,b; 1985; Cabot et al., 1991a). Cohen et al. (1970), working in the pigeon, described three major subdivisions of the dorsal motor nucleus of the vagus nerve (DMV) based on cytoarchitectonic and morphological criteria. The principal medullary location of neurons showing signs of degeneration after section of the cardiac vagal branches was in a region extending from the obex to the rostral pole of the DMV, with the highest density of degenerating cells in an area between 0.6 and 0.8 mm rostral to the obex. At this rostrocaudal level, these cells were primarily located in the most ventral region of the DMV. The results of these experiments suggested that the central arrangement of vagal cardioinhibitory neurons in birds was different than the mammalian condition; in mammals, the primary locus for these neurons is the nucleus ambiguus, ventrolateral to the DMV (reviewed by Hopkins, 1987).

In the pigeon, focal electrical stimulation of the regions of the DMV shown anatomically to contain cell bodies of putative cardioinhibitory neurons produced short-latency decreases in heart rate; this response is shown in Figure 18.25 (Cohen and Schnall, 1970). The response was rapid, occurring within one or two cardiac cycles after the start of stimulation, suggesting that cardioinhibitory preganglionic cell bodies were being directly stimulated. If stimulation was continued, complete AV blockade could be produced in some animals; a depressor response invariably occurred secondary to all negative chronotropic responses (Figure 18.25). There was no lateral asymmetry in this response: stimulating in the DMV on either side produced similar cardioinhibitory responses. The cardiac effects produced by central stimulation could be mimicked by stimulating the vagal trunks in the neck or at the thoracic inlet (Cohen and Schnall, 1970). Field potential and single-unit recordings made in the pigeon DMV during stimulation of the vagal trunk provided further confirmation that the cell bodies of a large number of cardioinhibitory neurons were located in the central zone of the DMV rostral to the obex (Schwaber and Cohen, 1978b).

Schwaber and Cohen (1978a), in an electrophysiological study of the vagus nerves, found that when the cervical vagus was stimulated at progressively greater intensities,

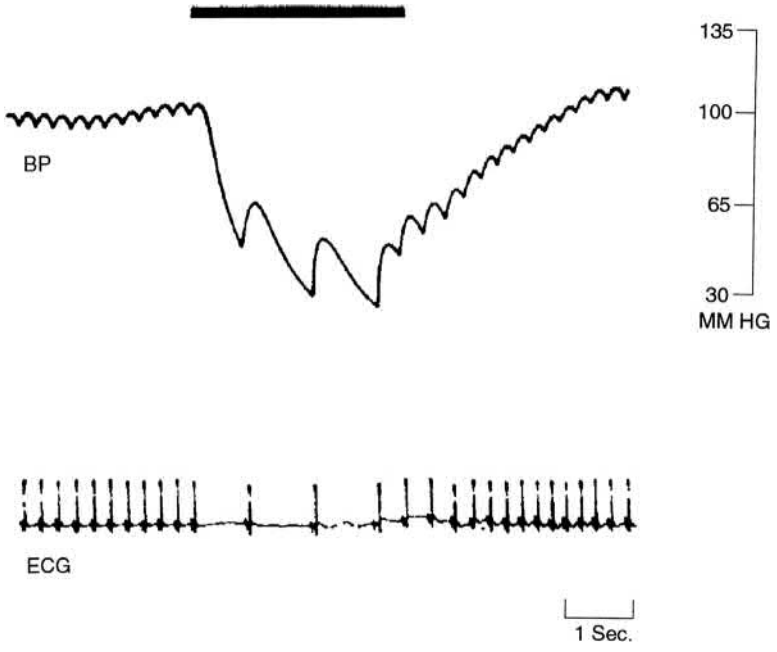

FIGURE 18.25 Arterial blood pressure (BP) and cardiac chronotropic (ECG) responses to focal electrical stimulation in the area of the dorsal motor nucleus of the vagus nerve in the pigeon. The duration of the stimulus train (50 Hz pulses) is shown by the solid horizontal bar above the traces. *From Cohen and Schnall (1970).*

the onset of bradycardia coincided with the elicitation of a specific component of the compound AP (B1 wave, Figure 18.26). This component was generated by the activation of a group of vagal axons conducting in the velocity range of 8 to 14 m s^{-1}. When the vagus nerve was stimulated with sufficient intensity to evoke both the A and B1 components (trace B of Figure 18.26) and a polarizing voltage was applied to the nerve to block the A but not the B1 component, the cardioinhibitory response was maintained. This led the authors to conclude that fibers in the vagus nerve responsible for generating the B1 component of the compound AP were responsible for cardioinhibition. This was confirmed in experiments in which field potential and single-unit activity were mapped in the DMV in correlation with synchronous compound APs recorded from the vagus nerve during stimulation of this nerve (Schwaber and Cohen, 1978b). In these experiments, stimulus-evoked activation of the B1 component in the vagus nerve produced the shortest latency, highest amplitude responses in the region of the DMV, which had been shown in previous studies to contain the somata of putative cardioinhibitory neurons. In addition to the evidence from stimulus-evoked potentials, recordings of spontaneously active single units in the DMV rostral to the obex in awake, paralyzed pigeons demonstrated rhythmic discharge patterns phase-locked to

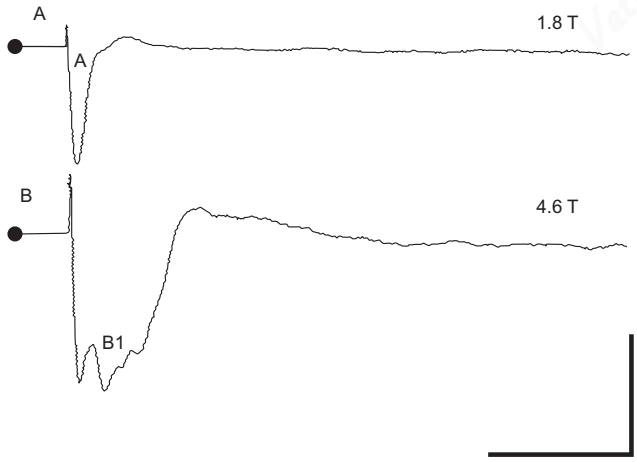

FIGURE 18.26 Compound action potentials evoked in the right vagus nerve by electrical stimulation at the midcervical level in the pigeon. Responses to stimuli of two intensities are shown. (A) Stimulation at 1.8 times the intensity which just evokes a response (threshold intensity, T) produces a short-latency component labeled the A wave, representing the fastest conducting fibers in the vagus (start of stimulus is indicated by the dot at the left side of trace). No change in heart rate is associated with the activation of this group of fibers. (B) Stimulation at 4.6 × T evokes responses in an additional, more slowly conducting group of fibers; this component of the compound action potential is labeled the B1 wave. The fibers responsible for this component conduct in the range of 8−14 m s^{-1} and when activated produce bradycardia. The vertical bar represents 250 μV; the horizontal bar represents 5 ms. *From Schwaber and Cohen (1978a)*

mechanical events in the cardiac cycle (Gold and Cohen, 1984). These authors also showed that single-unit neuronal activity in this area was decreased or eliminated by external conditioning stimuli (light flash, foot shock) which caused heart rate to increase (see Section 18.5.5).

The above anatomical and physiological evidence, taken together, indicates that in the avian brain preganglionic vagal cardioinhibitory neurons are located in the ventrolateral region of the DMV rostral to the obex. However a reexamination of the question of the location of these neurons was undertaken by Cabot et al. (1991a), using a more sensitive method for retrograde neuroanatomical tracing. These authors injected small volumes of the binding fragment of tetanus toxin into selected regions of the pigeon heart. This neurotracer was taken up by local nerve fibers and terminals at the injection site and transported retrogradely to label the somata of vagal preganglionic cardiac neurons in the medulla by two possible routes, both giving similar end results. The first of these was via direct uptake of neurotracer by fibers or terminals of the preganglionic neurons running through or close to the injection sites in the heart; in this case, the tracer would be transported directly back to the cell bodies. The second route was via transsynaptic transport. Fibers and terminals of postganglionic intracardiac neurons took up the neurotracer from the injection sites, and upon traveling to the somata and other processes of these neurons, the tracer would then cross synaptic clefts to the preganglionic terminals contacting the postganglionic cells. From these terminals, the tracer was transported to the somata of the preganglionic neurons. After intracardiac injection of the tracer, labeling of preganglionic vagal neurons was found in two locations in the medulla (Figure 18.27). The majority of label was found in neurons located ventrolateral to the DMV, in a site homologous to the nucleus ambiguus of the mammalian brainstem; these neurons were clustered within 0.5 mm of the obex as shown in the bottom panel of Figure 18.27. A smaller number of labeled neurons were found in more rostral sections in an area bordering the ventrolateral margin of the DMV (top panel of Figure 18.27), in close proximity to the region delineated in the degeneration studies of Cohen et al. (1970) and just ventral to the area described in the functional studies of Schwaber and Cohen (1978a,b). The results of Cabot et al. (1991a) have forced a reevaluation of the central organization of neurons controlling the avian heart, indicating that this organization has much more in common with the mammalian condition than was previously believed. However, these anatomical data have not been confirmed by physiological studies. In addition, it still remains for the membrane and firing properties of vagal cardioinhibitory preganglionic neurons to be investigated to determine if there are functionally discrete subpopulations within this group of neurons and, if so, whether there is any correlation

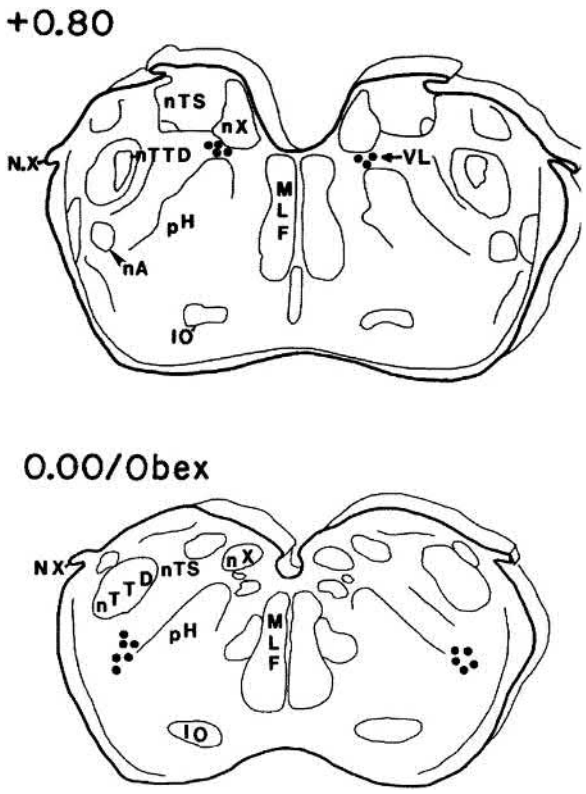

FIGURE 18.27 Outline drawings of transverse sections of the pigeon medulla in the region of the obex, depicting the location of vagal preganglionic neurons labeled by retrograde transport of tetanus toxin binding fragment C injected into the heart (see text for explanation). The top panel shows a section cut 0.8 mm rostral to the obex, with labeled neurons (*filled circles*) located just ventral to the dorsal motor nucleus of the vagus (nX) in the nucleus ventrolateralis (VL). The bottom panel, representing a section taken at the level of the obex, shows additional labeled neurons in an area of the medulla which may be the avian homolog of the mammalian nucleus ambiguus (nA), ventrolateral to nX. *IO*, inferior olivary nucleus; *MLF*, medial longitudinal fasciculus; *nTS*, nucleus and tractus solitarius; *nTTD*, nucleus and tractus trigemini descendens; *NX*, vagal nerve rootlet; *pH*, plexus of Horsley. *From Cabot et al. (1991a).*

between the functional properties of neurons and their potential roles in controlling specific aspects of cardiodynamic function.

Little is known of the nature and origins of inputs to medullary vagal cardiomotor neurons in birds. Berk and Smith (1994) have shown in the pigeon that peptide containing projections to these neurons arise from the area of the nucleus of the tractus solitarius (NTS). The NTS is one target for afferent information from visceral receptors carried in the vagus, glossopharyngeal, and other cranial nerves, and such peptidergic projections from the NTS to cardiomotor neurons may represent an important viscerovisceral reflex pathway, as has been described in mammals (Loewy and Spyer, 1990). In addition to inputs of peripheral origin, there is an extensive pattern of projections to the DMV from structures located more rostrally in the brain. Berk and Finkelstein (1983) and Berk (1987) demonstrated projections from the bed nucleus of the stria terminalis, the ventral paleostriatum, and the medial and lateral hypothalamus to the DMV. These forebrain inputs thus represent potential pathways through which central nervous control of cardiac function may be exerted in the interests of homeostasis, as well as providing pathways for neutrally mediated alterations in cardiac function which may be required during exercise, feeding, or other behaviors, or in response to changes in the external environment. In addition, Cohen and coworkers have explored the central anatomical pathways mediating conditioned responses (CRs) which target medullary cardiomotor neurons in birds (see Section 18.5.5). These cardiomotor neurons therefore integrate information from visceral and other receptors and from higher levels of the central nervous system to control cardiodynamics, but our knowledge of the integrative mechanisms involved is scant at present.

18.5.3.2.2.2 Parasympathetic control ACh acts in the bird heart to depress atrial and ventricular myocyte contractility, rate of discharge of pacemaker tissue, and rate of conduction through the specialized conductive tissues. ACh, released from preganglionic terminals, activates excitatory nicotinic receptors on the membranes of postganglionic neurons in the heart and these neurons in turn release ACh from their effector terminals to inhibit cardiac functions. Intrinsic postganglionic parasympathetic neurons release the majority of ACh which overflows from the isolated heart during vagal nerve stimulation. Only a small fraction of the total amount of ACh recovered in these experiments is released from vagal preganglionic terminals, as shown by a large reduction in vagally evoked ACh release after treatment of the isolated heart preparation to prevent release of the neurotransmitter from postganglionic terminals (Loffelholz et al., 1984).

ACh has different effects on the cell membrane conductance and thus on contractile properties of myocytes in the avian atria and ventricles. Inoue et al. (1983), using intracellular electrode techniques *in vitro*, investigated the effects of ACh on membrane ion conductance of atrial and ventricular myocytes to determine how these might differ. They found that, in ventricular muscle cells, ACh reduced the force of contraction, diminishing both amplitude and time course of the AP, but did not change either resting membrane potential or whole-cell resistance. On the other hand, in atrial myocytes, ACh hyperpolarized the membrane and reduced whole-cell resistance (implying an increase in steady-state ionic conductance) as well as causing a reduction in amplitude and time course of the AP. ACh binds to muscarinic receptors on myocyte membranes, and the authors found that this induced similar decreases in calcium-dependent sodium currents in the two types of cells. However, atrial myocytes exhibited in addition a muscarinic mediated increase in outward potassium current

which accounted for the hyperpolarization and reduction in resistance induced by ACh; this mechanism was not present in ventricular myocytes. These differences in response to ACh imply that the same neurotransmitter can differentially control atrial and ventricular contractility.

There are several subtypes of muscarinic receptor present in the mammalian heart (see Deighton et al., 1990 for review), and some of these receptor subtypes are also present in the avian heart. The majority of muscarinic receptors on mammalian myocardial cells are of the M_2 subtype (Deighton et al., 1990; Jeck et al., 1988), and this subtype is believed to mediate complex intracellular mechanisms leading to the inhibition of myocyte functions which are ultimately responsible for the parasympathetic control of the heart. In a comparison of muscarinic receptor types in the chicken and guinea pig hearts, Jeck et al. (1988) found that receptors of the M_1 subtype predominated in the myocardium of the chicken while the most prevalent type in the guinea pig heart was the M_2 subtype, as found in other studies of the mammalian heart. Detailed analyses of the muscarinic receptor subtypes present in the hearts of other avian species have not been conducted, but if the results of Jeck et al. (1988) in the chicken represent the general avian situation, there are likely to be major differences in receptor-mediated intracellular mechanisms of mucarinic inhibition of myocyte function between birds and mammals.

In avian atrial tissue *in vitro*, *in situ,* or isolated hearts, it is widely accepted that ACh has a strong negative inotropic effect (e.g., Jeck et al., 1988 and review by Sturkie, 1986), but studies of specific cholinergic effects on ventricular inotropy have been few in the bird. Avian ventricular tissue has a higher density of cholinergic innervation than does that of mammals as outlined above and a higher proportion of the total number of intracardiac neurons is associated with the ventricles of the avian than the mammalian heart (see above, and Smith, 1971b). On the basis of early anatomical evidence suggesting a high density of cholinergic innervation of the ventricular myocytes in birds, Bolton and Raper (1966) compared responses of strips of the right ventricle of fowl and guinea pig hearts *in vitro* to endogenously released and exogenously applied ACh. Field stimulation of electrically paced ventricular strips produced a strong decrease in force of contraction of fowl ventricular tissue, while guinea pig ventricular tissue responded with an increase in force. Atropine, blocking muscarinic receptors, eliminated the negative inotropic response of the fowl ventricle to stimulation, and a strongly positive response was then observed; however, atropine had no effect on the response of the guinea pig ventricle to stimulation. The authors proposed that the fowl heart has a capacity for effective parasympathetic inhibition of ventricular inotropy, mediated by intracardiac release of ACh. Furthermore, blockade of this response unmasked a stimulus-evoked increase in force of contraction which the authors determined was the result of release of NE from sympathetic nerve terminals. They concluded that, in contrast with the mammalian condition, the fowl right ventricle was innervated by both the sympathetic and parasympathetic limbs of the autonomic nervous system. Subsequent *in vitro* work has confirmed these observations (Bolton, 1967; Biegon et al., 1980; Biegon and Pappano, 1980).

The first experimental approach used to explore general questions of parasympathetic efferent control of the avian heart, dating from the early part of this century, was to examine the effects of exogenously applied ACh on the activity of P-cells in the right atrium (reviewed by Jones and Johansen, 1972; and Cabot and Cohen, 1980). More detailed characterization of this system has resulted from investigations carried out by Loffelholz and co-workers, and others. In the *in vitro* right atrium, ACh release provoked by field stimulation and by stimulation of the attached right vagus nerve produced a fall in pacemaker discharge rate (Pappano and Loffelholz, 1974; Pappano, 1976; Brehm et al., 1992). This chronotropic effect was blocked by atropine but not by the ganglionic blocker hexamethonium, so it must have been mediated by direct release of ACh from postganglionic parasympathetic neurons in the atrial wall (Pappano and Loffelholz, 1974). On the other hand, hexamethonium in the absence of atropine blocked all effects of electrical stimulation of the attached vagal stump. Vagally mediated bradycardia therefore occurred as a result of the synaptic activation of intracardiac postganglionic neurons by preganglionic terminals. As with cholinergic control of the inotropic state of the atrial and ventricular myocardium discussed above, control of pacemaker rate operates via the synaptic relay of impulses from pre- to postganglionic neurons within intracardiac ganglia.

18.5.3.2.2.2.1 Dromotropic effects. There have been no studies of the direct effects of ACh on the rate of impulse conduction through the specialized conducting cells of the avian heart and few studies of the overall parasympathetic control of this function. There are technical difficulties in identifying the locations of conducting tissues in a viable *in vitro* preparation of cardiac tissue, so work on this intriguing problem in birds has largely been conducted on hearts *in situ.* In the chicken, Goldberg et al. (1983) showed that AV conduction time could be significantly prolonged by stimulation of either vagus nerve; there was no bilateral asymmetry in this response. However, in order to unmask this dromotropic effect, the heart was paced through electrodes attached to the SA node, both to control heart rate and to prevent shifts in pacemaker position during vagal nerve stimulation. Bogusch (1974), using anatomical techniques, identified cholinergic fibers and terminals in the region of conducting cells near the AV

border and proposed a functional role for this innervation, but the study of Goldberg et al. (1983) appears to be the only physiological confirmation of this role in the bird (also see Section 18.2.3.3).

18.5.3.2.2.2.2 Chronotropic effects. The study of vagal control of heart rate in birds has a long history going back to the recognition in the last 18th century that activation of the vagus nerves could produce large reductions in heart rate and, in some cases, arrest the heart (see Cabot and Cohen, 1980 for a summary of early work). As these reviewers have pointed out, the nature of vagally mediated bradycardia has been intensively reinvestigated using recently developed techniques in a variety of avian species (Johansen and Reite, 1964; Bopelet, 1974; Peterson and Nightingale, 1976; Langille, 1983; Lindmar et al., 1983; Goldberg et al., 1983; Lang and Levy, 1989; Butler and Jones, 1968; Cohen and Schnall, 1970; Jones and Purves, 1970; and others). The negative chronotropic effects of ACh in the pharmacological studies cited above are paralleled by the effects of electrical stimulation of the vagus nerves. Several preparations have been used to assess the chronotropic consequences of vagal stimulation. These include *in vitro* atrial tissue, isolated beating hearts with attached vagal stumps, open-thorax anesthetized preparations, and anesthetized or awake animals in which only the vagi in the cervical region were exposed. Vagal control of the heart is apparently very robust in all of these preparations, and each type of preparation yields results which complement the findings obtained from the others.

Examples of stimulus-induced bradycardia obtained in pigeon are shown in Figure 18.28. The peripheral cut ends of the right (top panel) and left (bottom panel) cervical vagus nerves were stimulated with trains of pulses at a frequency of 50 Hz. In each case, the contralateral vagus nerve was intact. In these examples, the intensity of stimulation used was capable of arresting the heart. A close parallel to the negative chronotropic effect of peripheral vagal nerve stimulation can be produced by focal electrical stimulation in the medulla (Cohen and Schnall, 1970), where anatomical studies (see above) have shown that cardiac vagal preganglionic neurons are located.

The effectiveness of the left and right vagi in controlling heart rate has been shown by some workers to be equivalent, while other workers have found strong bilateral asymmetry in this system. Bopelet (1974), Peterson and Nightingale (1976), and Goldberg et al. (1983) reported no

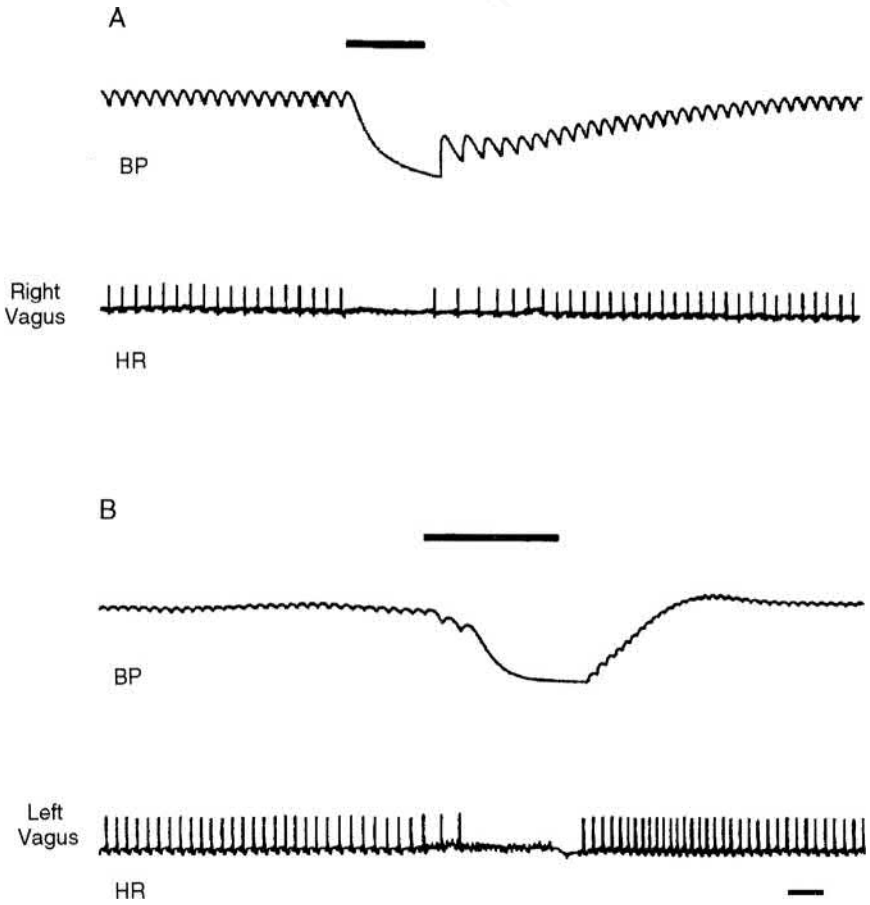

FIGURE 18.28 Effects of stimulating the right (A) and left (B) vagus nerves on heart rate (HR) and arterial blood pressure (BP) in two pigeons. The nerves were exposed in the neck and stimulated with 50 Hz trains of pulses. Stimulus duration indicated by the horizontal bars above the BP traces. Horizontal bar below the bottom trace represents 1 s. *From Cohen and Schnall (1970).*

difference in the chronotropic response of the fowl heart to electrical stimulation of left and right vagus nerves. In the same species, however, Sturkie (1986) and Lang and Levy (1989) reported that the right vagus was more effective in altering heart rate than was the left. Johansen and Reite (1964), in ducks and seagulls, Jones and Purves (1970) in ducks, and Cohen and Schnall (1970) in pigeons, all reported a similar asymmetrical response to electrical stimulation of the vagus nerves. Furthermore, in a systematic study of vagal control of heart rate in the duck, Butler and Jones (1968) showed by means of cold blockade of the vagi in the neck and by unilateral and bilateral section of these nerves that vagal dominance could change sides over time. However, the latter authors did not stimulate the peripheral cut ends of the vagi after nerve section, so it is not known whether the origin of this bilateral asymmetry was within the central nervous system or at the heart.

Lindmar et al. (1983) have quantified the amounts of ACh released in the isolated chicken heart by stimulation of the attached left and right vagal stumps in an attempt to determine if there were bilateral differences in the intracardiac connections of these nerves. If fibers from each vagus innervated approximately the same number of postganglionic intracardiac neurons, the amount of ACh released by stimulation of either nerve alone would be expected to be similar, and this was in fact found to be the case. If there were no overlap in the populations of intracardiac neurons innervated by each vagus, then the sum of ACh released by unilateral stimulation of each nerve should be the same as that released by simultaneous bilateral nerve stimulation. However, Lindmar et al. (1983) found that the sum of ACh released by separate nerve stimulation was significantly greater than that released by bilateral stimulation, indicating that a large proportion of intracardiac neurons must have been bilaterally innervated. In these experiments, it was not possible to separate the responses of postganglionic neurons innervating the pacemaker tissue from the responses of neurons subserving other functions, but if it is assumed that the overall pattern of bilateral innervation found by Lindmar et al. (1983) can be applied to the specific subpopulation of neurons controlling heart rate, then this pool of neurons may be controlled by preganglionic fibers running in either nerve. There would thus be little reason to expect that side-to-side shifts in vagal dominance result from factors acting to change the relative intracardiac influences of these nerves. This line of reasoning supports the notion that changes in the pattern of activity of vagal preganglionic neurons in the medulla may be responsible for spontaneous shifts in the dominant vagus nerve. Such central nervous factors might be investigated using the approach of Gold and Cohen (1984) to simultaneously record spontaneous activity from neurons in medullary vagal complexes on both sides.

18.5.3.2.2.2.3 Inotropic effects. Despite the evidence cited above for strong negative inotropic effects of endogenously released or exogenously applied ACh in the avian heart *in vitro*, the inotropic effects of vagal stimulation on *in situ* hearts is controversial. Folkow and Yonce (1967) unmasked a strong reduction in one index of left ventricular contractility, that of peak left ventricular chamber pressure, in the duck heart in response to vagal nerve stimulation when heart rate was kept constant by electrical pacing. These authors also found that CO declined with vagal stimulation during pacing. Since vagal stimulation was shown not to affect peripheral resistance in this study, the fall in CO must have been caused by a decrease in stroke volume. While contractile force was not measured directly, the authors attributed both the fall in left ventricular pressure and in CO to a vagally mediated decrease in ventricular contractility. That this effect was neurally mediated was demonstrated by the elimination of the effects of vagal stimulation after atropine was administered intravenously. Furnival et al. (1973), using another index of ventricular contractility, that of maximum rate of change of left ventricular pressure, reported results contrary to those of Folkow and Yonce (1967). In their comparative study of the responses of ventricular contractility to vagal stimulation in the dog, duck, and toad, Furnival et al. (1973) reported that only the amphibian heart displayed a significant reduction in contractility. These authors proposed that the ventricles of the ducks in the experiments of Folkow and Yonce (1967) had been subject to very high end-diastolic pressures as a consequence of the experimental protocol, were probably in failure as a result of this treatment, and thus responded abnormally to vagal stimulation. Yet Lang and Levy (1989), using the same index of ventricular contractility in the chicken as that employed by Furnival et al. (1973) in the duck, concluded that vagal stimulation could produce decreases of more than 50% in contractile force. Furthermore, the inotropic responses to vagal stimulation in the chicken heart reported by Lang and Levy (1989) were considerably more powerful than those that could be obtained in mammalian hearts.

The controversy surrounding this issue likely hinges on problems inherent in the methods used to evaluate ventricular contractility. Resolution of this issue will only be possible when more direct indices of contractility, such as direct attachment of Walton-Brodie type force gauges to the ventricular walls, estimation of beat-by-beat ejection fraction, or the measurement of CO in combination with ventricular and systemic pressures for calculating stroke work, are employed.

18.5.3.2.2.2.4 Tonic parasympathetic activity. Studies of tonic parasympathetic restraint of heart rate in several bird species have shown that this, like sympathetic tone, varies over a wide range. The factors discussed in Section 18.5.3.2.1, which affect the evaluation of

sympathetic tone (state of anesthesia, presence or absence of tone from the other autonomic limb), apply equally to the analysis of vagal tone, and the protocols used in studies of the extent of vagal restraint will therefore influence the way in which the results of these studies are interpreted. In a study by Johansen and Reite (1964) in awake or anesthetized ducks with intact sympathetic cardiac innervation, section of one vagus nerve (right or left) produced no change in heart rate; the chronotropic response to subsequent section of the remaining vagus was an increase in heart rate up to 65% above that in intact or unilaterally vagotomized animals. These results imply the presence of strong tonic vagal restraint of the heart; however, the authors found that after bilateral vagotomy, β-blockade revealed a high degree of sympathetic tone to the heart. Since the authors did not perform the converse experiment of β-blockade prior to bilateral vagotomy in this study, neither the balance between parasympathetic and sympathetic tone nor the actual degree of parasympathetic restraint on the heart could be ascertained. In unanesthetized ducks, Butler and Jones (1968), using a combination of cold block and section of the cervical vagi, showed that mean resting heart rate rose about 180% over the rate prior to these manipulations. In another study by the same authors, pharmacological blockade of the parasympathetic nervous system with atropine caused mean heart rate to increase to about 150% over the control value in awake ducks (Butler and Jones, 1971). In both of these studies, the sympathetic nervous system was functional during evaluations of parasympathetic tone. In chickens, Butler (1967) found that heart rate increased to 138% over the control value after bilateral vagal nerve section; in contrast to this, Bopelet (1974) reported an increase of only 8%, and Peterson and Nightingale (1976) found no change in rate in chickens after bilateral vagotomy. Sympathetic influence on the heart had not been eliminated in any of these studies. Sturkie and co-workers (reviewed by Sturkie, 1986) addressed the problem of evaluating parasympathetic tone to the heart by examining the effects of pharmacological or surgical vagotomy in the absence of sympathetic cardiac influences in the chicken using the rationale discussed in Section 18.5.3.2.1. They found that the net restraining effect of tonic parasympathetic activity on the chicken heart was the equivalent of a 20% reduction in heart rate from the rate of the completely decentralized heart. This estimate of vagal tone is substantially lower than the estimates of other workers in chickens (Butler 1967) or in ducks (Johansen and Reite, 1964; Butler and Jones, 1968, 1971) in which the sympathetic cardiac innervation was functional. The degree of parasympathetic restraint on the heart in the latter studies may have been exaggerated by the presence of ongoing sympathetic drive after the lifting of vagal influence.

18.5.3.2.3 Control of CO

The volume of blood pumped by either the left or right ventricle per unit time is termed CO. The total volume of blood pumped by the heart per unit time is therefore twice the CO, since the outputs of both sides of the heart must be exactly matched over time. CO, usually expressed in units of milliliters per minute, is the product of the rate of contraction of the heart (beats per minute) and the volume pumped during each beat, or stroke volume (mL). Rate and stroke volume are determined by factors which may be intrinsic or extrinsic to the heart. Intrinsic factors include atrial P-cell activity and contractile properties of the cardiac muscle fibers. Extrinsic factors affecting rate and stroke volume include autonomic nervous activity and levels of circulating cardiotropic hormones. CO over a given time period will thus be determined by the complex interplay of these intrinsic and extrinsic factors. Some of these have been discussed in previous sections, and references will be made to them as necessary.

18.5.3.2.3.1 Role of heart rate in control of CO The basal level of heart rate in the absence of external influences is primarily determined by the inherent membrane properties of the P-cells of the SA node (Section 18.2.3). The rate of depolarization, and thus the rate of discharge of APs in these cells, is set by the ion conductances through their membranes (particularly K^+), but this process is itself partly dependent on physical factors such as the concentrations of extracellular ions and temperature. Under most circumstances, these physical factors are kept within fairly narrow limits by homeostatic mechanisms and should therefore not affect heart rate substantially.

The interaction of the sympathetic and parasympathetic branches of the autonomic nervous system controls heart rate in a complex, nonlinear manner. Part of this complexity arises from the fact that the full chronotropic effects of vagal stimulation on heart rate occur within a few heart beats whereas it may take up to 30 s for the full expression of the cardiac response to sympathetic stimulation. Consequently, the most rapid changes in heart rate appear to be dominated by the parasympathetic system. The major reason for the nonlinearity is that the degree of parasympathetic−sympathetic interaction at the heart may be changed by increasing output of one of these limbs.

The relationship of heart rate to bilateral stimulation of the distal cut ends of the vagus and cardiac sympathetic nerves has been examined in the duck *A. platyrhynchos* (Furilla and Jones, 1987b). Increasing sympathetic activation at zero vagal activity increases heart rate by over 200 beats min^{-1} while increasing sympathetic drive at maximal vagal activation only increases heart rate by 50 beats/min. Similarly, increasing vagal activation causes heart rate to fall by more than 200 beats min^{-1} at zero sympathetic

activity and by nearly 400 beats min^{-1} at maximal sympathetic activity. Obviously, the greater the vagal drive, the more this input is able to occlude sympathetic effects on the heart, accounting for the nonlinearity in the interplay between the two branches of the autonomic nervous system at the cardiac pacemaker. This increased parasympathetic effectiveness in cardiac control is termed accentuated antagonism and may be mediated through two mechanisms. First, in response to sympathetic stimulation above a certain threshold, there is a cholinergically mediated reduction in prejunctional release of NE. Second, the magnitude of the postjunctional response to a given level of sympathetic stimulation is attenuated by ACh (Levy, 1971).

Short-term heart rate fluctuations are caused by the continued tug-of-war between the two branches of the autonomic nervous system at the pacemaker. This interplay may overlie long-term changes in heart rate caused, for instance, by changes in levels of circulating hormones. The normal homeostatic processes tend to reduce variability and maintain constancy of internal physiological functions, and short-term fluctuations in heart rate are usually seen as perturbations away from the norm. If a series of cardiac intervals is recorded from an animal, the duration of intervals within the series appears quite irregular with apparently random fluctuations occurring all the time. Whether these fluctuations are truly random or patterned, in the latter case providing evidence for chaotic control of heart rate (Denton et al., 1990; Goldberger et al., 1990), is a matter of some controversy. The strongest evidence for chaotic control of heart rate may lie in the morphology of the nerves innervating the heart. The nerves divide repeatedly, like the branching of a tree which is an intrinsically fractal structure. Hence, if the anatomy is fractal then why should the day to day workings of the system not be fractal as well? (Goldberger, cited in Pool, 1989; Goldberger, 1991).

In any event, it is clear that, rather than maintaining a homeostatic steady state, heart rate fluctuates considerably, even when recorded over short time periods (Figure 18.29A). The interbeat intervals form a time series which can be transformed into the frequency domain by Fourier analysis, revealing the presence of periodic components within the series. The square of the absolute value of the Fourier transform yields the power spectrum of the heart rate variability (PS/HRV; Kamath and Fallen, 1993).

The PS/HRV of an intact, resting, duck (*Aythya affinis*) is shown in Figure 18.29B(i). This plot reveals a respiratory sinus arrhythmia as a single major peak at the respiratory frequency. This is a manifestation of respiratory modulation of cardiac parasympathetic activity (Shah et al., 2010; the response to sympathetic heart stimulation is too slow to significantly affect heart rate at a high frequency). Blockade of the sympathetic nervous system with a β-antagonist tends to increase heart rate variability although the amplitude of the high-frequency components are reduced (Figure 18.29B(ii)), while parasympathetic blockade with atropine gives a regular, unvarying heart rate (Figure 18.29B(iii)). This confirms that short-term heart rate control is dominated by the parasympathetic nervous system in *Aythya affinis*. Similar control of heart rate variability has been found in hatchling emu (*Dromaius novaehollandiae*; Shah et al., 2010).

The PS/HRV is a quantifier of autonomic responsiveness (Saul, 1990) and allows evaluation of cardiovascular regulation in birds over long-time courses and during many types of activities. Also, the influence of other periodic functions such as arterial blood pressure and vasomotor fluctuations on PS/HRV can be evaluated using this technique. Telemetric recording of heart rate, combined with frequency analysis of cardiac function, will open new doors for studying control of physiological processes in unrestrained, active birds.

18.5.3.2.3.2 Role of stroke volume in control of CO Stroke volume, like heart rate, is dependent upon factors intrinsic and extrinsic to the heart. As all myocytes within the heart contract during each beat, the primary intrinsic factors which determine stroke volume are the inherent contractile properties of each muscle fiber and the resting lengths of all the fibers. The amount of force developed during contraction by a cardiac muscle fiber at a specified precontraction length is properly termed "contractility," but this term has also been used more loosely to describe the collective contractile properties of all muscle fibers associated with one chamber of the heart. A major problem in quantifying contractility is that the force developed by a single cardiac muscle fiber is difficult to measure in working hearts. Consequently, a number of indirect indices have been developed to estimate this variable. These include measuring cardiac outflow volume over time to calculate stroke volume; recording the ventricular peak systolic pressure developed against a fixed afterload or into a constant arterial pressure; and measuring the rate of rise of ventricular pressure during systole. The major assumption in all of these methods is that the measured variable reflects the contractility of all muscle fibers integrated over the dimensions of the whole chamber. However, the variety of indices of contractility used by investigators under different experimental conditions has made it difficult to compare estimates across studies. The direct measurement of volume flow from the ventricle would appear to give the most reliable index of cardiac contractility, being independent of the complicating effects of changing arterial or ventricular pressures. This measurement is also among the most difficult to make, requiring highly invasive procedures to place the appropriate instrumentation.

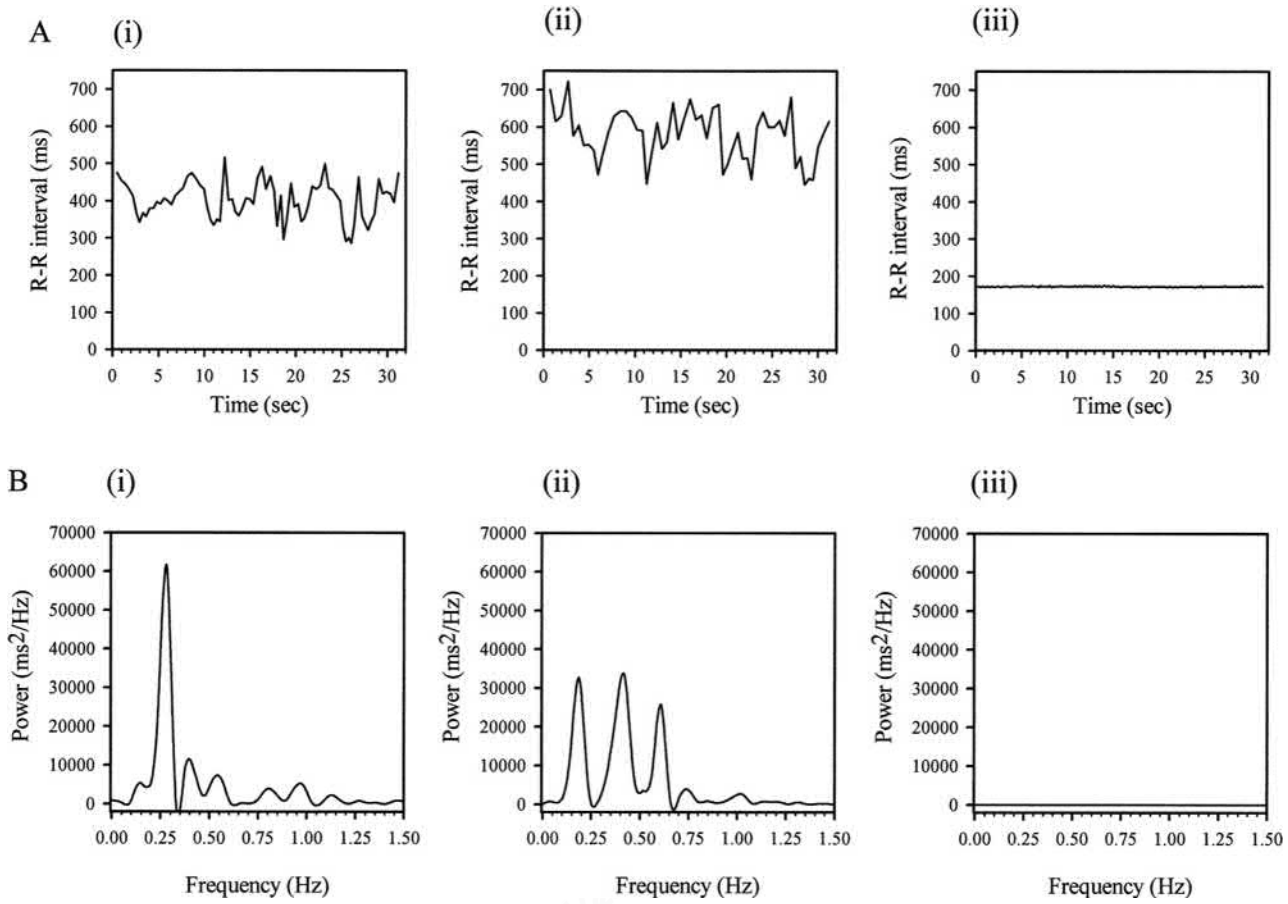

FIGURE 18.29 (A) 30-s duration time series of interbeat intervals (R−R intervals) recorded by radiotelemetry from a duck (*Aythya affinis*) while the animal was resting quietly on the water surface. (i) Control; (ii) after sympathetic nervous system blockade with Nadolol (a β-adrenergic antagonist); and (iii) after parasympathetic nervous system blockade with the muscarinic antagonist atropine. (B) Power spectra of heart rate variability derived from the time series shown in (A). (i) Control; (ii) after Nadolol blockade; and (iii) after atropine blockade. Since the time series were too short to adequately display extremely low-frequency components, these components were removed with a high-pass filter from the power spectra. *From McPhail et al. (unpublished data).*

By analogy with the contraction of skeletal muscle, the amount of force developed by a contracting cardiac muscle fiber depends upon its precontraction length ("preload"). This principle was first applied to the heart by Otto Frank (summarized in Rushmer, 1976), who showed that, within limits, the greater the preload on ventricular muscle in diastole, the more tension was developed during the next systole. This length−tension relationship was further investigated by Ernest Starling and co-workers, who demonstrated that the amount of blood ejected by the left ventricle during systole was proportional to the volume of blood in the ventricle at the end of the diastolic filling phase of the cardiac cycle. These concepts have been combined into the Frank−Starling relationship to describe the intrinsic responses of ventricular stroke volume to changes in cardiac venous return, expressed graphically in Figure 18.30. Elevated contractility of each muscle fiber in the ventricle is evoked by increasing the preload on all of the fibers by increasing the volume of blood filling the ventricle before each beat; this is reflected in an overall increase in ventricular stroke volume. The curve designated A in Figure 18.30 is termed a ventricular function curve. The relationship embodied in this curve demonstrates an autoregulatory feature of cardiac function known as heterometric regulation: a change in the resting fiber length (heterometry) results in a change in contractility in the same direction. This regulatory mechanism is an intrinsic property of cardiac muscle. The consequence of this mechanism for the overall function of the heart is that, if all other conditions remain constant, CO will be determined by venous return. An increase in venous return to the left ventricle via the left atrium will result in greater end-diastolic stretch of the ventricle walls and an increase in stroke volume at the next beat; conversely, stroke volume will be reduced if cardiac return falls. In short, the heart "pumps what it gets" if all other factors are unchanging.

Cardiac contractility is influenced by extrinsic factors in addition to the intrinsic Frank−Starling mechanism. Circulating hormones such as EPI and the autonomic

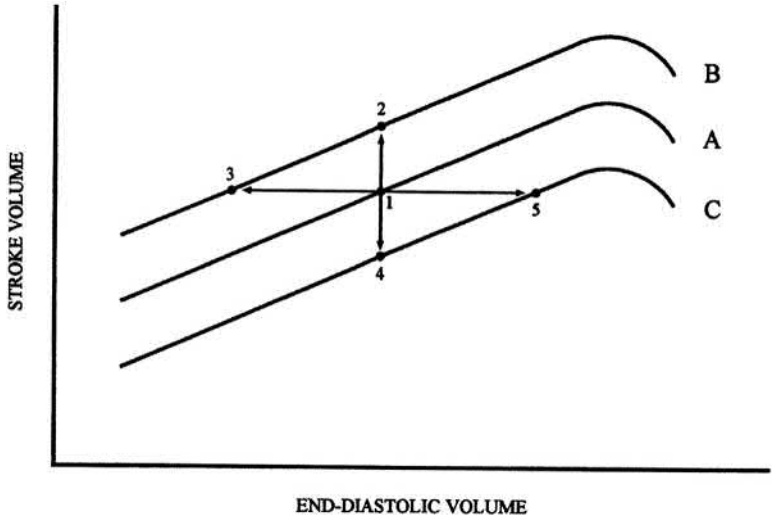

FIGURE 18.30 Idealized graphical representation of the Frank–Starling relationship for cardiac ventricular muscle. (A) Intrinsic ventricular function curve depicting the relationship between end-diastolic volume (representing degree of stretch of muscle fibers) and stroke volume (index of contractility) in the absence of extrinsic influences. The curve peaks and begins to decline at high end-diastolic volumes because resting sarcomere length is maximal here. (B and C) Factors extrinsic to the heart which alter inotropic function of cardiac muscle reset the ventricular function curve to operate over different ranges of stroke volume, independent of end-diastolic volume or initial fiber length. (B) Elevated cardiac sympathetic drive or circulating catecholamines have positive inotropic effects, resetting the curve toward higher stroke volumes. (C) Elevated vagal drive has negative inotropic effects, resetting the curve toward lower stroke volumes. Points 1 through 5 are the operating points assumed for the text discussion of the effects of extrinsic factors on ventricular function.

neurotransmitters NE and ACh (see Sections 18.5.3.1 and 18.5.3.2) directly affects the contractility of cardiac muscle fibers. These extrinsic factors are superimposed on the intrinsic autoregulatory factors governing stroke volume and can shift the whole ventricular function curve (curve A in Figure 18.30) toward higher (curve B) or lower (curve C) stroke volumes at the same resting muscle fiber length or degree of ventricular filling. This type of regulation of stroke volume is referred to as homeometric regulation to emphasize the fact that changes in contractility can occur independent of resting fiber length. An increase in sympathetic drive to the heart or an increase in the level of circulating catecholamines will increase ventricular inotropic function homeometrically; thus a greater stroke volume will result from the same degree of cardiac filling, as indicated in Figure 18.30 by the arrow from point 1 on curve A to point 2 on curve B. Another way to consider this is that after such a shift in the curve a much smaller end-diastolic volume will give the same stroke volume (arrow from point 1 to point 3). On the other hand, elevated vagal drive to the heart of birds can decrease the contractility of ventricular muscle and will shift the ventricular function curve toward a lower stroke volume (curve C in Figure 18.30). At the new operating point, the same degree of preload will result in a lower stroke volume (arrow from point 1 to point 4); alternatively, a much larger end-diastolic volume will be required to maintain the same stroke volume (arrow from point 1 to point 5).

The arterial pressure against which the ventricle pumps ("afterload") is a major extrinsic factor in determining the magnitude of stroke volume. The pressure generated during the isometric phase of ventricular contraction is a function of the contractility of the muscle fibers, and when chamber pressure exceeds that in the aorta the valves open and blood is ejected from the ventricle during the isotonic phase. If the preload on the ventricle is increased by elevating the arterial blood pressure without a change in contractility or end diastolic volume, stroke volume of subsequent beats will be reduced because more energy will be required to raise chamber pressure above the new level of arterial pressure. Initially, this will leave a larger fraction of the previous end-diastolic volume still in the chamber at the end of systole, resulting in an increased level of resting tension on the muscle fibers during the next filling phase. This increased tension, according to the Frank–Starling mechanism, will quickly result in increased contractility during subsequent beats, restoring stroke volume by heterometric regulation in the face of the increased arterial pressure.

In many species of birds, CO is adjusted to match perfusion requirements of the tissues in a variety of conditions, such as during exercise, hypoxia, or submersion (see Section 18.6). These adjustments appear to be made primarily through alterations in heart rate with stroke volume remaining relatively unchanged. Changes in CO during exercise are driven by increased heart rate in ducks (Bech and Nomoto, 1982; Kiley et al., 1985), geese (Fedde et al., 1989), and turkeys (Boulianne et al., 1993a,b). However, in the emu (Grubb et al., 1983) and the chicken (Barnas et al., 1985), stroke volume may increase by up to 100% during exercise, contributing significantly to elevated CO. Reflex changes in CO mediated by systemic arterial baroreceptor input also appear to operate via alterations in heart rate, leaving stroke volume relatively unchanged (Section 18.5.4.2). In summary, during exercise, hypoxia,

or submersion, birds display significant changes in heart rate, arterial blood pressure, and venous return from the resting condition. In the transition from the resting condition to these altered states, stroke volume also varies. However, in most of the species examined so far, stroke volume returns to values close to those at rest after a short period of initial adjustment. This indicates that intrinsic autoregulation of CO has the potential to play an important role in the maintenance of stroke volume in the face of largescale circulatory adjustments.

18.5.4 Reflexes controlling the circulation

18.5.4.1 Chemoreflexes

In birds, reflex adjustments of CO and vascular caliber are generated by chemoreflexes in response to changes in levels of oxygen, carbon dioxide, and pH in the cerebrospinal fluid and in arterial blood. Receptors sensitive to CO_2 in cerebrospinal fluid are present in the avian central nervous system (Jones et al., 1982), but no detailed studies of the location or transduction properties of these receptors have been done in birds. However, if these receptors are similar to those found in mammals, they may be located at or near the surface of the ventrolateral medulla (reviewed by Schlaefke, 1981). Arterial chemoreceptors in birds are located primarily in the carotid bodies, bilateral structures lying caudal to the thyroid gland, and close to the ultimobranchial gland and nodose ganglia of the vagus nerves and the carotid artery (from which they are supplied with blood) (Adams, 1958; Jones and Purves, 1970; Kameda, 2002). The carotid bodies are innervated by the vagus and the recurrent laryngeal nerves (Kameda, 2002). Chemoreceptors have also been reported in aortic bodies associated with the roots of the great vessels in several species of birds (Tcheng et al., 1963; Ito et al., 1999).

The discharge characteristics of arterial chemoreceptors in response to changes in arterial PCO_2 ($PaCO_2$), PO_2 (PaO_2), and arterial pH (pHa) have been studied in the duck and chicken. Receptor discharge rate increases proportionally with $PaCO_2$ and in inverse proportion to PaO_2 (Bouverot and Leitner, 1972; Bamford and Jones, 1976; Nye and Powell, 1984; Hempleman et al., 1992). Discharge sensitivities to changes in $PaCO_2$ and PaO_2 have been quantified by Hempleman et al. (1992) for carotid body chemoreceptors in the duck. When PaO_2 was maintained at a normoxic level (near 100 mmHg) mean chemoreceptor sensitivity to step changes in $PaCO_2$ (produced by changing the fraction of CO_2 in the air breathed by the bird) was +0.20 impulses s^{-1} mmHg $PaCO_2^{-1}$. Hypoxia (PaO_2 56 mmHg) potentiated chemoreceptor discharge in response to altered $PaCO_2$ (Figure 18.31). In this condition, the same step changes in $PaCO_2$ as given in normoxia resulted in a sensitivity of +0.32 impulses/s mmHg $PaCO_2$.

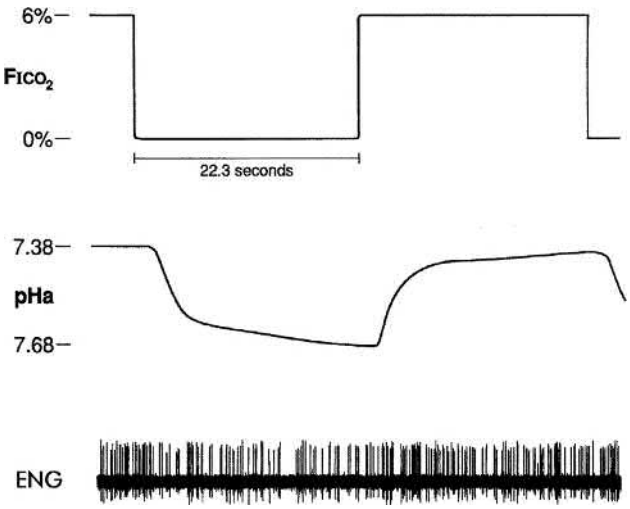

FIGURE 18.31 Single-fiber arterial chemoreceptor response recorded from vagal slip [bottom trace, electroneurogram (ENG)] to step changes in inspired CO_2 level [top trace, fraction of CO_2 in inspired gas (F_ICO_2)] during hypoxia (10% O_2 in inspired gas) in a duck. Arterial pH [middle trace (pH_a)] also changes in step with inspired CO_2. Chemoreceptor discharge is sensitive to the level of CO_2 and pH_a and to rate of change of these variables. *From Hempleman et al. (1992).*

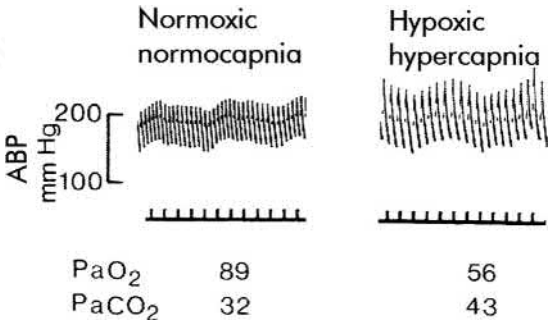

FIGURE 18.32 Effect of systemic hypoxic hypercapnia on heart rate and blood pressure in mallard duck. Animal was artificially ventilated after spontaneous respiratory movements were suppressed with intravenous pancuronium bromide. (Left panel, upper trace) Arterial blood pressure and heart rate during ventilation with air; systemic arterial blood gas values are shown at bottom. (Right panel) When blood gas values were adjusted to match those at end of 1 min submersion by altering CO_2 and O_2 levels in inspired gas, heart rate decreased as a result of arterial chemoreflex activation. In both panels the ticks on the bars under the pressure traces indicate 1-s intervals. *From Butler and Taylor (1973).*

In the absence of CO_2 in the inspired air, step changes in PaO_2 from the normoxic level to about half this level resulted in a mean sensitivity of about −0.10 impulses s^{-1} mmHg PaO_2^{-1}. Carotid body chemoreceptors are thus about twice as sensitive to changes in absolute levels of arterial CO_2 as to O_2. Some of the chemoreceptors sampled in this study were also sensitive to the rate of change of O_2 and CO_2 in the blood, indicating that proportional and rate-related information on arterial blood gas status are both transmitted to the central nervous system.

However the maximum rate of change of discharge of most rate-sensitive chemoreceptors was in the lower frequency range of physiologically occurring blood gas oscillations. Therefore, only relatively low frequencies of blood gas oscillation, such as those occurring at rest or during low-intensity activities, will be faithfully transduced. At higher oscillation frequencies, such as those occurring during panting or high-intensity exercise, chemoreceptor inputs to the central nervous system probably represent "mean" blood gas levels averaged over several oscillatory cycles (Figure 18.32).

Arterial chemoreceptors are spontaneously active at normoxic and normocapnic blood gas levels in birds, and these receptors have been proposed to play an important role in setting the level of eupneic ventilation under these conditions (Bouverot and Leitner, 1972). However, the role of arterial chemoreceptors in reflex control of the avian circulation is less clear. Analyses of the circulatory effects of chemoreceptor activation are complicated by parallel changes in ventilation. During apneic asphyxia in ducks, blood oxygen tension falls, CO_2 tension rises, and carotid body chemoreceptors become progressively more strongly stimulated; this input plays a major role in initiating and maintaining an intense bradycardia (Jones and Purves, 1970; Butler and Taylor, 1973). However, if blood gases in spontaneously breathing ducks are artificially adjusted to mimic the hypoxic and hypercapnic levels achieved during apneic asphyxia, chemoreflex drive acts to increase ventilation, leading to elevated drive from pulmonary receptors. In this state, there is little or no change in heart rate (Butler and Taylor, 1973, 1983). When the rise in ventilation (and thus the elevation in pulmonary receptor input) is prevented by controlling tidal volume and respiratory frequency during hypoxic hypercapnia in paralyzed but unanesthetized animals, heart rate falls to a level midway between that in normoxic, normocapnic animals and that obtained at end-dive (Butler and Taylor, 1973, 1983). This effect is illustrated in Figure 18.18. Subsequent cessation of respiration by stopping the ventilator pump then results in the full expression of chemoreceptor mediated bradycardia: heart rate falls to the same level as at end-dive (Butler and Taylor, 1973, 1983). These experiments show that in ducks, as in mammals, the cardiovascular responses to strong arterial chemoreceptor stimulation during spontaneous breathing are masked by elevated ventilatory drive. Butler and Taylor (1983) have suggested that pulmonary receptors activated by increased ventilation contribute to occlusion of the cardiac chemoreflex.

Input from peripheral arterial chemoreceptors can reflexively alter peripheral vascular resistance, but the general role of chemoreceptors in control of the vasculature has not been established. Indirect evidence for chemoreflex effects on the vasculature comes from a study by Bouverot et al. (1979), who showed a trend toward increased peripheral resistance in carotid body-intact ducks subjected to arterial hypoxia while breathing spontaneously. The same stimulus in animals after denervation of the carotid bodies led to a 40% fall in peripheral resistance, indicating a potential role for these chemoreceptors in generating the vascular response to hypoxia. As with cardiac responses to carotid body stimulation, elevated ventilation during hypoxia may mask the full extent of reflexogenic vasoconstriction. In the study of Bouverot et al. (1979), no attempt was made to evaluate this interaction by controlling ventilation.

It is clear that the full role of arterial chemoreflexes in circulatory control has yet to be defined in birds. Elevated carotid body input can result in both ventilatory and cardiac responses, and both of these responses are important in maintaining oxygen delivery to and CO_2 washout from working tissues. Further experiments are necessary to establish the relative importance of these limbs of the chemoreflex in matching ventilation with perfusion to cope with changes in internal and external levels of these gases.

18.5.4.2 Baroreflexes

Arterial blood pressure provides the driving force for perfusion of the systemic vascular beds and must therefore be maintained within limits that ensure optimal tissue blood flow under a variety of physiological conditions. Blood pressure in birds is maintained by the baroreflex, a mechanism employing negative feedback (see reviews by Bagshaw, 1985 and Smith, 1994). Adjustments in blood pressure produced by the baroreflex are driven by afferent signals from arterial baroreceptors. These are mechanoreceptors with their receptor endings embedded in connective tissue of the arterial wall, where they sense changes in arterial pressure as variations in wall tension. An increase in intraarterial pressure results in an increase in circumference of the vessel wall, which in turn stretches baroreceptor endings to increase their frequency of discharge of APs. Arterial baroreceptors in birds are located primarily in the walls of the aorta close to the left ventricular valves (Jones, 1973). Their axons course to the brainstem via aortic nerves which arise from the nodose ganglia of the vagus (Nonidez, 1935). In the few studies of avian baroreceptor function done to date, discharge characteristics in response to changes in blood pressure appear to be similar to those of mammalian high threshold, slowly adapting baroreceptors (Jones, 1969, 1973). Spontaneous baroreceptor impulse generation is phase locked to mechanical events in systole of the cardiac cycle. Baroreceptors are also sensitive to the rate of rise of the pressure pulse. It thus appears that baroreceptors are capable of transmitting information on cardiac rate, peak systolic pressure, and the slope of the aortic pressure waveform (which may in turn reflect cardiac contractility) to the central nervous system.

Mean arterial blood pressures of resting birds are higher than those recorded in mammals of equivalent body weight at rest; indeed, mean resting pressures may exceed 150 mmHg in some avian species (Altman and Dittmer, 1971). Avian baroreceptor discharge occurs at resting levels of blood pressure in birds (Jones, 1969, 1973), so it is likely that the baroreflex is tonically active at these pressures. Changes in blood pressure sensed at the receptors are represented to the baroreflex circuitry in the central nervous system by changes in baroreceptor afferent discharge frequency. The baroreflex acts to adjust pressure in a direction opposite to that of the initial pressure change. This reflex operates through both peripheral vascular and cardiac effectors to return blood pressure toward a set level after disturbances. Pressure is thus maintained within fairly narrow limits over time to ensure a constant pressure head for tissue perfusion. Little is known of the central nervous mechanisms involved in blood pressure regulation in birds. Inhibition of NMDA by ketamine attenuated the pressor response in the pigeon suggesting a role for the vagal nerve as in mammals (Lucitti and Hedrick, 2006). It is assumed that the basic organization of central components of the baroreflex is similar to the arrangement in mammals (Lucitti and Hedrick, 2006).

The primary cardiovascular response to changes in blood pressure is a baroreflex-mediated change in CO, seen in Figure 18.33A as a rapid fall in heart rate in response to a pharmacologically induced pressure increase. Such reflex responses are completely abolished by bilateral section of the aortic nerves (Figure 18.33B). The sensitivity of the blood pressure–heart rate relationship ranges from −0.5 to −3.13 beats min^{-1} $mmHg^{-1}$, depending on species and method of evaluation (chickens, Bagshaw and Cox, 1986; ducks, Smith and Jones, 1990; 1992; and Millard, 1980; pigeon Luctti and Hedrick, 2006; see Smith, 1994 for further discussion). The baroreflex-mediated effects of changing pressure at the receptors can be mimicked by electrical stimulation of the central cut end of an aortic nerve in an animal in which both aortic nerves are sectioned. This method was used by Smith and Jones (1992) to explore the dynamic role of baroreceptors in controlling the circulation. Stimulation of the aortic nerve in barodenervated animals evokes a decrease in arterial blood pressure in proportion to the stimulus frequency when stimulus current is set just above threshold for a response (Figure 18.34). This response works primarily through a fall in CO, mediated by decreased heart rate with no change in stroke volume (Smith and Jones, 1992). This response follows the same pattern as the baroreflex-mediated response to pharmacologically induced pressure changes in baroreceptor-intact birds; that is, in both intact and denervated animal's baroreflex activation was expressed primarily through changes in heart rate. However, the baroreflex can engage peripheral vasomotion as well as cardiac responses: in barodenervated animals, stimulation of the aortic nerve with a current intensity several times the threshold level produced decreases in peripheral resistance as well as in heart rate (Smith and Jones, 1992). These data suggest that when relatively small disturbances in pressure occur they will be compensated by

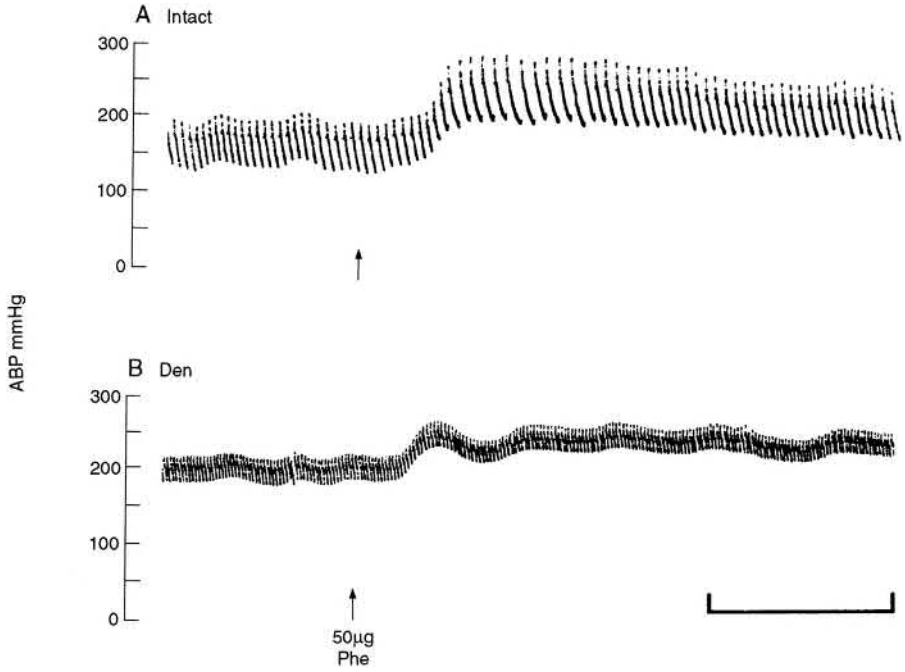

FIGURE 18.33 Heart rate responses to increased arterial blood pressure (ABP) induced by bolus i.v. doses of phenylephrine (Phe, injected at *arrows*) in the same duck (A) before and (B) after barodenervation by section of aortic nerves. Baroreflex-mediated bradycardia was eliminated by denervation of baroreceptors. Note increased preinjection blood pressure and heart rate in barodenervated animals, indicating a degree of baroreflex-mediated restraint on cardiovascular system in baroreceptor intact animal. *From Smith (unpublished data).*

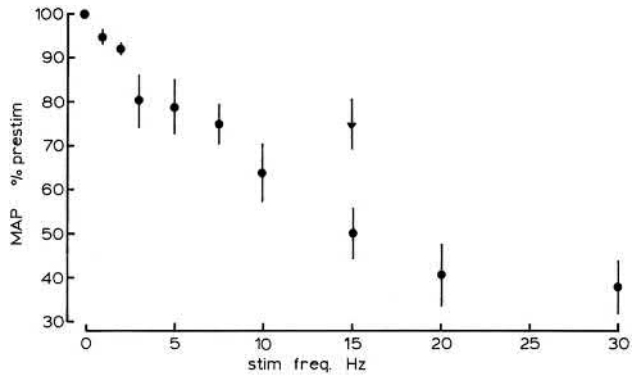

FIGURE 18.34 Normalized responses of mean arterial blood pressure (MAP) to electrical stimulation of aortic nerve in awake ducks spontaneously breathing air (P_aO_2 88 mmHg, P_aCO_2 26 mmHg; *closed circles*) or a hypoxic hypercapnic gas mixture (P_aO_2 62 mmHg, P_aCO_2 44 mmHg; *triangle*). Pressure response at each frequency of nerve stimulation is expressed as a percentage change in MAP relative to MAP just prior to stimulation. Loading the chemoreceptors attenuated the depressor effect of aortic nerve stimulation at 15 Hz. Error bars represent: S.E.M. for five trials in normoxic conditions and three trials during hypoxic hypercapnia in three animals. Stimulus pulse duration and amplitude were constant within each trial. *From Smith (unpublished data).*

adjusting CO, but larger changes in pressure will be corrected by a combination of cardiac and peripheral vascular adjustments.

The effectiveness of baroreflex control of the circulation can be modified by interaction with other reflexes, such as the chemoreflex, which may be concurrently engaged. In an effort to determine the cause of an apparent reduction in baroreflex function observed during submersion in ducks (Jones et al., 1983; Millard, 1980), Smith and Jones (1992) stimulated the aortic nerve in barodenervated ducks before and during periods of elevated chemoreceptor drive. Stimulation of chemoreceptors was accomplished by ventilating animals with a gas mixture which simulated the hypoxic and hypercapnic blood gas values observed at the end of 2 min of submersion; this significantly decreased the capability of aortic nerve stimulation to affect mean arterial pressure. This is shown in Figure 18.34 by a 50% decrease in the pressure response to aortic nerve stimulation at a frequency of 15 Hz during hypoxic hypercapnia (triangle), compared with the responses during air breathing (closed circles). That this occlusive response was due to chemoreceptor activation was further demonstrated by the attenuation of baroreflex function during perfusion of one vascularly isolated carotid body with venous blood in otherwise normoxic, normocapnic animals which were spontaneously breathing (Smith and Jones, 1992). It therefore appears that the chemoreceptor drive that develops after the first minute of submersion (Jones and Purves, 1970) is at least partly responsible for the attenuation of baroreflex control of cardiovascular variables which occurs during this period.

18.5.4.3 Reflexes from cardiac receptors

Small nerve terminals in the shape of simple knobs, plates, or rings as well as straight or spirally wound nerve endings have been observed in anatomical studies of avian atria and ventricles (Ábrahám, 1969; also see review by Jones and Milsom, 1982), but bird hearts do not appear to have the complex and highly developed sensory receptor endings present in large numbers in mammalian hearts. Few functional studies of avian cardiac receptors and their reflexogenic effects have been done. Jones (1969) established in the duck that some afferent fibers in the cervical vagus had receptor endings associated with the heart, responding to punctate stimulation near the AV junction and discharging spontaneously in patterns which were phase-locked to mechanical events in the cardiac cycle. In the chicken, Estavillo and Burger (1973a,b) found that a majority of cardiac receptors with their cell bodies in the nodose ganglia had receptive fields located in the left ventricle near the aortic valves. Discharge patterns of these receptors were either phase-locked to the cardiac cycle or were irregular and apparently unrelated to mechanical events in the cycle. The discharge of receptors of both types could be modulated by varying inspired CO_2 and pHa independently or together. In this study, the discharge rate of phasically firing cardiac receptors was proportional to arterial blood pressure over a wide pressure range, and this relationship was reset toward lower discharge rates at increased CO_2 levels. Bilateral section of the middle cardiac nerve, carrying the axons of cardiac receptors in the chicken, produced an immediate rise in arterial blood pressure (Estavillo, 1978; Estavillo et al., 1990) reminiscent of that produced in ducks after section of the aortic nerve (Figure 18.33).

Avian cardiac receptors have been proposed to contribute to blood pressure regulation and to the control of ventilation, providing sensory feedback on intracardiac pressures and volumes. Such feedback may be modulated by changes in the levels of $PaCO_2$ and pHa (Estavillo and Burger, 1973b; Estavillo et al., 1990). In the latter study, bilateral section of the middle cardiac nerve considerably blunted the increase in ventilation elicited by systemic hypercapnia, in addition to promoting elevated blood pressure.

Birds exhibit a Bezold–Jarisch reflex similar to mammals. It manifests in ducks as a fall in heart rate and arterial blood pressure when cardiac receptors are stimulated (Blix et al., 1976; Jones et al., 1980). Blix et al. (1976) proposed, on the basis of pharmacological stimulation of cardiac receptors, that this reflex contributed to the generation and maintenance of the cardiac chronotropic response to submersion. In a reexamination of this issue, Jones et al. (1980) loaded and unloaded the cardiac receptors by altering left ventricular pressure to provide more realistic physiological

stimulation of these receptors before and during submersion. The results of this study failed to confirm a link between cardiac receptor activation and diving bradycardia.

There is as yet insufficient evidence to determine the overall function of reflexes driven by inputs from cardiac receptors. While these receptors can influence blood pressure and ventilation, they do not appear to have a primary role in pressure or ventilatory regulation. However, they may mediate some of the dynamic interactions between respiratory and circulatory systems, thus helping to correct ventilation–perfusion mismatches which can develop during exercise or in adverse environmental conditions.

18.5.4.4 Reflex cardiovascular effects from skeletal muscle afferents

Reflex-mediated changes in arterial blood pressure, heart rate, and other cardiovascular variables accompany exercise, hypoxia, and hypoxic hypercapnia in birds. In several studies designed to deduce the respective roles of peripheral arterial chemoreceptors, chemosensitive areas of the central nervous system and arterial baroreceptors in these cardiovascular responses, it has been suggested that inputs from these receptor groups do not account for all of the changes observed. Thus inputs from other receptor type must also be involved. In mammals, there is a significant reflexogenic increase in mean arterial blood pressure induced by skeletal muscle activity; receptors for this response appear to be intramuscular terminals of group III afferent fibers (small myelinated fibers) and group IV fibers (unmyelinated or C-fibers) coursing in somatic nerves (see Coote, 1975 for review). Kiley et al. (1979) implicated muscle afferents in the cardiovascular responses to exercise in ducks, and Lillo and Jones (1983) proposed that somatic muscle afferents in ducks were at least partly responsible for those portions of the cardiac and vascular responses in hypoxic hypercapnia and ischemia which were independent of chemoreceptor activation. Furthermore, Solomon and Adamson (1997) demonstrated that ducks express an "exercise pressor" reflex similar to that in mammals. This effect consists of an increase in mean arterial pressure (largely due to elevation of diastolic pressure) induced by and sustained during static contraction of a large hind limb muscle, the gastrocnemius. The authors concluded that this was a reflex effect since section of the sciatic nerve carrying afferent fibers from the muscle to the spinal cord eliminated the pressor response to muscle contraction. Whether the intramuscular receptors involved in these responses were sensing mechanical events related to muscle contraction or chemical signals resulting from intramuscular metabolite buildup as the primary physiological stimulus for this reflex was not clear from this study. The authors acknowledged that receptors sensing either modality, or both, could be driving reflex changes in pressure. The studies done to date on reflex effects of activating skeletal muscle afferents suggest that direct sensory feedback from exercising or hypoxically stressed muscle to the neural circuitry controlling the circulation could be involved in initiating or intensifying cardiovascular responses to muscle activity. Such a mechanism would serve to increase the perfusion of working muscle, but the full contribution of these reflexes remains to be determined.

18.5.5 Integrative neural control

As discussed in the previous sections, the major reflexes controlling cardiovascular function are the chemoreflex, the baroreflex, and reflexes driven by receptors within the heart and skeletal muscle. Under some conditions, these reflexes may interact, as in the case of chemoreflex occlusion of the baroreflex detailed in Section 18.5.4.2. Furthermore, there are a number of other reflexes which can affect the circulation as part of more global homeostatic control systems, such as those regulating temperature and ventilation. All reflexes influencing the circulation do so through the final common pathways of the autonomic nervous system innervating the heart and vasculature, and several of these reflexes may be engaged at the same time during physiological challenges to the animal. Integrative control of the circulation by the nervous system therefore operates through complex interactions among cardiovascular and other reflexes, but the nature of these interactions is still incompletely understood in any vertebrate group. This large-scale integration makes investigation of the properties of any one reflex a considerable challenge, particularly in unanesthetized animals. One approach to this problem is to ensure that only afferents specific to the reflex in question are stimulated, while activation of afferents associated with other reflexes is prevented. However even this may not be enough to prevent complications in analysis since efferent activity associated with one reflex, and the consequences of this activity, can produce secondary activation of other reflexes. A case in point is the activation of pulmonary reflexes consequent to an increase in ventilation driven by primary stimulation of the arterial chemoreflex. The design of further studies of avian cardiovascular reflexes embedded in complex control systems must therefore take into account the integrative nature of these systems.

A single neural mediated response, such as a change in heart rate, involving the stimulation of one or more afferent or efferent pathways by a frequently induced or naturally performed behavior, may be subject to habituation or conditioning. Habitation refers to a decrement in the response (not due to sensory adaptation or motor fatigue) resulting from repeated presentations of a single triggering stimulus. In contrast, conditioning involves the animal learning a relationship between two different stimuli. In

classical conditioning, (Pavlov, 1927) a conditioned and an unconditioned stimulus are presented with little temporal dissociation between them.

The animal learns the relation between these stimuli so that after the initial trials the reflex response can then be evoked by presenting the only the conditioned stimulus. A reflex, once conditioned, will anticipate, augment, and have similar effects as the unconditioned reflex.

Cohen and his collaborators have developed a model of conditioned learning in the pigeon for exploring cellular neurophysiological mechanisms of long-term associative learning. In this model, animals are trained to respond with a transient and quantifiable increase in heart rate (the CR) to a conditioning stimulus (CS, a 6-s whole-field retinal illumination) by pairing the CS with an unconditional stimulus (US) consisting of a 0.5-s foot shock. After an initial training period of 30−50 paired-stimulus trials, further CS without US reliably evokes CRs. The properties of this CR in the pigeon are very robust, remaining stable for long periods (up to weeks) without habituating (Cohen, 1980, 1984). Such longevity facilitates electrophysiological investigations of changes in properties of neurons involved in the development of associative learning in this system. Using this model as a platform, Cohen and co-workers have anatomically and physiologically characterized the central visual pathways for the CS, the somatosensory pathways for the US, and the descending tracts converging on the autonomic motor neurons of the final common pathway efferent to the heart in the pigeon. Much of this group's work on the efferent components of this system has already been cited in the description of the neuronal circuitry controlling cardiac function appearing earlier in this chapter.

The central and peripheral nervous pathways involved in the CR have been reviewed in detail by Cohen (1980, 1984) and are briefly summarized here. Ganglion cells throughout the retina respond with a phasic burst of APs at the start of a 6-sec period of whole-field retinal illumination. This phasic wave of excitation is transmitted synchronously along multistage pathways in the central nervous system to preganglionic sympathetic and parasympathetic motor neurons in the spinal cord and brainstem, respectively. These preganglionic neurons in turn control pools of cardiac postganglionic autonomic neurons in a synergistic manner, acting to potentiate a transient sympathetic cardio acceleration and to facilitate concurrent withdrawal of parasympathetic cardio inhibition.

Studies of the development of CRs after lesioning selected components of the central visual pathways and electrophysiological studies during the conditioning process in pharmacologically immobilized pigeons have shown that the CS is conveyed in parallel through multiple pathways to the visual area of the telencephalon. These include (1) a thalamofugal pathway involving the principal optic nucleus (the avian homolog of the mammalian lateral geniculate nucleus) and (2) a tectofugal pathway projecting through the optic tectum and the nucleus rotundus (Cohen, 1980). In addition, there may be a third visual input pathway implicated in the CR, projecting through the pretectal area and the thalamus. While retinal responses to repeated CS are not modified during the development of conditioning, responses of second and higher-order neurons in the CS pathway are facilitated during this process. The time course of these changes parallels the time course of the development of the conditioned heart rate response, so neurons or their impinging synaptic fields in successive stages in the CS pathways are likely sites for modulation of cardiovascular control during associative learning.

The descending pathways involved in this conditioned cardiac response have been well established. Neurons in the medial region of the hypothalamus, along with those located in the ventral brainstem, project to preganglionic sympathetic and parasympathetic cardiomotor neurons. The medial hypothalamus in turn receives inputs from the avian homolog of the mammalian amygdala, an area which, in both groups of animals, evokes marked cardioactive effects when stimulated.

Furthermore, lesions of the avian amygdala or its hypothalamic projection either produce deficits in conditioning or can prevent development of the CR (Cohen, 1980). The telencephalic projections conveying visual information to the avian amygdala have, however, not as yet been established in detail. Convergence of the CS and US has been demonstrated at each of the established stages in the central pathway of this response. It thus appears that training-induced modification of the CS works through long-term heterosynaptic facilitation in this pathway, and such facilitation constitutes an important element in the constellation of neurophysiological mechanisms for associative learning.

The broad outlines of the central and peripheral neural pathways involved in efferent control of the circulation in birds have been established but relatively little is known about details of specific afferent and intermediary connections within the central pathways of any of the cardiovascular reflexes in birds. The working assumption guiding studies of these reflexes is that their pathways are similar to those in mammals, but given the differences in cardiovascular reflexogenic zones between birds and mammals, this is not necessarily a valid assumption. Birds have, for instance, only one major arterial baroreceptor site while mammals have two. In addition, most of the input from avian arterial chemoreceptors originates from the carotid bodies while in mammals both aortic and carotid chemoreceptors contribute to cardiovascular chemoreflexes. The organization of the neural circuitry for cardiovascular

control in birds has not been investigated in detail, so the similarity of this circuitry to that of mammals remains an open question.

18.5.6 Development of cardiovascular control

More recent advancements in general knowledge of cardiovascular control mechanisms in birds have been predominately focused on the embryonic phase of avian life history. Seminal works have extensively documented anatomical maturation of the heart and vasculature. Here we provide an overview of cardiovascular control during development in birds. It is important to recognize that the majority of studies investigating avian development have focused on the domestic chicken and the maturation of cardiovascular control is no exception.

18.5.6.1 Ontogeny of autonomic nervous system control of the heart

18.5.6.1.1 Cardiac autonomic innervation

The ontogeny of parasympathetic and sympathetic fiber innervation of the developing avian embryo heart differs. Branches of the vagus nerve (X) perforate the embryonic chicken ventricle at 15% of incubation and innervate all cardiac chambers by 35% of incubation (Pappano, 1975). Cardiac and sinal branches reach the truncus and atria around 20% of incubation (Kuratani and Tanaka, 1990). In contrast, sympathetic cardiac nerves from the sympathetic ganglia do not reach the heart until 50% of incubation (Higgins and Pappano, 1979; Kirby et al., 1980) and penetrate the myocardium at 75% of incubation (Verberne et al., 1999). The sympathetic fiber origin is either the first pair of thoracic ganglia (Kirby et al., 1980) or the cervical ganglia (Verberne et al., 1999).

Field stimulation studies have found that function lags behind the anatomical appearance of innervation. A cholinergic-dependent negative chronotropic response appeared as early as 60% of incubation in response to autonomic receptor drugs and atrial field stimulation. The negative chronotropic response appeared earlier, at 50% of incubation, when pretreated with the cholinesterase inhibitor physostigmine (Pappano and Löffelholz, 1974). In contrast, an adrenergic-dependent, positive chronotropic response to field stimulation was not observed until hatching (Pappano and Löffelholz, 1974). An adrenergic dependent response was produced as early as 50−60% of incubation by potentiating the release of catecholamines from postganglionic neurons with tyramine (Pappano, 1975; Crossley, 1999). This potentiating effect of tyramine increased with age until 90% of incubation (Crossley et al., 2003b). Collectively the data suggest functional control by the autonomic nervous system lags behind the innervation of the heart.

18.5.6.1.2 Cardiac cholinergic and adrenergic receptors

It has long been established that embryonic chicken P-cells express muscarinic cholinergic receptors as early as 10% of incubation (Cullis and Lucas, 1936; Coraboeuf et al., 1970; Pappano and Löffelholz, 1974). Stimulation of these receptors produces an ACh-dependent negative chronotropic response that is blocked by the cholinergic antagonist atropine. There are two stages to the development of ACh's negative chronotropic action (Dufour et al., 1960). Between 15% and 30% of incubation, increased ACh sensitivity is due to changes in membrane permeability. This is followed by functional parasympathetic innervation of the heart, which occurs between 40% and 55% of incubation (Pappano, 1977).

As early as 10% of incubation, P-cells exhibit β-adrenergic receptor mediated chronotropic responses with cells expressing both β_1 and β_2 receptors (Berry, 1950; Fingl et al., 1952; McCarty et al., 1960; Lenselink et al., 1994). P-cell sensitivity to EPI is constant from 60% to 85% of incubation and decreases during the later 85% to 95% of incubation (Löffelholz and Pappano, 1974). This decrease in sensitivity is associated with increased circulating catecholamine levels during the later stage of embryonic development (Crossley et al., 2003b). The embryonic chicken ventricle also possesses β-adrenergic receptors at 20% of incubation that respond to β-adrenergic stimulation with inotropic and chronotropic cardiac effects (McCarty et al., 1960; Shigenobu and Sperelakis, 1972; Frieswick et al., 1979; Higgins and Pappano, 1981). Maximal adrenergic stimulation produces a constant twitch force, but the isoproterenol ED_{50} of embryonic White Leghorn ventricular tissue increases from 75% to 90% of incubation. This is followed by a decrease prior to hatching suggesting development of a reduced adrenergic sensitivity (Higgins and Pappano, 1981). Tyramine (10 mg kg^{-1}) produces a similar inotropic and chronotropic effect on the embryonic chicken heart during this developmental period (Crossley, 1999). An age-dependent decrease in sensitivity to EPI over this incubation window has also been shown in a broiler strain of embryonic chickens due in part to internalization of β-adrenergic receptors (Lindgren and Altimiras, 2009). Overall developing chickens exhibit β-adrenergic−mediated inotropic and chronotropic cardiovascular responses early in incubation.

18.5.6.2 Ontogeny of vascular contractility

18.5.6.2.1 Vascular reactivity regulation

Embryonic circulation must meet the demands of a rapidly growing embryo while also developing into their adult phenotype. Adult vascular smooth muscle and endothelial cells must regulate vascular tone, blood pressure, and blood flow distribution. During vascular morphogenesis,

developing vascular smooth muscle and endothelial cells must proliferate, migrate, and produce the extracellular matrix, while at the same time, acquiring the physiological capacity to regulate vascular tone though smooth muscle activity (Owens et al., 2004; Rzucidlo et al., 2007).

As noted in Section 18.5.2.1, smooth muscle contraction relies on phosphorylation of MLC20 by the Ca^{2+}-dependent MLCK and the Rho-kinase pathway. The expression of MLC20, MLCK, and MLCP in chicken embryo vascular smooth muscle occurs as early as 50% of incubation (Ogut and Brozovich, 2000). The embryonic aorta tonically contracts in response to increased cytosolic Ca^{2+} as early as 40% of incubation. The levels of MLC20 phosphorylation plateau at 75% of incubation (Ogut and Brozovich, 2000). The Rho kinase pathway, providing Ca^{2+} sensitization, appears to mature during embryonic development. Contractions of the femoral artery and ductus arteriosus are inhibited by the Rho-kinase pathway inhibitors Y-27632 and hydroxyfasudil (Greyner and Dzialowski, 2008; Zoer et al., 2010). The effect of Rho Kinase inhibitors increased with incubation age, suggesting a developmental augmentation in the RhoA/Rho kinase-mediated increase in calcium sensitivity of the contractile apparatus.

18.5.6.2.2 Vascular adrenergic receptors

The vasculature expresses adrenergic receptors early in embryonic development. EPI increases arterial pressure in the embryo after 15% of incubation demonstrating that ARs are present and functional (Hoffman and VanMierop, 1971; Girard, 1973). Pharmacological manipulation to identify receptor types with specific adrenergic receptor agonists and antagonists indicate that α-adrenergic and β-adrenergic receptors are present as early as 30% of incubation (Saint-Petery and VanMierop, 1974; Koide and Tuan, 1989). Further studies to isolate differences between vascular beds of the embryo indicate that as early as 60% incubation, the mesenteric circulation expresses α-adrenergic receptors (Rouwet et al., 2000). Chicken femoral and carotid arteries increase α_1-adrenergic receptor and receptor-independent stimulation contractile reactivity from 70% to 90% incubation (Le Noble et al., 2000). In contrast, pulmonary arteries lack α-adrenergic—mediated contraction during all of embryonic development (Villamor et al., 2002). Stimulation of β-adrenergic receptors produces a relaxation in some vessels including the femoral artery. Both the sensitivity and responsiveness of the vasculature to by β-adrenergic simulation increased with incubation age.

While ARs appear functional in the arterial vasculature as early as 15% of incubation, there is a delay in sympathetic nervous control. Arterial vascular constriction to exogenous NE is present before any neurogenic responses (Le Noble et al., 2000). Sympathetic control of arterial vascular resistance seems to be restricted to the later stages of embryonic development in chickens. The femoral artery contracts to perivascular nerve stimulation late stage embryonic chicken femoral arteries. In contrast, neither the carotid nor pulmonary arteries responded to nerve stimulation. In summary, there is an increase in adrenergic control of the vasculature that initially comes from circulating catecholamines and later sympathetic nervous control.

18.5.6.2.3 Vascular cholinergic receptors and endothelial control

Cholinergic control of vessel reactivity appears early in the developing avian embryo. Muscarinic receptor stimulation relaxes the aorta, femoral artery, carotid artery, mesenteric arteries, pulmonary arteries, and ductus arteriosus of chicken embryos in a NO-mediated endothelium-dependent manner (Greyner and Dzialowski, 2008; Le Noble et al., 2000; Rouwet et al., 2000; Martinez-Lemus et al., 2003; Nishimura et al., 2003; Villamor et al., 2002). This endothelium-dependent, NO-mediated relaxation appears to be a critical for regulating embryonic circulation during early development. There is early expression of NO synthase mRNA in multiple tissues of the developing chicken cardiovascular system as early as 15% of incubation (Groenendijk et al., 2005). As early as 50% of incubation, isolated cardiomyocytes respond to sodium nitroprusside, an NO donor, and L-arginine, the NO precursor, suggesting the NO/cGMP pathway is already functional (Ungureanu-longrois et al., 1997). Isolated CAM arteries contract in respond to ACh (Lindgren et al., 2010), and NO produces increased CAM blood flow as early as 50% of incubation (Dunn et al., 2005). Early in incubation, NO donors decrease ventricular preload without changing arterial resistance, which may occur through venodilation (Bowers et al., 1996). At 45% of incubation, sodium nitroprusside produces a vasodilation, suggesting early maturation of the cellular pathway involving cGMP activation (Altimiras and Crossley, 2000). In addition, NO plays a role in maintaining systemic vascular dilation at 70% and 90% of incubation in chickens (Iversen et al., 2014). Finally, the endothelium-dependent relaxation of pulmonary and systemic arteries is constant during internal and external pipping (Villamor et al., 2002; Le Noble et al., 2000). The hatching chicken lacks depression of pulmonary endothelial function observed in neonatal mammals.

Other mediators of endothelium-dependent relaxation have received limited attention in embryonic chickens. Adenosine is involved in the CAM angiogenic response to hypoxia at 50% and 65% of incubation. Embryonic whole body vascular resistance decreases in response to adenosine at 50% to 70% of incubation (Adair et al., 1989). Adenosine receptors have been found on embryonic red blood

cells at 50% of incubation (Glombitza et al., 1996). These studies indicate that adenosine receptors are present in the developing chicken cardiovascular system.

18.5.6.3 Developmental integration of autonomic cardiovascular regulation

18.5.6.3.1 Afferent pathways

The carotid bodies and special mechanosensory nerve endings in the aorta provide the main cardiovascular reflexes in birds. The carotid bodies constitute the primary loci for peripheral chemoreceptors sensing arterial oxygen and carbon dioxide tensions and pH (Section 18.5.4.1). Initially, carotid bodies consisting of mesenchyme-like cells appear around 25% of incubation and by 40% of incubation have migrated to the adult location (Murillo-Ferrol, 1967). At 60% of incubation, the parenchyma has a large number of dispersed granule-containing cells, glomus cells or Type I cell (Kameda, 1994). The appearance of these cells coincides with peak serotonin immunoreactivity (Kameda, 1990), and appearance of long axon synaptic junctions with glomus cells (Kameda, 1994). At 70% of incubation, the developing glomus cells already express features of mature glomus cells (Kameda, 1994). Hypoxic-induced glomus cell catecholamine secretion increases after hatching and is coupled to decreased constitutive catecholamine release (Donnelly, 2005).

Refelxogenic sensory afferents of the cardiovascular system originate from the nodose ganglion. The nodose ganglion bifurcate after emerging from the cell body with one branch to the heart and viscera and the other centrally located, making connections within the central nervous system and solitary tract nucleus. The primordium of the ganglion appears at 15% of incubation and is followed by proliferation of ganglion, peaking at 30% of incubation. An apoptosis-induced decrease in cell number occurs by the time of hatching (Harrison et al., 1994). Early neuron development is independent of neurotrophins and becomes dependent on brain-derived neurotrophic factor as the neurons develop toward their target tissues. The development of the neurons is regulated by other trophic factors such as nerve growth factor during embryonic development (Hedlund and Ebendal, 1980).

Overall, the development of connection between the cardiovascular reflexogenic afferent pathways with the central nervous system occurs during the first half of incubation. The sensitivity of the carotid bodies increases when the animal hatches, however, the changes occurring in baroreceptive areas are unknown.

18.5.6.3.2 Tonic heart regulation

The role of cholinergic tonic activity does not appear to be involved in maintenance of baseline cardiovascular function during early embryonic development. The cholinergic muscarinic receptor antagonist atropine does not alter heart rate in White Leghorn chicken incubation until after hatching or just prior to (Pickering, 1895; Saint-Petery and VanMierop, 1974; Tazawa et al., 1992; Crossley and Altimiras, 2000) and has no effect on arterial pressure (Tazawa et al., 1992; Crossley and Altimiras, 2000). However this is not universal for embryonic birds, as different species differ in terms of the presence of a heart rate response to atropine administration (Crossley et al., 2003b; Swart et al., 2014). Embryonic chicken strains including broilers, black Sumatran Bantams, and red Jungle fowl vary in terms of the presence of functional cholinergic tone on heart rate, appearing as early as early as 60% to as late as 90% of incubation (Crossley et al., 2003b; Chiba et al., 2004; Crossley and Altimiras, 2012). An absence of cholinergic tone does not exclude possible recruitment and intermittent activity of the parasympathetic nervous system. Continuous recordings of instantaneous heart rate in embryonic chickens reveal heart rate decelerations likely due to transient increased parasympathetic activity (Kato et al., 2002). Although cholinergic receptors are expressed early in development and the parasympathetic efferent pathway is functional under some conditions at 60% of incubation, cardiovascular function and development continues without a tonic cholinergic stimulation throughout at least the first half of incubation.

In contrast, there is clear adrenergic tone present during the majority of embryonic bird development. α-adrenergic and β-adrenergic receptor mediated stimulatory tones on both heart rate and arterial pressure appear early in development (Saint-Petery and VanMierop, 1974; Koide and Tuan, 1989; Tazawa et al., 1992; Crossley and Altimiras, 2000). As early as 30% of incubation, a positive β-adrenergic chronotropic tone on heart rate and arterial pressure appears (Saint-Petery and VanMierop, 1974; Girard, 1973). This tone is critical to basal baseline function (Tazawa et al., 1992; Crossley, 1999; Crossley and Altimiras, 2000). In chickens, the magnitude of the β-adrenergic chronotropic tone increases in strength from 10% to 20% as the embryos progress from 40% to 95% of incubation, respectively (Crossley, 1999). Baseline heart rate is unchanged after pharmacological blockade of sympathetic nervous terminals with 6-hydroxydopamine or ganglionic blockade with (Tazawa et al., 1992; Crossley, 1999; Crossley et al., 2003b). This suggests that adrenergic heart rate tone in chicken embryos originates from circulating catecholamines. A similar change in the β-adrenergic heart rate tone during the final 30% of incubation has been observed in emus, domestic geese, and Canada geese (Crossley et al., 2003a; Swart et al., 2014).

While the direct effects of β-adrenergic inhibition on the heart is mediated through direct actions on the heart and pacemaker tissue, the mechanisms regulating the depressive actions of α-adrenergic receptor antagonists on

heart rate present from 40% of incubation through hatching is unclear (Koide and Tuan, 1989; Tazawa et al., 1992; Crossley, 1999; Crossley and Altimiras, 2000). While this tone is present and the magnitude is maximal between 60% and 95% of incubation, α-adrenergic receptors have been reported to be absent in the chicken heart (Crossley, 1999; Chess-Williams et al., 1991). Therefore, the bradycardic response to α-adrenergic receptor blockade may be secondary to the pronounced vasodilation after α-adrenergic receptor antagonist treatment (Crossley and Altimiras, 2000). Vasodilation may produce blood pooling in the CAM vasculature, reduced venous return, or decreasing heart rate and CO.

18.5.6.3.3 Tonic vasculature regulation

Total and regional vascular resistance and capacitance is regulated by the sympathetic nervous system in adult vertebrates. This vascular control is mediated by changes in catecholamine release from sympathetic nerve terminals as well as the adrenal medulla. These ligands bind to ARs types that are heterogeneously distributed with the dominant AR type dependent on the vascular bed. This allows differential hemodynamic responses to systemic catecholamine release. The vascular tone resulting from activation of different receptors is dependent on the vascular areas affected and if stimulation is arising from sympathetic nerve endings or circulating catecholamines (Guimaraes and Moura, 2001).

A strong α-AR tone maintaining vasculature constriction is active in some vascular beds and is functional from 30% to 95% of incubation (Girard, 1973; Saint-Petery and VanMierop, 1974; Koide and Tuan, 1989; Tazawa et al., 1992; Crossley, 1999; Crossley and Altimiras, 2000). A α-AR mediated vascular tone prevails in the skeletal muscles and has limited effects on the heart, intestines, and yolk sac (Mulder et al., 2001). Further α-ARs are absent from the CAM vascular tree illustrating the regionalization of AR types (Lindgren et al., 2010). While the time course has not been elucidated, a similar strong α-AR vascular tone has been observed in the Black Sumatran Bantam, Red Jungle fowl, and broiler chickens (Crossley unpublished observation, Crossley and Altimiras, 2012). In White Leghorns, the receptor subtype responsible for maintaining vascular tone in embryonic chickens is likely α_1-adrenergic receptors given similar responses following a nonspecific α-adrenergic receptor antagonist (phentolamine) and an α_1-adrenergic receptors specific antagonist (prazosin) (Crossley and Altimiras, 2000). In White Leghorn chicken embryos, there is an increase in the dependence on α-adrenergic receptor mediated vasoconstriction from a 10% contribution to resting arterial pressure to over 55% just prior to hatching (Crossley, 1999). Limited numbers of studies conducted in other species show that embryonic emus, domestic geese, and Canada geese possess a pronounced α-AR tone during the final 30% of incubation (Crossley et al., 2003a; Swart et al., 2014). Overall it is clear that embryonic chickens depend on α-mediated vasoconstriction during the majority of development, which is a feature shared by the other avian species investigated.

A β-AR vasodilator tone opposes the α-AR mediated vascular tone during embryonic development. The β-AR vasodilator tone in White Leghorn chickens appears at 30% of incubation, increases in magnitude from 35 to 60% of incubation where it stabilized until the final 5% of incubation where it disappears (Saint-Petery and VanMierop, 1974; Crossley, 1999; Girard, 1973). An active β-tone depressing arterial pressure is present in other chicken strains from 60% to 90% of incubation (Koide and Tuan, 1989; Tazawa et al., 1992; Crossley and Altimiras, 2012). This tone reaches maximal strength at 90% of incubation in other strains of embryonic chickens and in embryonic emus (Crossley et al., 2003b; Crossley and Altimiras, 2012). Unlike the chickens and emus, domestic and Canada geese embryos have a β-AR vasodilator tone at 70% of incubation that is absent at 90% (Swart et al., 2014), so clearly regulatory mechanisms may differ between species.

As with adrenergic tone on heart rate, the adrenergic vascular tone during development is due to levels of circulating plasma catecholamines. This is supported by measurements following sympathectomy with 6-hydroxydopamine or hexamethonium ganglionic blockade illustrating that resting arterial pressure in embryonic chickens in unaltered by the treatment (Crossley, 1999; Crossley and Altimiras, 2000; Crossley et al., 2003b).

18.5.6.3.4 Baroreflex regulation

Investigations of developing baroreflex function have been limited to domestic chicken breeds and have focused on characterizing reflex parameters of the cardiac limb or heart rate responses to changes in arterial pressure only (Altimiras and Crossley, 2000; Elfwing et al., 2011; Mueller et al., 2013). Two methods have been successfully utilized to quantify changes in baroreflex gain (sensitivity) and set point during chicken development; pharmacological assessment or Oxford method and spontaneous baroreflex sensitivity assessments (Altimiras and Crossley, 2000; Elfwing et al., 2011; Mueller et al., 2013). They both show baroreflex function in chickens is present as early as 80% of 21-day incubation period, dependent in part on the breed studied (Altimiras and Crossley, 2000; Elfwing et al., 2011). In addition to the timing of operation during chicken development, changes in baroreflex function have also been reported. Gain of the reflex provides an index of baroreflex maturation during chicken incubation however components

such as set point and threshold are also informative. In White Leghorns chicken embryos, the baroreflex has been reported to be functional at 85% of incubation (Altimiras and Crossley, 2000), but only 17% of the embryos showed a change in heart rate after experimental manipulation of blood pressure. This rapidly increases to 33% at 90% of incubation with a fivefold increase in baroreflex gain upon hatching (Altimiras and Crossley, 2000). Using the spontaneous assessment method in which the correlation between spontaneous fluctuations in arterial pressure and heart rate are analyzed, the reflex is functional by 80% of incubation while the gain remains constant from this point until 95% of incubation in broiler chickens (Elfwing et al., 2011). Interestingly, spontaneous gain in embryonic broiler chickens is relatively constant from 80% to 95% averaging 59.8 kPa min^{-1}. This is a higher gain than that determined with the Oxford method in the same breed, which increased progressively from 10.9 to 30 kPa min^{-1} over the same developmental period (Elfwing, 2007). Previous arguments regarding the utility of each methodological approach have been made (Di Rienzo, 2001; Elfwing et al., 2011) and may account for these reported differences in ontogeny of chicken baroreflex function. Overall while previous studies have been novel and informative about the ontogeny of avian baroreflex function, the domestic chicken has been the lone model organism. Investigations of multiple species from different avian lineages with different precocial vs. altricial developmental strategies are crucial to identify the commonalities of the ontogeny of baroreflex function in birds.

Equally informative will be investigations of the interactions between baroreflex function and other regulatory mechanisms during ontogeny, however, modulation of baroreflex of function via systemic hormones and central neuropeptides has been unexplored. Angiotensin II (AT) is an important regulatory peptide that is crucial for blood volume homeostasis in adults and is a contributor to an integrative series of signaling pathways that impacts baroreflex function. In embryonic chickens, AT modulates baroreflex function decreasing both baroreflex gain and operating point at 90% of incubation (Mueller et al., 2013). This change was attributed, in part, to a decrease in vagal inhibition that may be the result of the known elevated plasma levels of AT in embryonic chickens (Crossley et al., 2010). Thus to deepen the understanding of the development of this reflex, the ontogeny of baroreflex function must be assessed in concert with the maturation of other regulatory components of the embryonic cardiovascular system.

18.5.6.3.5 Cardiovascular response to hypoxia

The embryonic cardiovascular response to hypoxia has been as useful tool in assessing the capacity of developing regulatory mechanisms to response to an environmental insult in addition to exploring the maturation of a typical adult response to the stress. Hypoxia has been suggested to be a relevant nature occurrence during avian ontogeny (Anderwartha et al., 2011). Investigators have utilized two methods to characterize the cardiovascular response to reductions in oxygen; prolonged and acute exposures. In domestic chickens, prolonged bouts (>15 min) of hypoxic exposure results in a negligible heart rate response early embryos (15−25%), a depression in heart rate the middle of incubation (67−76%), and an increase in heart rate late (95−100%) in incubation (Khandoker et al., 2003; Andrewartha et al., 2011). Changes in arterial pressure and blood flow distributions have been yet to be investigated under prolonged periods of hypoxic exposure.

Arterial pressure responses to hypoxic exposure have been conducted primarily using acute hypoxia (<10 min). In general, hypoxia causes hypotension in embryonic chickens which is dependent on the level of hypoxia throughout embryonic development (Tazawa, 1981; Crossley et al., 2003b). Embryonic emus respond similarly at 60% of incubation, however, they transition to a hypertensive response prior to hatching (Crossley et al., 2003a). Acute hypoxia also depresses heart rate in embryonic chickens ranging from 43% to 100% of incubation with the intensity of the response dependent on the level of oxygen unlike the response seen during prolonged exposures (Tazawa, 1981; Tazawa et al., 1985; Crossley et al., 2003a). In contrast, embryonic emus either maintain or increase heart rate during hypoxic exposures during the final 30% of incubation (Crossley et al., 2003a). Blood flow measurements during hypoxic exposures beyond 30% of bird incubation in are limited. Tazawa et al. (1985) measured blood flow in the allantoic artery, the major artery supplying the CAM, of an embryonic chicken at ~70% of incubation reporting a slight decrease during hypoxia from the baseline value of 4.1−4.4 mL min^{-1} (Tazawa et al., 1985). Later work reported that severe hypoxia (0−5% O_2) reduces allantoic artery blood flow as much as 0.7 mL min^{-1} in embryonic chickens from 40% to 76% of incubation (Van Golde et al., 1997). Given that under normoxic conditions, the CAM vascular receives between 52% and 41% of CO in embryos ranging from 50% to 90% of incubation, the depression caused by hypoxia represent an important redistribution of flow (Mulder et al., 1997). The pattern of redistribution favored the increased perfusion to the heart and brain while decreasing it to the liver, yolk, and carcass (Mulder et al., 1998). Direct measures of femoral arterial blood flow also illustrate a reduction in limb perfusion during hypoxic exposures (Iversen et al., 2014). Overall the embryonic chicken response to acute hypoxic exposure is a depression of overall cardiovascular function.

The mechanisms that underlie the changes in cardiovascular function have been investigated in the embryonic chickens. In the White Leghorn, hypoxia decreases arterial

pressure in embryos from 43% to 100% of incubation (Crossley, 1999). Initially this response was partially attributed a direct effect of reduced O_2 on the vasculature inducing a relative dilation (Crossley et al., 2003b). From 70% to 90% of incubation, the hypoxic dilation is limited by an α-adrenergic and cholinergic receptor stimulation with a dilatory β-adrenergic stimulation contributing in the final ~20% of incubation (Crossley et al., 2003b). While the increased vascular cholinergic effects may result from a reflexive mechanisms, the adrenergic stimulations can be attributed to elevation in plasma catecholamines in response to hypoxic exposures in during the final 30–40% of incubation (Mulder et al., 2000; Crossley et al., 2003b). NO has been found to mediate the vasodilation at 70% and 90% of incubation as an additional contributing factor to the hypoxic hypotension in embryonic chickens (Iverson et al., 2014).

Heart rate responses to hypoxia may be partially due to the direct actions of low oxygen on cardiac muscle and pacemaker tissue of the embryo (Van Golde et al., 1997; Crossley et al., 2003b). During the final 10% of incubation, the hypoxic bradycardia may be affected by an α-adrenergic stimulation and a cholinergic inhibition induced by direct effects of low oxygen on autonomic nerve terminals as well as chromaffin tissue (Crossley et al., 2003b). It should be noted that α-adrenergic receptor mediated redistributions of CO including preferential perfusion of the heart is an important component of the embryonic chicken response and inhibition may contribute to the reported chronotropic actions of α-adrenergic during hypoxia (Mulder et al., 1998, 2001).

Clearly additional regulatory systems in multiple species must be investigated to further develop the model of how the embryonic cardiovascular system responds periods of hypoxia, however, the embryo may rely on peripheral mechanisms, such as NO, with limited action from the autonomic nervous system.

18.5.6.4 Development of humoral and local effectors of cardiovascular function

A number of hormones play an active role in cardiovascular regulation of the developing embryo. The best studied include angiotensin II (AII), ET, and natriuretic peptide (NP), and their roles in the adult have been outlined in Section 18.5.2.3. All of these hormones have been found relatively early in development of the chicken embryo.

The components of the renin-angiotensin system are present during early embryonic chicken development. The egg laying female provisions AII converting enzyme (ACE) at measurable levels in freshly laid eggs. Over the first 2 days of development, whole embryo levels of ACE-mRNA increase (Savary et al., 2005), and pathways for angiotensin synthesis and signal transduction are present. Between 15% and 20% of incubation, cardiac tissue, brachial arch tissue, and mesonephric tissue all express AII receptor mRNA (Kempf and Corvol, 2001). The CAM expresses AII receptors during at least the last half of incubation (Moellera et al., 1996) and responds to AII at 35% of incubation (Le Noble et al., 1991, 1993).

Angiotensin II appears to be a tonic regulator of cardiovascular function in the developing chicken. *In vivo* AII produces a dose-dependent increase in arterial pressure that increases in intensity from 60% of incubation until hatching (Crossley et al., 2010). In addition, embryonic chickens possess high levels of circulating AII over this same time frame and blockade of ACE results in a relative hypotension at 90% of incubation (Crossley et al., 2010; Muellar et al., 2013). While the embryonic animal responds to AT with an increase in blood pressure similar to adult birds, the embryo lacks the initial AII-induced hypotension reported in adults (Crossley et al., 2010). Embryonic chickens also do not depend entirely on α-adrenergic receptors stimulation for the AII-induced hypertension and antagonists for the AII type 1 receptor (AII1R) are ineffective in embryonic chickens until hatching (Crossley et al., 2010). The ACE is active in chicken aortas as early as 50% of incubation, and it increases in activity with development (Topouzis et al., 1992). Angiotensin also relaxes isolated aortic rings of embryonic chickens at 90% of incubation (Nishimura et al., 2003). These isolated vessels are lacking the sympathetic nerve inputs that would provide a constrictive response. Collectively the data illustrate that AII is an important component of embryonic chicken cardiovascular regulation with similarities and differences from the cardiovascular response in adult birds.

Both AII type 1 and type 2 receptors are present on the developing heart (Rabkin, 1996). Angiotensin II can act on the developing chicken heart to produce a positive inotropic effect at 85% of incubation (Freer et al., 1976). Exposure of AII during 35% to 90% of incubation produces cardiac hypertrophy through activation of the AII1R and up regulation of myosin light chain (Mathew et al., 2004; Baker and Aceto, 1990; Aceto and Baker, 1990). The observed cardiac hypertrophy may be due to direct action of AII on the heart and/or in response to changes in embryonic vasculature function. It is clear there is a role for angiotensin in chicken cardiovascular development and regulation and *in vivo* studies are necessary to further clarify the significance of the role.

The locally produced vasoconstrictor, ET, is expressed ubiquitously throughout the developing chicken cardiovascular system (Kempf et al., 1998). The myocardium and the outflow tract express ET receptor subtype mRNA transcripts as 15% of incubation (Groenendijk et al., 2008). ET converting enzyme 1 activates ET and is first detected at 20% of incubation (Ballard and Mikawa, 2002; Hall et al., 2004). ET produces changes in cardiovascular function in

both *in vivo* and *in vitro* studies. *In vivo* administration of ET antagonists at 20% of incubation resulted in reduced cardiac function (Groenendijk et al., 2008). An *in vitro* ET-mediated positive inotropic effect was observed in cultured cardiomyocytes from 50% of incubation embryos (Bézie et al., 1996). Myograph studies on isolated aorta, pulmonary arteries, and ductus arteriosus all show a vasoconstriction in response to ET (Wingard and Godt, 2002; Villamor et al., 2002, 2004; Martinez-Lemus et al., 2003; Agren et al., 2007). Active wall tension in response to ET −1 increases before hatching which could be critical for the transition to *ex ovo* life (Martinez-Lemus et al., 2003; Villamor et al., 2004).

NPs help regulate sodium and water balance and maintain cardiovascular homeostasis (Takei, 2000; Toop and Donald, 2004; Trajanovska et al., 2007). Mammals express three NP subtypes: atrial natriuretic peptide (ANP), B-type natriuretic peptide (BNP), and C-type natriuretic peptide (CNP). The subtypes ANP and BNP are produced and released from cardiac myocytes in response to increases in ventricular volume (Takei, 2000; Toop et al., 2004; Trajanovska et al., 2007). The chicken genome has four potential NP genes including BNP and CNP (Akizuki et al., 1991; Houweling et al., 2005; Trajanovska, 2007). Natriutetic peptides produce a relaxation of the vasculature that appears as early as 20% of embryonic development (Nakazawa et al., 1990). Studies on isolated cardiomyocytes found a response to NPs beginning at 50% of incubation (Bézie et al., 1996 Koide et al., 1996). These studies suggest that the receptors are present both on the heart and in the vasculature of the developing embryo. There is also some indication that ET and NP interact to regulate cardiomyocyte contractility in embryonic chickens (Bézie et al., 1996). The functional role during development remains to be fully characterized.

18.6 Environmental cardiovascular physiology

18.6.1 Flight

Avian flight requires adaptations of the respiratory and cardiovascular systems to supply sufficient O_2 to the working muscles. Given the inherent complexity of measuring these parameters in active birds, it is not surprising that few studies have examined cardiovascular adjustments that support flight. Two of the most complete studies examined cardiovascular and respiratory function in flying domestic pigeons (*Columba livia domestica*; Butler et al., 1977; Peters et al., 2005). During flight at wind tunnel speeds of 10 m s^{-1} (Butler et al., 1977) or 18.4 m s^{-1} (Peters et al., 2005), O_2 consumption increased between 10 and 17 fold. CO increased 7.4 fold and blood oxygen extraction 2.4 fold during flight, increasing convective O_2 transport to meet metabolic demands of flight muscle. During these flying bouts, heart rate which is the primary mechanism for elevating CO in these animals increased from a resting rate of 110 beats min^{-1} to flying rate of 663 beats min^{-1} (Peters et al., 2005). Interestingly the exercise induced increase in pigeon heart rate during flight is of a similar magnitude to that of flying bats and larger than those observed in running mammals (reviewed in Peters et al., 2005).

The magnitude of change in CO and O_2 consumption is flight mode dependent in birds. For example, during soaring and gliding flight, heart rate is similar to that of resting birds, while flapping flight increases heart rate 2.2 to 7.4 times with the greatest acceleration occurring during takeoff (Peters et al., 2005; Sapir et al., 2010; Sakamoto et al., 2013). There was a strong correlation between heart rate, flight mode, and time spent flapping in the brown-browed Albatross (*Thalassarche melanophrys*; Sakamoto et al., 2013). During the transition from gliding to flapping, heart rate changed almost instantaneously in the Cape gannet (*Morus capensis*; Ropert-Coudert et al., 2006). While the method of flight is correlated with changes in heart rate, flight speed does not appear to alter this cardiovascular parameter (Ward et al., 2002). At wind speeds ranging from 0 to 16 m s^{-1}, heart rate of flying cockatiels (*Nymphicus hollandicus*) is relatively constant, averaging 817 beats /min^{-1} an increase of 2.3 fold from resting levels (Ros, Guarino, and Biewener, unpublished data).

Tissue perfusion is presumably modified during flight as well with an increased distribution of CO to flight muscles during activity; however, this parameter has not been quantified to date. The data available quantify skeletal muscle perfusion during walking and running. Ellerby et al. (2005) found that during bipedal locomotion in birds, locomotory muscle perfusion increased significantly. In guinea fowl (*Numida meleagris*) as walking speed increased to 90% of VO_2 max, CO increased by 4.9 fold through increased heart rate and stroke volume (Ellerby et al., 2005). The majority of this increase in CO perfused the leg muscles, while blood flow to the brain, spleen, stomach, pancreas, intestines, and kidneys did not change. Bech and Nomoto (1982) reported that sciatic artery blood flow increased 3.7 times in Pekin ducks (*Anas domesticus*) running on a treadmill suggesting similar CO modifications occur in this species. Tissue perfusion to leg muscles in ducks increased some fivefold in ducks swimming at close to maximum sustainable rates (Butler et al., 1988). Therefore by extension one could assume that similar increases in blood perfusion to flight muscle occur during moderate to energetic flapping flight. In contrast, gliding should result in limited changes in muscle flow rates especially given the lower expected CO during these types of flying.

18.6.1.1 Altitude

Avian species, such as the bar-headed goose (*Anser indicus*), are unique in vertebrates in that they make annual migrations across mountain ranges at altitudes between 5500 and 7250 m (Hawkes et al., 2013). At these high elevations, the inspired partial pressure of oxygen (P_IO_2) falls to approximately 50 mmHg, a sea level equivalent of 7% O_2. In the O_2 cascade, maximum aerobic capacity is limited by convective movement of O_2 by the cardiovascular system (Hillman et al., 2013). Therefore, to achieve the feats of strenuous activity in a low O_2 environment at high altitudes modifications to the cardiovascular system should be anticipated, allowing for maintenance of high-aerobic activity under low-oxygen conditions. A number of studies have examined cardiovascular adjustments of high-altitude migrators (bar-headed geese, *A. indicus*; Hawkes et al., 2014; Lague et al., 2016, 2017; Meir et al., 2019), high-altitude residents (Lague et al., 2017, 2020), and low-land species to decreasing levels of O_2 both at rest and during flight. While CO increases in response to decreasing O_2 levels in both the bar-headed goose and the Barnacle goose, bar-headed geese begin to increase CO at a higher O_2 level than in Barnacle geese (Lague et al., 2016). Birds migrating at high altitude and living at high altitude are both able to increase CO in response to lowered O_2, but appear to adjust different cardiovascular responses to achieve the same elevation in CO. In response to decreased inspired O_2 levels, bar-headed geese elevate CO through increases in heart rate while Barnacle geese (*Branta leucopsis*) elevate CO through increasing stroke volume (Lague et al., 2017).

During activity, the capacity to maintain an elevated heart rate in low O_2 environments is paramount and has been investigated in bar-headed geese and Barnacle geese (Hawkes et al., 2014; Meir et al., 2019). During hypoxic exposure to 7% O_2, bar-headed geese were able to maintain running for 15 min and increase of heart rate from a normoxic running rate of 385 to 453 beats min^{-1} in hypoxia (Hawkes et al., 2014). When running at 7% O_2, Barnacle geese were unable to increase heart rate to the levels observed during normoxic running and were unable to run for more than 4 min. During normoxic flight at speeds between 45 and 54 km h^{-1}, heart rate increased roughly 2.5- to 3-fold while oxygen consumption increased 16-fold over resting values in these geese. Heart rate data for flights at 21%, 10.5%, and 7% O_2 suggest that these animals are able to maintain the elevated heart rate with the associated CO under hypoxic flight conditions that mirror the oxygen levels experienced during migratory behavior (Meir et al., 2019). Therefore, these animals are able to maintain the cardiovascular changes observed at sea level during active hypoxic flight to ensure sufficient O_2 delivery to the flight muscles.

Coronary vasodilation is critical to maintaining O_2 delivery during bouts of reduce O_2 availability or an increase in myocardial oxygen demand. Both of these factors presumably come into play during high-altitude flight in birds. In Pekin ducks and bar-headed geese, coronary perfusion has been reported to be 3.5 mL min^{-1} g^{-1} of wet heart weight at sea level when the P_IO_2 was 142 mmHg (Faraci et al., 1984). Exposure to severe hypoxia (28 mmHg P_IO_2) increases coronary blood perfusion 5.5 and 2.7 times, respectively, in ducks and geese (Faraci et al., 1984) via a hypoxic coronary vasodilation (Figure 18.35). Although bar-headed geese are accomplished high-altitude fliers, in contrast to ducks, counter intuitively these animals did not increase coronary blood perfusion to the same extent under hypoxic conditions. This may be compensated for by greater ventricle capillary density in the bar-head goose compared to other species (Scott et al., 2011).

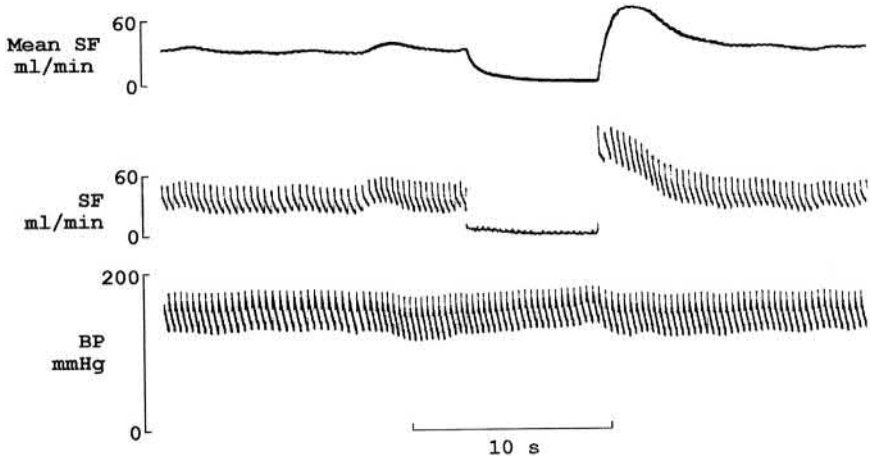

FIGURE 18.35 Responses of the coronary circulation to hypoxia in Pekin ducks and bar-headed geese. (Left) coronary blood flow (mL min^{-1} g^{-1}); (right) coronary vascular resistance (mmHg ml min^{-1} g^{-1}) as a function of the arterial O_2 partial pressure (P_aO_2). All values are means ± S.E. (n = 5) except at 25 Torr, where means for two geese were plotted. An asterisk represents significant difference from normoxia (highest P_aO_2 level) at $P \leq .05$. *From Faraci et al. (1985)*

Carbon dioxide is also a potent coronary vasodilator in mammals, coupling increased aerobic metabolism in the myocardium to an increased rate of oxygen delivery while hypocapnia increases coronary resistance and decreased coronary perfusion. This would obviously be deleterious during high-altitude migratory flight. Interestingly, the relationship between coronary blood flow and P_aCO_2 in bar-headed geese appears to be quite different than mammals. Over a range of P_aCO_2 from about 30 to 60 mmHg, there is a linear increase in coronary flow with P_aCO_2, as in the mammal. However, in the hypocapnic condition, when P_aCO_2 is 30 mmHg or lower, there appears to be no effect of P_aCO_2 on coronary resistance (Faraci and Fedde, 1986). Whether this represents a mechanism to ensure myocardial oxygen delivery during high-altitude flight remains to be determined.

Activity at high elevation subjects tissue to reduced P_IO_2 and hypocapnia. The hypocapnia and subsequent respiratory alkalosis results from increased CO_2 washout from greater hypoxemia driven ventilation (Faraci et al., 1985; Scott and Milsom, 2007). This condition could dramatically influence tissue metabolic function with the greatest impact on highly aerobic tissues of the central nervous system. In domestic geese, cerebral blood flow decreased as P_aCO_2 falls from 50 to 20 mmHg but then reached a plateau; however, PO_2 of cerebral tissue continued to fall as P_aO_2 fell below 20 mmHg, suggesting differences in cerebral vascular sensitivity to these two conditions (Bickler and Julian, 1992). Carbon dioxide is normally a potent vasodilator within the cerebral circulation (Faraci and Fedde, 1986; Grubb et al., 1977), however, the cerebral vasculature is fairly insensitive in domestic geese (*Anser anser*) and Pekin ducks while bar-headed geese are very insensitive to severe hypocapnia (Bickler and Julian, 1992; Faraci and Fedde, 1986; Grubb et al., 1977).

Given the range of altitude bird species inhabit and transiently experience during season migration differing degrees in flight muscle capillarity may also correlate with flight at high elevation. It could be predicted that high-elevation species would exhibit a relatively greater capillary density to muscle fiber density increasing the total surface area of contact between capillaries and fibers. This phenotype is evident in a number of species that fly at high elevation and that have relatively higher muscle capillarity and smaller fiber sizes. In bar-headed geese and Andean coots (*Fulica ardesiaca*) native to 4200 m the pectorals muscles, as well as some limb muscles in the coot, the number of capillaries per muscle fiber is increased compared with low-land species (Scott et al., 2009; Leon-Velarde et al., 1993). Further in the bar-headed goose, mitochondria of aerobic fibers are redistributed so they are adjacent to capillaries (Scott et al., 2009). These compensatory changes can be induced during ontogeny as evident in increased capillary-to-fiber ratio and possible changes in diffusion distances in Canada goose goslings (*Branta canadensis*) hatching from eggs raised under hypoxic conditions (Snyder et al., 1984; Snyder, 1987). In contrast, wild adult pigeons actively flying at 3800 m maintain similar capillary geometry and density compared to controls at sea level (MathieuCostello et al., 1996). Equally important are factors such as changes in P_{50}, the oxygen-carrying capacity of blood, or the myoglobin content of muscle fibers which are also significant adaptations involved in the response. Increases in carrying capacity and high levels of tissue oxygen extraction have been demonstrated in unexercised pigeons acclimatized to high altitude (Weinstein et al., 1985) and bar-headed geese (Scott, 2011). In short, while the current understanding of cardiovascular and respiratory adjustments that must accompany flight at elevation has progressed, further extensive investigations must be undertaken to explain the capacity of birds to sustain activity in low-oxygen environments.

18.6.1.2 Migration

Extensive migrations involving continuous fasting flight for long periods of time are undertaken annually by many bird species. Migrating birds exhibit extraordinary phenotypic plasticity in organs size and body mass. This organ mass plasticity manifesting as hypertrophy of the heart and other organs is akin to that observed in infrequent feeding reptiles such as snakes (Secor and Diamond, 1998; Andersen et al., 2005). For example, the barnacle goose heart hypertrophies before migration composing approximately 1.1% of body mass (Bishop et al., 1995). In contrast, the heart of a typical bird is roughly 0.8% of body mass (Section 18.2.1.2). Heart hypertrophy of the red knot (*Calidris canutus islandica*) and bar-tailed godwit (*Limosa lapponica taymyrensis*) is correlated with increased power requirements needed for migration (Piersma et al., 1999; Landys-Ciannelli et al., 2003). The garden warbler (*Sylvia borin*) migrating across the Sahara exhibited a decrease in heart mass and flight muscle mass that was restored within nine days of recovery feeding (Bauchinger et al., 2005). Few studies have examined the cardiovascular physiology associated with these long migrations and associated hypertrophy of the heart. During migration of Svalbard Barnacle geese (*Branta leucopsis*), heart rate falls on successive days from 317 to 226 beats min^{-1} (Butler et al., 1998). Butler et al. (1998) suggested that progressive bradycardia was due to decreased O_2 demand as body mass fell while heart mass remains fixed during the migration. Thus, changes in CO appear to be influenced most heavily by heart rate changes. It remains to be seen how these changes in heart mass before, during, and after migration influence cardiovascular function and performance in these species.

18.6.2 Swimming and diving

Bird species engage in surface swimming and submerged or diving swimming. In tufted ducks (*Aythya fuligula*), surface swimming at maximal sustainable speeds is associated with a 70% increase in CO from 276 to 466 mL min^{-1} (Bevan and Butler, 1992). As with flight, swimming is associated with changes in regional vascular perfusion with myocardium and active leg musculature blood flow increasing by 30% and 300%, respectively, while flow to other regions remained the same or decreased (Bevan and Butler, 1992). Similar patterns are evident in the redhead duck (*Aythya americana*) during short periods of underwater swimming which results in a 200% to 500%, increase in hind legs perfusion (Stephenson and Jones, 1992). Clearly selective perfusion takes place during swimming likely via an interaction between vasodilation in active muscle and vasoconstriction in visceral organs and inactive muscle (Figure 18.36; Butler et al., 1988; Bevan and Butler, 1992).

During a dive, animals must function with the limited O_2 stores carried within the body during the dive duration. The majority of dives are shorter than the aerobic dive limit (ADL), the length of time that a dive can be aerobic relying on the O_2 stores in the body. A large number of diving species, such as ducks and cormorants, perform multiple short dives of less than 60 s in duration. Others species, such as the emperor penguin (*Aptenodytes forsteri*), dive for longer periods of more than 20 min (Meir et al., 2008). These different diving behaviors should by necessity result in species having different physiological capacities to ensure effective O_2 transport, however, regardless of dive duration, the pattern of cardiovascular responses are similar.

The phases of the cardiovascular response to a voluntary dive include an initial tachycardia during the immediate predive followed by a diving "bradycardia." After surfacing, there is usually a postdive tachycardia. The predive and postdive tachycardia is suggested to aid in loading and replenishing of O_2 stores and elimination of CO_2 (Butler and Jones, 1997). In many species, the diving bradycardia is not a true bradycardia in that the diving heart rate remains elevated in comparison to the resting heart rate.

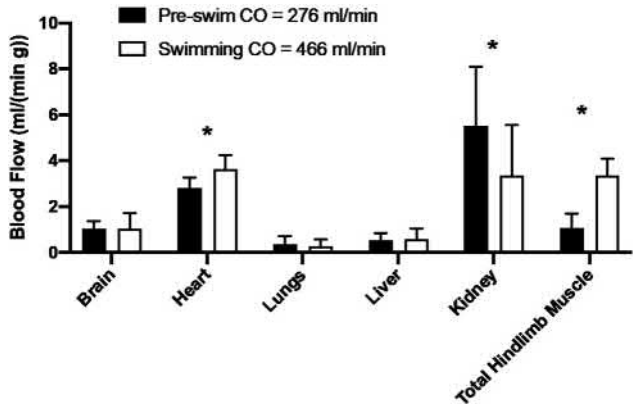

FIGURE 18.36 Mean mass-specific blood flow to selected tissues in six tufted ducks before (*shaded bars*) and during swimming at a mean velocity of 0.69 m s^{-1} (*open bars*). *Asterisks* indicate significant differences between preswimming and swimming values. *Data from Butler et al. (1988).*

In diving ducks, Jones and Holeton (1972b), Lillo and Jones (1982), Jones et al. (1983), Smith and Jones (1992), and Bevan and Butler (1992) showed that stroke volume was maintained during the large decreases in CO generated during submersion, suggesting the primary factor dictating CO during these events is heart rate. In addition, there is a negative correlation between minimum heart rate and dive duration as well as depth (Bevan et al., 1997; Meir et al., 2008). The extent of the diving bradycardia may be correlated with changes in blood oxygen levels, regulated by variation in parasympathetic output in ducks (McPhail and Jones, 1999). In diving cormorants (*Phalacrocorax auritus*), heart rate during a shallow dive was dependent upon the level of inspired oxygen (Enstipp et al., 2001). Predive inspiration of hypoxic gas resulted in a stronger bradycardia, and predive inspiration of hyperoxic gas resulted in the opposite response. Similar changes in response to inspired oxygen levels and diving has been observed in the lesser scaup duck (*Aythya affinis*; Borg et al., 2004).

Penguins have been extensively studied to understand their capacity for extended active diving bouts. During dives that are greater than the ADL, Emperor penguins become relatively bradycardic just prior to returning to the surface (Meir et al., 2008). Lesser scaup ducks decrease heart rate below resting levels during forced dives only (Borg et al., 2004). During long voluntary dives of 30 min or if this species is exposed to 9% O_2, heart rate falls below resting values during the later portions of the dive suggest that a true diving bradycardia may only occur when blood PO_2 levels become severely reduced (Borg et al., 2004). Changes in tissue perfusion have been suggested to accompany heart rate responses to diving. During long dives, Emperor penguins have blood lactate levels that suggest changes in blood flow to the skeletal muscles during the dive (Ponganis et al., 2009). The ADL is the duration at which the dive becomes anaerobic and is indicated by blood lactate levels during postdive recovery. The majority of birds carry out multiple short dives that fall within their ADL; however, blood lactate levels remain low in animals that have passed their ADL, with levels increasing during postdive period. There is also data suggesting a potential arteriovenous shunt through the extremities in the emperor penguin (Ponganis et al., 2009). Ponganis et al. (2009) propose that this shunt may be important during the initial phases of the dive by allowing enhanced transport of O_2 from the gas exchange surface to the venous system.

Regulation of the cardiovascular response to diving has been explored is some species. Baroreceptor input has been shown to have no direct role in generating or maintaining heart rate responses to voluntary submersion in diving ducks, since these animals display the same degree of bradycardia after denervation of arterial baroreceptors as before (Furilla and Jones, 1987a). However, baroreceptors may play a role in control of heart rate in dabbling ducks (*A. platyrhynchos*) which have been trained to dive voluntarily. Predive heart rate in dabblers ranged from 100 to about 500 beats min^{-1} but, regardless of the rate preceding any particular dive, rate during the dive tended to a value of approximately 250 beats min^{-1} (Furilla and Jones, 1987b). This response implies that heart rate was being regulated at a set value during voluntary dives. Removal of baroreceptor input by bilateral section of the aortic nerves eliminated the tendency of dive heart rate to approach the "set point" value, after barodenervation dive heart rate varied little from the prevailing predive rate (Furilla and Jones, 1987b). Given that the baroreflex normally regulates blood pressure by adjusting CO and vascular resistance, the physiological value of a baroreceptor-dependent "set point" for heart rate is uncertain. The behavior of arterial blood pressure during voluntary diving in dabbling ducks has not been established. However, there may be some inherent benefit to regulating heart rate under these conditions. If this is true, then strong phasic baroreceptor input to the central nervous system during systole would represent the primary afferent feedback route for heart rate–related information.

Stimulation of nasal receptors in diving ducks and chemoreceptors in dabbling ducks are the proximate causes of the development of diving bradycardia (Furilla and Jones, 1986; 1987a,b). Repeatedly submerging the head of a diving or dabbling duck in a laboratory situation causes the bradycardic response to habituate after 100 to 200 dives (Gabbott and Jones, 1987). In dabbling ducks, however, extending the period of submergence beyond 40 s virtually eliminates any attenuation of the cardiac response to submergence. Obviously, in dabbling ducks, input from the carotid body chemoreceptors is too intense for habitation after 60 s submergence. Similarly, exposing habituated animals to 10% or 15% oxygen in air before submergence causes prominent bradycardia although the very next trial, after breathing room air, evokes the habituated cardiac response. Interestingly, the heart rate response to diving after breathing air with low levels of oxygen is unaffected by training. Consequently, chemoreceptor input, which will be the same in naive and habituated ducks because blood gas levels are the same after 40 s submergence, can be habituated. Habituation of the response occurs within the central nervous system, below the thalamic level.

Even though CO is reduced during diving, the rate of perfusion of cerebral vasculature and thoracoabdominal cavity is maintained or elevated above predive levels (Heieis and Jones, 1988; Jones et al., 1979). In mallard and Pekin ducks, myocardial flow was, on average, 0.73 mL min^{-1} g^{-1} presubmersion and 0.88 mL $min^{-1}g^{-1}$ after 144–250 s of submergence. Cerebral flow increased from 0.43 to 3.68 mL min^{-1} g^{-1} over the same time period. In Pekin ducks forcibly submerged until P_aO_2 fell to 50 mmHg, cerebral blood flow increased from 1.58 to 3.2 mL min^{-1} g^{-1}. Clearly, regardless of the wide range of absolute values measured, cerebral blood flow increases in forced submersion asphyxia, maintaining oxygen delivery to brain tissue. A redistribution of blood flow away from more hypoxia tolerant regions toward more sensitive regions within the brain itself does not seem to occur in the Pekin duck (Stephenson et al., 1994). However, such heterogeneous regional changes in cerebral blood flow in response to asphyxia have been proposed to occur in neonatal mammals (Goplerud et al., 1989).
